An abstract, artistic photograph of a blue liquid or smoke plume. The plume originates from the top right, where a series of small, clear bubbles are visible at the surface. It then billows and swirls downwards and to the left, creating intricate, organic shapes. The color of the plume varies from a light, airy blue to a deep, dark navy blue, with the darkest areas concentrated in the lower right portion of the image. The background is a clean, bright white, which makes the blue plume stand out prominently.

# Preface

---

We have followed our usual tradition in that this new edition of the text is yet another thorough update of the content and its presentation. Our goal is to keep the book flexible to use, accessible to students, broad in scope, and authoritative, without adding bulk. However, it should always be borne in mind that much of the bulk arises from the numerous pedagogical features that we include (such as *Worked examples*, *Checklists of key equations*, and the *Resource section*), not necessarily from density of information.

The text is still divided into three parts, but material has been moved between chapters and the chapters themselves have been reorganized. We continue to respond to the cautious shift in emphasis away from classical thermodynamics by combining several chapters in Part 1 (Equilibrium), bearing in mind that some of the material will already have been covered in earlier courses. For example, material on phase diagrams no longer has its own chapter but is now distributed between Chapters 4 (*Physical transformation of pure substances*) and 5 (*Simple mixtures*). New *Impact* sections highlight the application of principles of thermodynamics to materials science, an area of growing interest to chemists.

In Part 2 (Structure) the chapters have been updated with a discussion of contemporary techniques of materials science—including nanoscience—and spectroscopy. We have also paid more attention to computational chemistry, and have revised the coverage of this topic in Chapter 10.

Part 3 has lost chapters dedicated to kinetics of complex reactions and surface processes, but not the material, which we regard as highly important in a contemporary context. To make the material more readily accessible within the context of courses, descriptions of polymerization, photochemistry, and enzyme- and surface-catalysed reactions are now part of Chapters 21 (*The rates of chemical reactions*) and 22 (*Reaction dynamics*)—already familiar to readers of the text—and a new chapter, Chapter 23, on *Catalysis*.

We have discarded the Appendices of earlier editions. Material on mathematics covered in the appendices is now dispersed through the text in the form of *Mathematical background* sections, which review and expand knowledge of mathematical techniques where they are needed in the text. The review of introductory chemistry and physics, done in earlier editions in appendices, will now be found in a new *Fundamentals* chapter that opens the text, and particular points are developed as *Brief comments* or as part of *Further information* sections throughout the text. By liberating these topics from their appendices and relaxing the style of presentation we believe they are more likely to be used and read.

The vigorous discussion in the physical chemistry community about the choice of a ‘quantum first’ or a ‘thermodynamics first’ approach continues. In response we have paid particular attention to making the organization flexible. The strategic aim of this revision is to make it possible to work through the text in a variety of orders and at the end of this Preface we once again include two suggested paths through the text. For those who require a more thorough-going ‘quantum first’ approach we draw attention to our *Quanta, matter, and change* (with Ron Friedman) which covers similar material to this text in a similar style but, because of the different approach, adopts a different philosophy.

The concern expressed in previous editions about the level of mathematical ability has not evaporated, of course, and we have developed further our strategies for

showing the absolute centrality of mathematics to physical chemistry and to make it accessible. In addition to associating *Mathematical background* sections with appropriate chapters, we continue to give more help with the development of equations, motivate them, justify them, and comment on the steps. We have kept in mind the struggling student, and have tried to provide help at every turn.

We are, of course, alert to the developments in electronic resources and have made a special effort in this edition to encourage the use of the resources on our website (at [www.whfreeman.com/pchem](http://www.whfreeman.com/pchem)). In particular, we think it important to encourage students to use the *Living graphs* on the website (and their considerable extension in the electronic book and *Explorations* CD). To do so, wherever we call out a *Living graph* (by an icon attached to a graph in the text), we include an *interActivity* in the figure legend, suggesting how to explore the consequences of changing parameters.

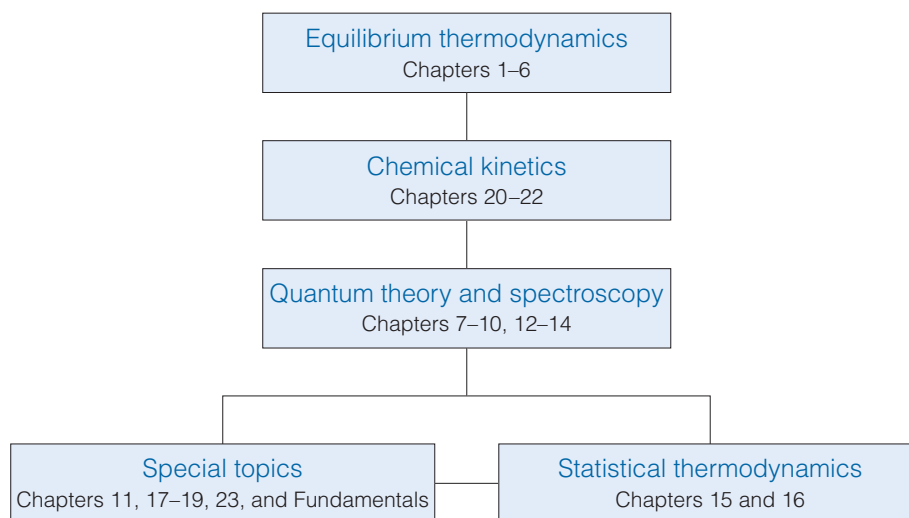

Many other revisions have been designed to make the text more efficient and helpful and the subject more enjoyable. For instance, we have redrawn nearly every one of the 1000 pieces of art in a consistent style. The *Checklists of key equations* at the end of each chapter are a useful distillation of the most important equations from the large number that necessarily appear in the exposition. Another innovation is the collection of *Road maps* in the *Resource section*, which suggest how to select an appropriate expression and trace it back to its roots.

Overall, we have taken this opportunity to refresh the text thoroughly, to integrate applications, to encourage the use of electronic resources, and to make the text even more flexible and up-to-date.

### Traditional approach

### Molecular approach

This text is available as a customizable ebook. This text can also be purchased in two volumes. For more information on these options please see pages xv and xvi.

# About the book

There are numerous features in this edition that are designed to make learning physical chemistry more effective and more enjoyable. One of the problems that make the subject daunting is the sheer amount of information: we have introduced several devices for organizing the material: see *Organizing the information*. We appreciate that mathematics is often troublesome, and therefore have taken care to give help with this enormously important aspect of physical chemistry: see *Mathematics support*. Problem solving—especially, ‘where do I start?’—is often a challenge, and we have done our best to help overcome this first hurdle: see *Problem solving*. Finally, the web is an extraordinary resource, but it is necessary to know where to start, or where to go for a particular piece of information; we have tried to indicate the right direction: see *About the Book Companion Site*. The following paragraphs explain the features in more detail.

## Organizing the information

### Key points

The *Key points* act as a summary of the main take-home message(s) of the section that follows. They alert you to the principal ideas being introduced.

#### 1.1 The states of gases

**Key points** Each substance is described by an equation of state. (a) Pressure, force divided by area, provides a criterion of mechanical equilibrium for systems free to change their volume. (b) Pressure is measured with a barometer. (c) Through the Zeroth Law of thermodynamics, temperature provides a criterion of thermal equilibrium.

The physical state of a sample of a substance, its physical condition, is defined by its physical properties. Two samples of a substance that have the same physical proper-

The most significant equations and concepts—which we urge you to make a particular effort to remember—are flagged with an annotation, as shown here.

mental fact that each substance is described by an **equation of state**, an equation that interrelates these four variables.

The general form of an equation of state is

$$p = f(T, V, n)$$

General form of  
an equation of state (1.1)

### Justifications

On first reading it might be sufficient simply to appreciate the ‘bottom line’ rather than work through detailed development of a mathematical expression. However, mathematical development is an intrinsic part of physical chemistry, and to achieve full understanding it is important to see how a particular expression is obtained. The *Justifications* let you adjust the level of detail that you require to your current needs, and make it easier to review material.

These relations are called the **Margules equations**.

#### Justification 5.5 The Margules equations

The Gibbs energy of mixing to form a nonideal solution is

$$\Delta_{\text{mix}} G = nRT \{x_A \ln a_A + x_B \ln a_B\}$$

This relation follows from the derivation of eqn 5.16 with activities in place of mole fractions. If each activity is replaced by  $\gamma x$ , this expression becomes

$$\Delta_{\text{mix}} G = nRT \{x_A \ln x_A + x_B \ln x_B + x_A \ln \gamma_A + x_B \ln \gamma_B\}$$

Now we introduce the two expressions in eqn 5.64, and use  $x_A + x_B = 1$ , which gives

$$\begin{aligned} \Delta_{\text{mix}} G &= nRT \{x_A \ln x_A + x_B \ln x_B + \xi x_A x_B^2 + \xi x_B x_A^2\} \\ &= nRT \{x_A \ln x_A + x_B \ln x_B + \xi x_A x_B (x_A + x_B)\} \\ &= nRT \{x_A \ln x_A + x_B \ln x_B + \xi x_A x_B\} \end{aligned}$$

as required by eqn 5.29. Note, moreover, that the activity coefficients behave correctly for dilute solutions:  $\gamma_A \rightarrow 1$  as  $x_B \rightarrow 0$  and  $\gamma_B \rightarrow 1$  as  $x_A \rightarrow 0$ .

At this point we can use the Margules equations to write the activity of A as

## Checklists of key equations

We have summarized the most important equations introduced in each chapter as a checklist. Where appropriate, we describe the conditions under which an equation applies.

| Property                                        | Equation                                                                                                                                         | Comment                                                              |
|-------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------|
| Chemical potential                              | $\mu_i = (\partial G/\partial n_i)_{T,p}$                                                                                                        |                                                                      |
| Fundamental equation of chemical thermodynamics | $dG = Vdp - SdT + \mu_A dn_A + \mu_B dn_B + \dots$                                                                                               | $G = n_A \mu_A + n_B \mu_B$                                          |

## Road maps

In many cases it is helpful to see the relations between equations. The suite of ‘Road maps’ summarizing these relations are found in the *Resource section* at the end of the text.

### Part 1 Road maps

#### Gas laws (Chapter 1)

##### Gas laws (Chapter 1)

#### The First Law (Chapter 2)

## Impact sections

Where appropriate, we have separated the principles from their applications: the principles are constant and straightforward; the applications come and go as the subject progresses. The *Impact sections* show how the principles developed in the chapter are currently being applied in a variety of modern contexts.

### IMPACT ON NANOSCIENCE

#### 18.1 Quantum dots

Nanoscience is the study of atomic and molecular assemblies with dimensions ranging from 1 nm to about 100 nm and nanotechnology is concerned with the incorporation of such assemblies into devices. The future economic impact of nanotechnology could be very significant. For example, increased demand for very small digital electronic devices has driven the design of ever smaller and more powerful microprocessors. However, there is an upper limit on the density of electronic circuits that can be incorporated into silicon-based chips with current fabrication technologies. As the ability to process data increases with the number of components in a chip, it follows that soon chips and the devices that use them will have to become bigger if processing

## Notes on good practice

Science is a precise activity and its language should be used accurately. We have used this feature to help encourage the use of the language and procedures of science in conformity to international practice (as specified by IUPAC, the International Union of Pure and Applied Chemistry) and to help avoid common mistakes.

**Answer** The number of photons is

$$N = \frac{E}{h\nu} = \frac{PA\Delta t}{h(c/\lambda)} = \frac{\lambda PA\Delta t}{hc}$$

Substitution of the data gives

$$N = \frac{(5.60 \times 10^{-7} \text{ m}) \times (100 \text{ J s}^{-1}) \times (1.0 \text{ s})}{(6.626 \times 10^{-34} \text{ J s}) \times (2.998 \times 10^8 \text{ m s}^{-1})} = 2.8 \times 10^{20}$$

Note that it would take the lamp nearly 40 min to produce 1 mol of these photons.

**Self-test 7.1** How many photons does a monochromatic (single frequency) infrared rangefinder of power 1 mW and wavelength 1000 nm emit in 0.1 s? [ $5 \times 10^{14}$ ]

**A note on good practice** To avoid rounding and other numerical errors, it is best to carry out algebraic calculations first, and to substitute numerical values into a single, final formula. Moreover, an analytical result may be used for other data without having to repeat the entire calculation.

## interActivities

You will find that many of the graphs in the text have an interActivity attached: this is a suggestion about how you can explore the consequences of changing various parameters or of carrying out a more elaborate investigation related to the material in the illustration. In many cases, the activities can be completed by using the online resources of the book's website.

before it is switched on, the lamp is at 20°C (293 K). When it is switched on, it emits nearly white light. •

While Rayleigh's was not, the Rayleigh–Jeans law excites the oscillators of the field. At the highest frequencies are results in the ultraviolet catastrophe: oscillators are excited only so large for the walls to suppose the latter remain unexcited. At the high frequency limit, the energy available.

**Fig. 7.7** The Planck distribution (eqn 7.8) accounts very well for the experimentally determined distribution of black-body radiation. Planck's quantization hypothesis essentially quenches the contributions of high frequency, short wavelength oscillators. The distribution coincides with the Rayleigh–Jeans distribution at long wavelengths.

**interActivity** Plot the Planck distribution at several temperatures and confirm that eqn 7.8 predicts the behaviour summarized by Fig. 7.3.

Louis Dulong and Alexis Berthollet (Section 2.4), of a number of slender experimental monatomic solids are the

classical physics in much the same way. If classical physics is used, the mean energy of each oscillator is  $kT$  for each direction of displacement. The average energy of each oscillator is then  $3kT$ . The distribution of this motion to

Further information

In some cases, we have judged that a derivation is too long, too detailed, or too different in level for it to be included in the text. In these cases, the derivations will be found less obtrusively at the end of the chapter.

Further information

**Further information 7.1 Classical mechanics**

Classical mechanics describes the behaviour of objects in terms of two equations. One expresses the fact that the total energy is constant in the absence of external forces; the other expresses the response of particles to the forces acting on them.

**(a) The trajectory in terms of the energy**

The velocity,  $v$ , of a particle is the rate of change of its position:

$$v = \frac{dr}{dt} \tag{7.44}$$

The velocity is a vector, with both direction and magnitude. (Vectors are discussed in *Mathematical background 5*.) The magnitude of the velocity is the speed,  $v$ . The linear momentum,  $p$ , of a particle of mass  $m$  is related to its velocity,  $v$ , by

$$p = mv \tag{7.45}$$

Like the velocity vector, the linear momentum vector points in the direction of travel of the particle (Fig. 7.31). In terms of the linear

**Fig. 7.31** The linear momentum of a particle is a vector property and points in the direction of motion.

momentum, the total energy—the sum of the kinetic and potential energy—of a particle is

$$E = E_k + V(x) = \frac{p^2}{2m} + V(x) \tag{7.46}$$

Resource section

Long tables of data are helpful for assembling and solving exercises and problems, but can break up the flow of the text. The *Resource section* at the end of the text consists of the *Road maps*, a *Data section* with a lot of useful numerical information, and *Character tables*. Short extracts of the tables in the text itself give an idea of the typical values of the physical quantities being discussed.

van der Waals equation of state

Mathematics support

A brief comment

A topic often needs to draw on a mathematical procedure or a concept of physics; a brief comment is a quick reminder of the procedure or concept.

**in magnetic fields**

fields, which remove the degeneracy of the quantized represented on the vector model as vectors precessing at

moment  $\mu$  in a magnetic field  $\mathcal{B}$  is equal to the

$$\tag{14.1}$$

duction and is measured in tesla, T; 1 T = is also occasionally used: 1 T =  $10^4$  G.

**A brief comment**

Scalar products (or ‘dot products’) are explained in *Mathematical background 5* following Chapter 9.

Mathematical background

It is often the case that you need a more full-bodied account of a mathematical concept, either because it is important to understand the procedure more fully or because you need to use a series of tools to develop an equation. The *Mathematical background* sections are located between some chapters, primarily where they are first needed, and include many illustrations of how each concept is used.

**MATHEMATICAL BACKGROUND 5**

**Vectors**

A vector quantity has both magnitude and direction. The vector shown in Fig. MB5.1 has components on the  $x$ ,  $y$ , and  $z$  axes with magnitudes  $v_x$ ,  $v_y$ , and  $v_z$ , respectively. The vector may be represented as

$$v = v_x i + v_y j + v_z k \tag{MB5.1}$$

where  $i$ ,  $j$ , and  $k$  are unit vectors, vectors of magnitude 1, pointing along the positive directions on the  $x$ -,  $y$ -, and  $z$ -axes. The magnitude of the vector is denoted  $v$  or  $|v|$  and is given by

$$v = (v_x^2 + v_y^2 + v_z^2)^{1/2} \tag{MB5.2}$$

**Fig. MB5.2** (a) The vectors  $u$  and  $v$  make an angle  $\theta$ . (b) To add  $v$  to  $u$ , we first join the tail of  $v$  to the head of  $u$ , making sure that the angle  $\theta$  between the vectors remains unchanged. (c) To finish the process, we draw the resultant vector by joining the tail of  $u$  to the head of  $v$ .

Problem solving

A brief illustration

A brief illustration is a short example of how to use an equation that has just been introduced in the text. In particular, we show how to use data and how to manipulate units correctly.

**A brief illustration**

The unpaired electron in the ground state of an alkali metal atom has  $l = 0$ , so  $j = \frac{1}{2}$ . Because the orbital angular momentum is zero in this state, the spin-orbit coupling energy is zero (as is confirmed by setting  $j = s$  and  $l = 0$  in eqn 9.42). When the electron is excited to an orbital with  $l = 1$ , it has orbital angular momentum and can give rise to a magnetic field that interacts with its spin. In this configuration the electron can have  $j = \frac{3}{2}$  or  $j = \frac{1}{2}$ , and the energies of these levels are

$$E_{3/2} = \frac{1}{2} hc\tilde{A} \left\{ \frac{3}{2} \times \frac{5}{2} - 1 \times 2 - \frac{1}{2} \times \frac{3}{2} \right\} = \frac{1}{2} hc\tilde{A}$$
$$E_{1/2} = \frac{1}{2} hc\tilde{A} \left\{ \frac{1}{2} \times \frac{3}{2} - 1 \times 2 - \frac{1}{2} \times \frac{3}{2} \right\} = -hc\tilde{A}$$

The corresponding energies are shown in Fig. 9.30. Note that the baricentre (the ‘centre of gravity’) of the levels is unchanged, because there are four states of energy  $\frac{1}{2} hc\tilde{A}$  and two of energy  $-hc\tilde{A}$ . •

## Examples

We present many worked examples throughout the text to show how concepts are used, sometimes in combination with material from elsewhere in the text. Each worked example has a *Method* section suggesting an approach as well as a fully worked out answer.

### Example 9.2 Calculating the mean radius of an orbital

Use hydrogenic orbitals to calculate the mean radius of a 1s orbital.

**Method** The mean radius is the expectation value

$$\langle r \rangle = \int \psi^* r \psi d\tau = \int r |\psi|^2 d\tau$$

We therefore need to evaluate the integral using the wavefunctions given in Table 9.1 and  $d\tau = r^2 dr \sin \theta d\theta d\phi$ . The angular parts of the wavefunction (Table 8.2) are normalized in the sense that

$$\int_0^\pi \int_0^{2\pi} |Y_{l,m_l}|^2 \sin \theta d\theta d\phi = 1$$

The integral over  $r$  required is given in Example 7.4.

**Answer** With the wavefunction written in the form  $\psi = RY$ , the integration is

$$\langle r \rangle = \int_0^\infty \int_0^\pi \int_0^{2\pi} r R_{n,l}^2 |Y_{l,m_l}|^2 r^2 dr \sin \theta d\theta d\phi = \int_0^\infty r^3 R_{n,l}^2 dr$$

For a 1s orbital

$$R_{1,0} = 2 \left( \frac{Z}{a_0} \right)^{3/2} e^{-Zr/a_0}$$

Hence

$$\langle r \rangle = \frac{4Z^3}{a_0^3} \int_0^\infty r^3 e^{-2Zr/a_0} dr = \frac{3a_0}{2Z}$$

## Self-tests

Each *Example* has a *Self-test* with the answer provided as a check that the procedure has been mastered. There are also a number of free-standing *Self-tests* that are located where we thought it a good idea to provide a question to check your understanding. Think of *Self-tests* as in-chapter exercises designed to help you monitor your progress.

**Self-test 9.4** Evaluate the mean radius of a 3s orbital by integration. [27a<sub>0</sub>/2Z]

## Discussion questions

The end-of-chapter material starts with a short set of questions that are intended to encourage reflection on the material and to view it in a broader context than is obtained by solving numerical problems.

### Discussion questions

- 9.1 Discuss the origin of the series of lines in the emission spectra of hydrogen. What region of the electromagnetic spectrum is associated with each of the series shown in Fig. 9.1?
- 9.2 Describe the separation of variables procedure as it is applied to simplify the description of a hydrogenic atom free to move through space.
- 9.3 List and describe the significance of the quantum numbers needed to specify the internal state of a hydrogenic atom.
- 9.4 Specify and account for the selection rules for transitions in hydrogenic atoms.
- 9.5 Explain the significance of (a) a boundary surface and (b) the radial distribution function for hydrogenic orbitals.
- 9.6 Outline the electron configurations of many-electron atoms in terms of their location in the periodic table.
- 9.7 Describe and account for the variation of first ionization energies along Period 2 of the periodic table. Would you expect the same variation in Period 3?
- 9.8 Describe the orbital approximation for the wavefunction of a many-electron atom. What are the limitations of the approximation?
- 9.9 Explain the origin of spin-orbit coupling and how it affects the appearance of a spectrum.
- 9.10 Describe the physical origins of linewidths in absorption and emission spectra. Do you expect the same contributions for species in condensed and gas phases?

## Exercises and Problems

The core of testing understanding is the collection of end-of-chapter *Exercises* and *Problems*. The *Exercises* are straightforward numerical tests that give practice with manipulating numerical data. The *Problems* are more searching. They are divided into ‘numerical’, where the emphasis is on the manipulation of data, and ‘theoretical’, where the emphasis is on the manipulation of equations before (in some cases) using numerical data. At the end of the *Problems* are collections of problems that focus on practical applications of various kinds, including the material covered in the *Impact* sections.

### Exercises

- 9.1(a) Determine the shortest and longest wavelength lines in the Lyman series.
- 9.1(b) The Pfund series has  $n_f = 5$ . Determine the shortest and longest wavelength lines in the Pfund series.
- 9.2(a) Compute the wavelength, frequency, and wavenumber of the  $n = 2 \rightarrow n = 1$  transition in  $\text{He}^+$ .
- 9.2(b) Compute the wavelength, frequency, and wavenumber of the  $n = 5 \rightarrow n = 4$  transition in  $\text{Li}^{2+}$ .
- 9.3(a) When ultraviolet radiation of wavelength 58.4 nm from a helium lamp is directed on to a sample of krypton, electrons are ejected with a speed of  $1.59 \text{ Mm s}^{-1}$ . Calculate the ionization energy of krypton.
- 9.3(b) When ultraviolet radiation of wavelength 58.4 nm from a helium lamp is directed on to a sample of xenon, electrons are ejected with a speed of  $1.79 \text{ Mm s}^{-1}$ . Calculate the ionization energy of xenon.
- 9.12(a) What is the orbital angular momentum of an electron in the orbitals (a) 1s, (b) 3s, (c) 3d? Give the numbers of angular and radial nodes in each case.
- 9.12(b) What is the orbital angular momentum of an electron in the orbitals (a) 4d, (b) 2p, (c) 3p? Give the numbers of angular and radial nodes in each case.
- 9.13(a) Locate the angular nodes and nodal planes of each of the 2p orbitals of a hydrogenic atom of atomic number  $Z$ . To locate the angular nodes, give the angle that the plane makes with the  $z$ -axis.
- 9.13(b) Locate the angular nodes and nodal planes of each of the 3d orbitals of a hydrogenic atom of atomic number  $Z$ . To locate the angular nodes, give the angle that the plane makes with the  $z$ -axis.
- 9.14(a) Which of the following transitions are allowed in the normal electronic emission spectrum of an atom: (a)  $2s \rightarrow 1s$ , (b)  $2p \rightarrow 1s$ , (c)  $3d \rightarrow 2p$ ?
- 9.14(b) Which of the following transitions are allowed in the normal electronic emission spectrum of an atom: (a)  $2s \rightarrow 1s$ , (b)  $2p \rightarrow 1s$ , (c)  $3d \rightarrow 2p$ ?

### Problems\*

#### Numerical problems

- 9.1 The *Humphreys series* is a group of lines in the spectrum of atomic hydrogen. It begins at 12 368 nm and has been traced to 3281.4 nm. What are the transitions involved? What are the wavelengths of the intermediate transitions?
- 9.2 A series of lines in the spectrum of atomic hydrogen lies at 656.46 nm, 486.27 nm, 434.17 nm, and 410.29 nm. What is the wavelength of the next line in the series? What is the ionization energy of the atom when it is in the lower state of the transition?
- 9.3 The  $\text{Li}^{2+}$  ion is hydrogenic and has a Lyman series at 740 747  $\text{cm}^{-1}$ , 877 924  $\text{cm}^{-1}$ , 925 933  $\text{cm}^{-1}$ , and beyond. Show that the energy levels are of the form  $-hcR/n^2$  and find the value of  $R$  for this ion. Go on to predict the wavenumbers of the two longest-wavelength transitions of the Balmer series of the ion and find the ionization energy of the ion.

the spectrum are therefore expected to be hydrogen-like, the differences arising largely from the mass differences. Predict the wavenumbers of the first three lines of the Balmer series of positronium. What is the binding energy of the ground state of positronium?

9.9 The *Zeeman effect* is the modification of an atomic spectrum by the application of a strong magnetic field. It arises from the interaction between applied magnetic fields and the magnetic moments due to orbital and spin angular momenta (recall the evidence provided for electron spin by the Stern-Gerlach experiment, Section 8.8). To gain some appreciation for the so-called *normal Zeeman effect*, which is observed in transitions involving singlet states, consider a p electron, with  $l = 1$  and  $m_l = 0, \pm 1$ . In the absence of a magnetic field, these three states are degenerate. When a field of magnitude  $\mathcal{B}$  is present, the degeneracy is removed and it is observed that the state with  $m_l = +1$  moves up in energy by  $\mu_B \mathcal{B}$ , the state with  $m_l = 0$  is unchanged, and the state with  $m_l = -1$  moves down in energy by  $\mu_B \mathcal{B}$ , where  $\mu_B = e\hbar/2m_e = 9.274 \times 10^{-24} \text{ J T}^{-1}$  is the Bohr magneton (see Section 13.1). Therefore, a

## Molecular modelling and computational chemistry

Over the past two decades computational chemistry has evolved from a highly specialized tool, available to relatively few researchers, into a powerful and practical alternative to experimentation, accessible to all chemists. The driving force behind this evolution is the remarkable progress in computer

technology. Calculations that previously required hours or days on giant mainframe computers may now be completed in a fraction of time on a personal computer. It is natural and necessary that computational chemistry finds its way into the undergraduate chemistry curriculum as a hands-on experience, just as teaching experimental chemistry requires a laboratory experience. With these developments in the chemistry curriculum in mind, the text's website features a range of computational problems, which are intended to be performed with special software that can handle 'quantum chemical calculations'. Specifically, the problems have been designed with the student edition of Wavefunction's *Spartan* program (*Spartan Student*<sup>TM</sup>) in mind, although they could be completed with any electronic structure

program that allows Hartree-Fock, density functional and MP2 calculations.

It is necessary for students to recognize that calculations are not the same as experiments, and that each 'chemical model' built from calculations has its own strengths and shortcomings. With this caveat in mind, it is important that some of the problems yield results that can be compared directly with experimental data. However, most problems are intended to stand on their own, allowing computational chemistry to serve as an exploratory tool.

Students can visit [www.wavefun.com/cart/spartaned.html](http://www.wavefun.com/cart/spartaned.html) and enter promotional code WHFPCHEM to download the *Spartan Student*<sup>TM</sup> program at a special 20% discount.

# About the Book Companion Site

---

The Book Companion Site to accompany *Physical Chemistry 9e* provides teaching and learning resources to augment the printed book. It is free of charge, and provides additional material for download, much of which can be incorporated into a virtual learning environment.

The Book Companion Site can be accessed by visiting

[www.whfreeman.com/pchem](http://www.whfreeman.com/pchem)

Note that instructor resources are available only to registered adopters of the textbook. To register, simply visit [www.whfreeman.com/pchem](http://www.whfreeman.com/pchem) and follow the appropriate links. You will be given the opportunity to select your own username and password, which will be activated once your adoption has been verified.

Student resources are openly available to all, without registration.

## For students

### Living graphs

A *Living graph* can be used to explore how a property changes as a variety of parameters are changed. To encourage the use of this resource (and the more extensive *Explorations in physical chemistry*; see below), we have included a suggested *interActivity* to many of the illustrations in the text.

### Group theory tables

Comprehensive group theory tables are available for downloading.

## For instructors

### Artwork

An instructor may wish to use the figures from this text in a lecture. Almost all the figures are available in electronic format and can be used for lectures without charge (but not for commercial purposes without specific permission).

### Tables of data

All the tables of data that appear in the chapter text are available and may be used under the same conditions as the figures.

## Other resources

### *Explorations in Physical Chemistry* by Valerie Walters, Julio de Paula, and Peter Atkins

*Explorations in Physical Chemistry* consists of interactive Mathcad® worksheets, interactive Excel® workbooks, and stimulating exercises. They motivate students to simulate physical, chemical, and biochemical phenomena with their personal computers. Students can manipulate over 75 graphics, alter simulation parameters, and solve equations, to gain deeper insight into physical chemistry.

*Explorations in Physical Chemistry* is available as an integrated part of the eBook version of the text (see below). It can also be purchased on line at <http://www.whfreeman.com/explorations>.

### *Physical Chemistry, Ninth Edition* eBook

The eBook, which is a complete online version of the textbook itself, provides a rich learning experience by taking full advantage of the electronic medium. It brings together a range of student resources alongside additional functionality unique to the eBook. The eBook also offers lecturers unparalleled flexibility and customization options. The eBook can be purchased at [www.whfreeman.com/pchem](http://www.whfreeman.com/pchem).

Key features of the eBook include:

- Easy access from any Internet-connected computer via a standard Web browser.
- Quick, intuitive navigation to any section or subsection, as well as any printed book page number.
- Living Graph animations.
- Integration of *Explorations in Physical Chemistry*.
- Text **highlighting**, down to the level of individual phrases.
- A **book marking** feature that allows for quick reference to any page.
- A powerful **Notes** feature that allows students or instructors to add notes to any page.
- A full **index**.
- **Full-text search**, including an option to search the glossary and index.
- Automatic saving of all notes, highlighting, and bookmarks.

Additional features for instructors:

- Custom chapter selection: Instructors can choose the chapters that correspond with their syllabus, and students will get a custom version of the eBook with the selected chapters only.

- Instructor notes: Instructors can choose to create an annotated version of the eBook with their notes on any page. When students in their course log in, they will see the instructor's version.

- Custom content: Instructor notes can include text, web links, and images, allowing instructors to place any content they choose exactly where they want it.

### Physical Chemistry, 9e is available in two volumes!

For maximum flexibility in your physical chemistry course, this text is now offered as a traditional, full text or in two volumes. The chapters from Physical Chemistry, 9e, that appear each volume are as follows:

Volume 1: Thermodynamics and Kinetics (1-4292-3127-0)  
 Chapter 0: Fundamentals  
 Chapter 1: The properties of gases  
 Chapter 2: The First Law  
 Chapter 3: The Second Law  
 Chapter 4: Physical transformations of pure substances  
 Chapter 5: Simple mixtures  
 Chapter 6: Chemical equilibrium  
 Chapter 20: Molecules in motion  
 Chapter 21: The rates of chemical reactions  
 Chapter 22: Reaction dynamics  
 Chapter 23: Catalysis

Volume 2: Quantum Chemistry, Spectroscopy, and Statistical Thermodynamics (1-4292-3126-2)  
 Chapter 7: Quantum theory: introduction and principles  
 Chapter 8: Quantum theory: techniques and applications  
 Chapter 9: Atomic structure and spectra  
 Chapter 10: Molecular structure  
 Chapter 11: Molecular symmetry  
 Chapter 12: Molecular spectroscopy 1: rotational and vibrational spectra  
 Chapter 13: Molecular spectroscopy 2: electronic transitions  
 Chapter 14: Molecular spectroscopy 3: magnetic resonance  
 Chapter 15: Statistical thermodynamics 1: the concepts  
 Chapter 16: Statistical thermodynamics 2: applications

Chapters 17, 18, and 19 are not contained in the two volumes, but can be made available on-line on request.

### Solutions manuals

As with previous editions, Charles Trapp, Carmen Giunta, and Marshall Cady have produced the solutions manuals to accompany this book. A *Student's Solutions Manual* (978-1-4292-3128-2) provides full solutions to the 'b' exercises and the odd-numbered problems. An *Instructor's Solutions Manual* (978-1-4292-5032-0) provides full solutions to the 'a' exercises and the even-numbered problems.

## About the authors

---

Professor Peter Atkins is a fellow of Lincoln College, University of Oxford, and the author of more than sixty books for students and a general audience. His texts are market leaders around the globe. A frequent lecturer in the United States and throughout the world, he has held visiting professorships in France, Israel, Japan, China, and New Zealand. He was the founding chairman of the Committee on Chemistry Education of the International Union of Pure and Applied Chemistry and a member of IUPAC's Physical and Biophysical Chemistry Division.

Julio de Paula is Professor of Chemistry at Lewis and Clark College. A native of Brazil, Professor de Paula received a B.A. degree in chemistry from Rutgers, The State University of New Jersey, and a Ph.D. in biophysical chemistry from Yale University. His research activities encompass the areas of molecular spectroscopy, biophysical chemistry, and nanoscience. He has taught courses in general chemistry, physical chemistry, biophysical chemistry, instrumental analysis, and writing.

# Acknowledgements

---

A book as extensive as this could not have been written without significant input from many individuals. We would like to reiterate our thanks to the hundreds of people who contributed to the first eight editions.

Many people gave their advice based on the eighth edition of the text, and others reviewed the draft chapters for the ninth edition as they emerged. We would like to thank the following colleagues:

Adedoyin Adeyiga, Cheyney University of Pennsylvania

David Andrews, University of East Anglia

Richard Ansell, University of Leeds

Colin Bain, University of Durham

Godfrey Beddard, University of Leeds

Magnus Bergstrom, Royal Institute of Technology, Stockholm, Sweden

We would like to thank two colleagues for their special contribution. Kerry Karaktis (Harvey Mudd College) provided many useful suggestions that focused on applications of the material presented in the text. David Smith (University of Bristol) made detailed comments on many of the chapters.

We also thank Claire Eisenhandler and Valerie Walters, who read through the proofs with meticulous attention to detail and caught in private what might have been a public grief. Our warm thanks also go to Charles Trapp, Carmen Giunta, and Marshall Cady who have produced the *Solutions manuals* that accompany this book.

Last, but by no means least, we would also like to thank our two publishers, Oxford University Press and W.H. Freeman & Co., for their constant encouragement, advice, and assistance, and in particular our editors Jonathan Crowe and Jessica Fiorillo. Authors could not wish for a more congenial publishing environment.

| I23.1 | Catalysis in the chemical industry | 900 |

# Fundamentals

**Chemistry** is the science of matter and the changes it can undergo. **Physical chemistry** is the branch of chemistry that establishes and develops the principles of the subject in terms of the underlying concepts of physics and the language of mathematics. It provides the basis for developing new spectroscopic techniques and their interpretation, for understanding the structures of molecules and the details of their electron distributions, and for relating the bulk properties of matter to their constituent atoms. Physical chemistry also provides a window on to the world of chemical reactions and allows us to understand in detail how they take place. In fact, the subject underpins the whole of chemistry, providing the principles in terms we use to understand structure and change and providing the basis of all techniques of investigation.

Throughout the text we shall draw on a number of concepts, most of which should already be familiar from introductory chemistry. This section reviews them. In almost every case the following chapters will provide a deeper discussion, but we are presuming that we can refer to these concepts at any stage of the presentation. Because physical chemistry lies at the interface between physics and chemistry, we also need to review some of the concepts from elementary physics that we need to draw on in the text.

## F.1 Atoms

**Key points** (a) The nuclear model is the basis for discussion of atomic structure: negatively charged electrons occupy atomic orbitals, which are arranged in shells around a positively charged nucleus. (b) The periodic table highlights similarities in electronic configurations of atoms, which in turn lead to similarities in their physical and chemical properties. (c) Monatomic ions are electrically charged atoms and are characterized by their oxidation numbers.

Matter consists of atoms. The atom of an element is characterized by its **atomic number**,  $Z$ , which is the number of protons in its nucleus. The number of neutrons in a nucleus is variable to a small extent, and the **nucleon number** (which is also commonly called the *mass number*),  $A$ , is the total number of protons and neutrons, which are collectively called **nucleons**, in the nucleus. Atoms of the same atomic number but different nucleon number are the **isotopes** of the element.

According to the **nuclear model**, an atom of atomic number  $Z$  consists of a nucleus of charge  $+Ze$  surrounded by  $Z$  electrons each of charge  $-e$  ( $e$  is the fundamental charge: see inside the front cover for its value and the values of the other fundamental constants). These electrons occupy **atomic orbitals**, which are regions of space where they are most likely to be found, with no more than two electrons in any one orbital. The atomic orbitals are arranged in **shells** around the nucleus, each shell being characterized by the **principal quantum number**,  $n = 1, 2, \dots$ . A shell consists of  $n^2$

individual orbitals, which are grouped together into  $n$  **subshells**; these subshells, and the orbitals they contain, are denoted s, p, d, and f. For all neutral atoms other than hydrogen, the subshells of a given shell have slightly different energies.

The sequential occupation of the orbitals in successive shells results in periodic similarities in the **electronic configurations**, the specification of the occupied orbitals, of atoms when they are arranged in order of their atomic number, which leads to the formulation of the **periodic table** (a version is shown inside the back cover). The vertical columns of the periodic table are called **groups** and (in the modern convention) numbered from 1 to 18. Successive rows of the periodic table are called **periods**, the number of the period being equal to the principal quantum number of the **valence shell**, the outermost shell of the atom. The periodic table is divided into s, p, d, and f **blocks**, according to the subshell that is last to be occupied in the formulation of the electronic configuration of the atom. The members of the d block (specifically the members of Groups 3–11 in the d block) are also known as the **transition metals**; those of the f block (which is not divided into numbered groups) are sometimes called the **inner transition metals**. The upper row of the f block (Period 6) consists of the **lanthanoids** (still commonly the ‘lanthanides’) and the lower row (Period 7) consists of the **actinoids** (still commonly the ‘actinides’). Some of the groups also have familiar names: Group 1 consists of the **alkali metals**, Group 2 (more specifically, calcium, strontium, and barium) of the **alkaline earth metals**, Group 17 of the **halogens**, and Group 18 of the **noble gases**. Broadly speaking, the elements towards the left of the periodic table are **metals** and those towards the right are **nonmetals**; the two classes of substance meet at a diagonal line running from boron to polonium, which constitute the **metalloids**, with properties intermediate between those of metals and nonmetals.

A monatomic **ion** is an electrically charged atom. When an atom gains one or more electrons it becomes a negatively charged **anion**; when it loses one or more electrons it becomes a positively charged **cation**. The charge number of an ion is called the **oxidation number** of the element in that state (thus, the oxidation number of magnesium in  $\text{Mg}^{2+}$  is +2 and that of oxygen in  $\text{O}^{2-}$  is –2). It is appropriate, but not always done, to distinguish between the oxidation number and the **oxidation state**, the latter being the physical state of the atom with a specified oxidation number. Thus, the oxidation number of magnesium is +2 when it is present as  $\text{Mg}^{2+}$ , and it is present *in* the oxidation state  $\text{Mg}^{2+}$ . The elements form ions that are characteristic of their location in the periodic table: metallic elements typically form cations by losing the electrons of their outermost shell and acquiring the electronic configuration of the preceding noble gas. Nonmetals typically form anions by gaining electrons and attaining the electronic configuration of the following noble gas.

## F.2 Molecules

---

**Key points** (a) Covalent compounds consist of discrete molecules in which atoms are linked by covalent bonds. (b) Ionic compounds consist of cations and anions in a crystalline array. (c) Lewis structures are useful models of the pattern of bonding in molecules. (d) The valence-shell electron pair repulsion theory (VSEPR theory) is used to predict the three-dimensional structures of molecules from their Lewis structures. (e) The electrons in polar covalent bonds are shared unevenly between the bonded nuclei.

---

A **chemical bond** is the link between atoms. Compounds that contain a metallic element typically, but far from universally, form **ionic compounds** that consist of cations and anions in a crystalline array. The ‘chemical bonds’ in an ionic compound

are due to the Coulombic interactions (Section F.4) between all the ions in the crystal, and it is inappropriate to refer to a bond between a specific pair of neighbouring ions. The smallest unit of an ionic compound is called a **formula unit**. Thus  $\text{NaNO}_3$ , consisting of a  $\text{Na}^+$  cation and a  $\text{NO}_3^-$  anion, is the formula unit of sodium nitrate. Compounds that do not contain a metallic element typically form **covalent compounds** consisting of discrete molecules. In this case, the bonds between the atoms of a molecule are **covalent**, meaning that they consist of shared pairs of electrons.

The pattern of bonds between neighbouring atoms is displayed by drawing a **Lewis structure**, in which bonds are shown as lines and **lone pairs** of electrons, pairs of valence electrons that are not used in bonding, are shown as dots. Lewis structures are constructed by allowing each atom to share electrons until it has acquired an **octet** of eight electrons (for hydrogen, a *duplet* of two electrons). A shared pair of electrons is a **single bond**, two shared pairs constitute a **double bond**, and three shared pairs constitute a **triple bond**. Atoms of elements of Period 3 and later can accommodate more than eight electrons in their valence shell and ‘expand their octet’ to become **hypervalent**, that is, form more bonds than the octet rule would allow (for example,  $\text{SF}_6$ ), or form more bonds to a small number of atoms (for example, a Lewis structure of  $\text{SO}_4^{2-}$  with one or more double bonds). When more than one Lewis structure can be written for a given arrangement of atoms, it is supposed that **resonance**, a blending of the structures, may occur and distribute multiple-bond character over the molecule (for example, the two Kekulé structures of benzene). Examples of these aspects of Lewis structures are shown in Fig. F.1.

Except in the simplest cases, a Lewis structure does not express the three-dimensional structure of a molecule. The simplest approach to the prediction of molecular shape is **valence-shell electron pair repulsion theory** (VSEPR theory). In this approach, the regions of high electron density, as represented by bonds—whether single or multiple—and lone pairs, take up orientations around the central atom that maximize their separations. Then the position of the attached atoms (not the lone pairs) is noted and used to classify the shape of the molecule. Thus, four regions of electron density adopt a tetrahedral arrangement; if an atom is at each of these locations (as in  $\text{CH}_4$ ), then the molecule is tetrahedral; if there is an atom at only three of these locations (as in  $\text{NH}_3$ ), then the molecule is trigonal pyramidal; and so on. The names of the various shapes that are commonly found are shown in Fig. F.2. In a refinement of the theory, lone pairs are assumed to repel bonding pairs more strongly than bonding pairs repel each other. The shape a molecule then adopts, if it is not

**A note on good practice** Some chemists use the term ‘molecule’ to denote the smallest unit of a compound with the composition of the bulk material regardless of whether it is an ionic or covalent compound and thus speak of ‘a molecule of  $\text{NaCl}$ ’. We use the term ‘molecule’ to denote a discrete covalently bonded entity (as in  $\text{H}_2\text{O}$ ); for an ionic compound we use ‘formula unit’.

**Fig. F.1** A collection of typical Lewis structures for simple molecules and ions. The structures show the bonding patterns and lone pairs and, except in simple cases, do not express the shape of the species.

**Fig. F.2** The names of the shapes of the geometrical figures used to describe symmetrical polyatomic molecules and ions.

**Fig. F.3** (a) The influences on the shape of the  $\text{SF}_4$  molecule according to the VSEPR model. (b) As a result the molecule adopts a bent see-saw shape.

determined fully by symmetry, is such as to minimize repulsions from lone pairs. Thus, in  $\text{SF}_4$  the lone pair adopts an equatorial position and the two axial S–F bonds bend away from it slightly, to give a bent see-saw shaped molecule (Fig. F.3).

Covalent bonds may be **polar**, or correspond to an unequal sharing of the electron pair, with the result that one atom has a partial positive charge (denoted  $\delta+$ ) and the other a partial negative charge ( $\delta-$ ). The ability of an atom to attract electrons to itself when part of a molecule is measured by the **electronegativity**,  $\chi(\text{chi})$ , of the element. The juxtaposition of equal and opposite partial charges constitutes an **electric dipole**. If those charges are  $+Q$  and  $-Q$  and they are separated by a distance  $d$ , the magnitude of the **electric dipole moment** is  $\mu = Qd$ . Whether or not a molecule as a whole is polar depends on the arrangement of its bonds, for in highly symmetrical molecules there may be no net dipole. Thus, although the linear  $\text{CO}_2$  molecule (which is structurally  $\text{OCO}$ ) has polar CO bonds, their effects cancel and the molecule as a whole is nonpolar.

### F.3 Bulk matter

**Key points** (a) The physical states of bulk matter are solid, liquid, or gas. (b) The state of a sample of bulk matter is defined by specifying its properties, such as mass, volume, amount, pressure, and temperature. (c) The perfect gas law is a relation between the pressure, volume, amount, and temperature of an idealized gas.

**Bulk matter** consists of large numbers of atoms, molecules, or ions. Its physical state may be solid, liquid, or gas:

A **solid** is a form of matter that adopts and maintains a shape that is independent of the container it occupies.

A **liquid** is a form of matter that adopts the shape of the part of the container it occupies (in a gravitational field, the lower part) and is separated from the unoccupied part of the container by a definite surface.

A **gas** is a form of matter that immediately fills any container it occupies.

A liquid and a solid are examples of a **condensed state** of matter. A liquid and a gas are examples of a **fluid** form of matter: they flow in response to forces (such as gravity) that are applied.

The state of a bulk sample of matter is defined by specifying the values of various properties. Among them are:

The **mass**,  $m$ , a measure of the quantity of matter present (unit: kilogram, kg).

The **volume**,  $V$ , a measure of the quantity of space the sample occupies (unit: cubic metre,  $\text{m}^3$ ).

The **amount of substance**,  $n$ , a measure of the number of specified entities (atoms, molecules, or formula units) present (unit: mole, mol).

An **extensive property** of bulk matter is a property that depends on the amount of substance present in the sample; an **intensive property** is a property that is independent of the amount of substance. The volume is extensive; the mass density,  $\rho$  (rho), the mass of a sample divided by its volume,  $\rho = m/V$ , is intensive.

The amount of substance,  $n$  (colloquially, ‘the number of moles’), is a measure of the number of specified entities present in the sample. ‘Amount of substance’ is the official name of the quantity; it is commonly simplified to ‘chemical amount’ or simply ‘amount’. The unit 1 mol is defined as the number of carbon atoms in exactly 12 g of carbon-12. The number of entities per mole is called **Avogadro’s constant**,  $N_A$ ; the currently accepted value is  $6.022 \times 10^{23} \text{ mol}^{-1}$  (note that  $N_A$  is a constant with units, not a pure number). The **molar mass of a substance**,  $M$  (units: formally kilograms per mole but commonly grams per mole,  $\text{g mol}^{-1}$ ) is the mass per mole of its atoms, its molecules, or its formula units. The amount of substance of specified entities in a sample can readily be calculated from its mass, by noting that

$$n = \frac{m}{M} \quad (\text{F.1})$$

A sample of matter may be subjected to a **pressure**,  $p$  (unit: pascal, Pa;  $1 \text{ Pa} = 1 \text{ kg m}^{-1} \text{ s}^{-2}$ ), which is defined as the force,  $F$ , it is subjected to, divided by the area,  $A$ , to which that force is applied. A sample of gas exerts a pressure on the walls of its container because the molecules of gas are in ceaseless, random motion and exert a force when they strike the walls. The frequency of the collisions is normally so great that the force, and therefore the pressure, is perceived as being steady. Although pascal is the SI unit of pressure (Section F.6), it is also common to express pressure in bar ( $1 \text{ bar} = 10^5 \text{ Pa}$ ) or atmospheres ( $1 \text{ atm} = 101\,325 \text{ Pa}$  exactly), both of which correspond to typical atmospheric pressure. We shall see that, because many physical properties depend on the pressure acting on a sample, it is appropriate to select a certain value of the pressure to report their values. The **standard pressure** for reporting physical quantities is currently defined as  $p^\circ = 1 \text{ bar}$  exactly. We shall see the role of the standard pressure starting in Chapter 2.

To specify the state of a sample fully it is also necessary to give its **temperature**,  $T$ . The temperature is formally a property that determines in which direction energy will flow as heat when two samples are placed in contact through thermally conducting walls: energy flows from the sample with the higher temperature to the sample with the lower temperature. The symbol  $T$  is used to denote the **thermodynamic temperature**, which is an absolute scale with  $T = 0$  as the lowest point. Temperatures above  $T = 0$  are then most commonly expressed by using the **Kelvin scale**, in which the gradations of temperature are called **kelvin** (K). The Kelvin scale is defined by setting the triple point of water (the temperature at which ice, liquid water, and water vapour are in mutual equilibrium) at exactly 273.16 K. The freezing point of water (the melting point of ice) at 1 atm is then found experimentally to lie 0.01 K below the triple point, so the freezing point of water is 273.15 K. The Kelvin scale is unsuitable for everyday

**A note on good practice** Be careful to distinguish atomic or molecular mass (the mass of a single atom or molecule; units kg) from molar mass (the mass per mole of atoms or molecules; units  $\text{kg mol}^{-1}$ ). *Relative molecular masses* of atoms and molecules,  $M_r = m/m_u$ , where  $m$  is the mass of the atom or molecule and  $m_u$  is the atomic mass constant, are still widely called ‘atomic weights’ and ‘molecular weights’ even though they are dimensionless quantities and not weights (the gravitational force exerted on an object). Even IUPAC continues to use the terms ‘for historical reasons’.

**A note on good practice** Note that we write  $T = 0$ , not  $T = 0 \text{ K}$ . General statements in science should be expressed without reference to a specific set of units. Moreover, because  $T$  (unlike  $\theta$ ) is absolute, the lowest point is 0 regardless of the scale used to express higher temperatures (such as the Kelvin scale or the Rankine scale). Similarly, we write  $m = 0$ , not  $m = 0 \text{ kg}$  and  $l = 0$ , not  $l = 0 \text{ m}$ .

measurements of temperature, and it is common to use the **Celsius scale**, which is defined in terms of the Kelvin scale as

$$\theta/^{\circ}\text{C} = T/\text{K} - 273.15 \quad \text{Definition of Celsius scale} \quad (\text{F.2})$$

Thus, the freezing point of water is  $0^{\circ}\text{C}$  and its boiling point (at 1 atm) is found to be  $100^{\circ}\text{C}$  (more precisely  $99.974^{\circ}\text{C}$ ). Note that in this text  $T$  invariably denotes the thermodynamic (absolute) temperature and that temperatures on the Celsius scale are denoted  $\theta$  (theta).

The properties that define the state of a system are not in general independent of one another. The most important example of a relation between them is provided by the idealized fluid known as a **perfect gas** (also, commonly, an ‘ideal gas’)

$$pV = nRT \quad \text{Perfect gas equation} \quad (\text{F.3})$$

Here  $R$  is the **gas constant**, a universal constant (in the sense of being independent of the chemical identity of the gas) with the value  $8.314 \text{ J K}^{-1} \text{ mol}^{-1}$ . Equation F.3 is central to the development of the description of gases in Chapter 1.

## F.4 Energy

**Key points** (a) Energy is the capacity to do work. (b) The total energy of a particle is the sum of its kinetic and potential energies. The kinetic energy of a particle is the energy it possesses as a result of its motion. The potential energy of a particle is the energy it possesses as a result of its position. (c) The Coulomb potential energy between two charges separated by a distance  $r$  varies as  $1/r$ .

Much of chemistry is concerned with transfers and transformations of energy, and it is appropriate to define this familiar quantity precisely: **energy** is the capacity to do work. In turn, work is defined as motion against an opposing force. The SI unit of energy is the joule (J), with

$$1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$$

(see Section F.7).

A body may possess two kinds of energy, kinetic energy and potential energy. The **kinetic energy**,  $E_{\text{k}}$ , of a body is the energy the body possesses as a result of its motion. For a body of mass  $m$  travelling at a speed  $v$

$$E_{\text{k}} = \frac{1}{2}mv^2 \quad \text{Kinetic energy} \quad (\text{F.4})$$

The **potential energy**,  $E_{\text{p}}$  or more commonly  $V$ , of a body is the energy it possesses as a result of its position. No universal expression for the potential energy can be given because it depends on the type of force that the body experiences. For a particle of mass  $m$  at an altitude  $h$  close to the surface of the Earth, the gravitational potential energy is

$$V(h) = V(0) + mgh \quad \text{Gravitational potential energy} \quad (\text{F.5})$$

where  $g$  is the **acceleration of free fall** ( $g = 9.81 \text{ m s}^{-2}$ ). The zero of potential energy is arbitrary, and in this case it is common to set  $V(0) = 0$ .

**A note on good practice** Although the term ‘ideal gas’ is almost universally used in place of ‘perfect gas’, there are reasons for preferring the latter term. In an ideal system (as will be explained in Chapter 5) the interactions between molecules in a mixture are all the same. In a perfect gas not only are the interactions all the same but they are in fact zero. Few, though, make this useful distinction.

One of the most important forms of potential energy in chemistry is the **Coulomb potential energy**, the potential energy of the electrostatic interaction between two point electric charges. For a point charge  $Q_1$  at a distance  $r$  in a vacuum from another point charge  $Q_2$

$$V(r) = \frac{Q_1 Q_2}{4\pi\epsilon_0 r} \quad \text{Coulomb potential energy} \quad (\text{F.6})$$

It is conventional (as here) to set the potential energy equal to zero at infinite separation of charges. Then two opposite charges have a negative potential energy at finite separations, whereas two like charges have a positive potential energy. Charge is expressed in coulombs (C), often as a multiple of the fundamental charge,  $e$ . Thus, the charge of an electron is  $-e$  and that of a proton is  $+e$ ; the charge of an ion is  $ze$ , with  $z$  the **charge number** (positive for cations, negative for anions). The constant  $\epsilon_0$  (epsilon zero) is the **vacuum permittivity**, a fundamental constant with the value  $8.854 \times 10^{-12} \text{ C}^2 \text{ J}^{-1} \text{ m}^{-1}$ . In a medium other than a vacuum, the potential energy of interaction between two charges is reduced, and the vacuum permittivity is replaced by the **permittivity**,  $\epsilon$ , of the medium. The permittivity is commonly expressed as a multiple of the vacuum permittivity

$$\epsilon = \epsilon_r \epsilon_0 \quad (\text{F.7})$$

with  $\epsilon_r$  the dimensionless **relative permittivity** (formerly, the *dielectric constant*).

The **total energy** of a particle is the sum of its kinetic and potential energies

$$E = E_k + E_p \quad (\text{F.8})$$

We make frequent use of the apparently universal law of nature that *energy is conserved*; that is, energy can neither be created nor destroyed. Although energy can be transferred from one location to another and transformed from one form to another, the total energy is constant.

## F.5 The relation between molecular and bulk properties

**Key points** (a) The energy levels of confined particles are quantized. (b) The Boltzmann distribution is a formula for calculating the relative populations of states of various energies. (c) The equipartition theorem provides a way to calculate the energy of some systems.

The energy of a molecule, atom, or subatomic particle that is confined to a region of space is **quantized**, or restricted to certain discrete values. These permitted energies are called **energy levels**. The values of the permitted energies depend on the characteristics of the particle (for instance, its mass) and the extent of the region to which it is confined. The quantization of energy is most important—in the sense that the allowed energies are widest apart—for particles of small mass confined to small regions of space. Consequently, quantization is very important for electrons in atoms and molecules, but usually unimportant for macroscopic bodies. For particles in containers of macroscopic dimensions the separation of energy levels is so small that for all practical purposes the motion of the particles through space—their translational motion—is unquantized and can be varied virtually continuously. As we shall see in detail in Chapter 7, quantization becomes increasingly important as we change focus from rotational to vibrational and then to electronic motion. The separation of rotational energy levels (in small molecules, about  $10^{-23} \text{ J}$  or  $0.01 \text{ zJ}$ , corresponding to about  $0.01 \text{ kJ mol}^{-1}$ ) is smaller than that of vibrational energy levels (about  $10 \text{ kJ mol}^{-1}$ ), which itself is smaller than that of electronic energy levels (about  $10^{-18} \text{ J}$  or  $1 \text{ aJ}$ , corresponding to about  $10^3 \text{ kJ mol}^{-1}$ ). Figure F.4 depicts these typical energy level separations.

**Fig. F.4** The energy level separations (expressed as wavenumbers) typical of four types of system.

### A brief comment

The uncommon but useful prefixes **z** (for zepto) and **a** (for atto) are explained in Section F.7 on the use of units.

**Fig. F.5** The Boltzmann distribution of populations for a system of five energy levels as the temperature is raised from zero to infinity.

### (a) The Boltzmann distribution

The continuous thermal agitation that the molecules experience in a sample when  $T > 0$  ensures that they are distributed over the available energy levels. One particular molecule may be in a state corresponding to a low energy level at one instant, and then be excited into a high energy state a moment later. Although we cannot keep track of the state of a single molecule, we can speak of the *average* numbers of molecules in each state. Even though individual molecules may be changing their states as a result of collisions, the average number in each state is constant (provided the temperature remains the same).

The average number of molecules in a state is called the **population** of the state. Only the lowest energy state is occupied at  $T = 0$ . Raising the temperature excites some molecules into higher energy states, and more and more states become accessible as the temperature is raised further (Fig. F.5). The formula for calculating the relative populations of states of various energies is called the **Boltzmann distribution** and was derived by the Austrian scientist Ludwig Boltzmann towards the end of the nineteenth century. Although we shall derive and discuss this distribution in more detail in Chapter 15, at this point it is important to know that it gives the ratio of the numbers of particles in states with energies  $E_i$  and  $E_j$  as

$$\frac{N_i}{N_j} = e^{-(E_i - E_j)/kT} \quad \text{Boltzmann distribution} \quad (\text{F.9})$$

where  $k$  is **Boltzmann's constant**, a fundamental constant with the value  $k = 1.381 \times 10^{-23} \text{ J K}^{-1}$ . This constant occurs throughout physical chemistry, often in a disguised (molar) form as the gas constant, for

$$R = N_A k \quad (\text{F.10})$$

where  $N_A$  is Avogadro's constant. We shall see in Chapter 15 that the Boltzmann distribution provides the crucial link for expressing the macroscopic properties of bulk matter in terms of the behaviour of its constituent atoms.

The important features of the Boltzmann distribution to bear in mind are:

- The higher the energy of a state, the lower its population.
- The higher the temperature, the more likely it is that a state of high energy is populated.
- More levels are significantly populated if they are close together in comparison with  $kT$  (like rotational and translational states), than if they are far apart (like vibrational and electronic states).

Figure F.6 summarizes the form of the Boltzmann distribution for some typical sets of energy levels. The peculiar shape of the population of rotational levels stems from the fact that eqn F.9 applies to *individual states*, and for molecular rotation the number of rotational states corresponding to a given energy increases with energy. Broadly speaking, the number of planes of rotation increases with energy. Therefore, although the population of each *state* decreases with energy, the population of the *levels* goes through a maximum.

One of the simplest examples of the relation between microscopic and bulk properties is provided by **kinetic molecular theory**, a model of a perfect gas. In this model, it is assumed that the molecules, imagined as particles of negligible size, are in ceaseless, random motion and do not interact except during their brief collisions. Different speeds correspond to different kinetic energies, so the Boltzmann formula can be used to predict the proportions of molecules having a specific speed at a particular temperature. The expression giving the fraction of molecules that have a particular speed is

**Fig. F.6** The Boltzmann distribution of populations for rotation, vibration, and electronic energy levels at room temperature.

called the **Maxwell distribution**, and has the features summarized in Fig. F.7. The Maxwell distribution, which is derived, specified, and discussed more fully in Chapter 20, can be used to show that the average speed,  $v_{\text{mean}}$ , of the molecules depends on the temperature and their molar mass as

$$v_{\text{mean}} \propto \left( \frac{T}{M} \right)^{1/2} \quad (\text{F.11})$$

That is, the average speed increases as the square-root of the temperature and decreases as the square-root of the molar mass. Thus, the average speed is high for light molecules at high temperatures. The distribution itself gives more information than the average value. For instance, the tail towards high speeds is longer at high temperatures than at low, which indicates that at high temperatures more molecules in a sample have speeds much higher than average.

### (b) Equipartition

The Boltzmann distribution can be used to calculate the average energy associated with each mode of motion of a molecule (as we shall see in detail in Chapters 15 and 16). However, for certain modes of motion (which in practice means translation of any molecule and the rotation of all except the lightest molecules) there is a short cut, called the **equipartition theorem**. This theorem (which is derived from the Boltzmann distribution) states:

In a sample at a temperature  $T$ , all quadratic contributions to the total energy have the same mean value, namely  $\frac{1}{2}kT$ .

Equipartition  
theorem

A ‘quadratic contribution’ simply means a contribution that depends on the square of the position or the velocity (or momentum). For example, because the kinetic energy of a body of mass  $m$  free to undergo translation in three dimensions is  $E_k = \frac{1}{2}mv_x^2 + \frac{1}{2}mv_y^2 + \frac{1}{2}mv_z^2$ , there are three quadratic terms. The theorem implies that the average kinetic energy of motion parallel to the  $x$ -axis is the same as the average kinetic energy of motion parallel to the  $y$ -axis and to the  $z$ -axis. That is, in a normal sample (one at thermal equilibrium throughout), the total energy is equally ‘partitioned’ over all the available modes of motion. One mode of motion is not especially rich in energy at the expense of another. Because the average contribution of each mode is  $\frac{1}{2}kT$ , the average kinetic energy of a molecule free to move in three dimensions is  $\frac{3}{2}kT$ , as there are three quadratic contributions to the kinetic energy.

We shall often use the equipartition theorem to make quick assessments of molecular properties and to judge the outcome of the competition of the ordering effects of intermolecular interactions and the disordering effects of thermal motion.

**Fig. F.7** The distribution of molecular speeds with temperature and molar mass. Note that the most probable speed (corresponding to the peak of the distribution) increases with temperature and with decreasing molar mass, and simultaneously the distribution becomes broader.

**interActivity** (a) Plot different distributions by keeping the molar mass constant at  $100 \text{ g mol}^{-1}$  and varying the temperature of the sample between 200 K and 2000 K. (b) Use mathematical software or the *Living graph* applet from the text’s web site to evaluate numerically the fraction of molecules with speeds in the range  $100 \text{ m s}^{-1}$  to  $200 \text{ m s}^{-1}$  at 300 K and 1000 K. (c) Based on your observations, provide a molecular interpretation of temperature.

## F.6 The electromagnetic field

**Key point** Electromagnetic radiation is characterized by its direction of propagation, its wavelength, frequency, and wavenumber, and its state of polarization.

Light is a form of electromagnetic radiation. In classical physics, electromagnetic radiation is understood in terms of the **electromagnetic field**, an oscillating electric and magnetic disturbance that spreads as a harmonic wave through empty space, the vacuum. The wave travels at a constant speed called the *speed of light*,  $c$ , which is about  $3 \times 10^8 \text{ m s}^{-1}$ . As its name suggests, an electromagnetic field has two components, an **electric field** that acts on charged particles (whether stationary or moving) and a **magnetic field** that acts only on moving charged particles. The electromagnetic field,

**Fig. F.8** (a) The wavelength,  $\lambda$ , of a wave is the peak-to-peak distance. (b) The wave is shown travelling to the right at a speed  $c$ . At a given location, the instantaneous amplitude of the wave changes through a complete cycle (the six dots show half a cycle) as it passes a given point. The frequency,  $\nu$ , is the number of cycles per second that occur at a given point. Wavelength and frequency are related by  $\lambda\nu = c$ .

**A note on good practice** You will hear people speaking of ‘a frequency of so many wavenumbers’. That is doubly wrong. First, wavenumber and frequency are two different physical observables. Second, wavenumber is a physical quantity, not a unit. The dimensions of wavenumber are  $1/\text{length}$  and it is commonly reported in reciprocal centimetres,  $\text{cm}^{-1}$ .

like any periodic wave, is characterized by a **wavelength**,  $\lambda$  (lambda), the distance between the neighbouring peaks of the wave, and its **frequency**,  $\nu$  (nu), the number of times in a given time interval at which its displacement at a fixed point returns to its original value divided by the length of the time interval, normally in seconds (Fig. F.8). The frequency is measured in *hertz*, where  $1 \text{ Hz} = 1 \text{ s}^{-1}$ . The wavelength and frequency of an electromagnetic wave are related by

$$\lambda\nu = c \quad (\text{F.12})$$

Therefore, the shorter the wavelength, the higher the frequency. The characteristics of a wave are also reported by giving the **wavenumber**,  $\tilde{\nu}$  (nu tilde), of the radiation, where

$$\tilde{\nu} = \frac{\nu}{c} = \frac{1}{\lambda} \quad (\text{F.13})$$

A wavenumber can be interpreted as the number of complete wavelengths in a given length. Wavenumbers are normally reported in reciprocal centimetres ( $\text{cm}^{-1}$ ), so a wavenumber of  $5 \text{ cm}^{-1}$  indicates that there are 5 complete wavelengths in 1 cm. A typical wavenumber of visible light is about  $15\,000 \text{ cm}^{-1}$ , corresponding to 15 000 complete wavelengths in each centimetre. The classification of the electromagnetic field according to its frequency and wavelength is summarized in Fig. F.9.

Electromagnetic radiation is **plane-polarized** if the electric and magnetic fields each oscillate in a single plane (Fig. F.10). The plane of polarization may be orientated in any direction around the direction of propagation with the electric and magnetic fields perpendicular to that direction (and perpendicular to each other). An alternative mode of polarization is **circular polarization**, in which the electric and magnetic fields rotate around the direction of propagation in either a clockwise or a counter-clockwise sense but remain perpendicular to it and each other.

According to classical electromagnetic theory, the intensity of electromagnetic radiation is proportional to the square of the amplitude of the wave. For example, the radiation detectors used in spectroscopy are based on the interaction between the electric field of the incident radiation and the detecting element, so light intensities are proportional to the square of the amplitude of the waves.

## F.7 Units

**Key points** (a) The measurement of a physical property is expressed as the product of a numerical value and a unit. (b) In the International System of units (SI), the units are formed from seven base units, and all other physical quantities may be expressed as combinations of these physical quantities and reported in terms of derived units.

The measurement of a physical property is expressed as

$$\text{Physical property} = \text{numerical value} \times \text{unit}$$

For example, a length ( $l$ ) may be reported as  $l = 5.1 \text{ m}$ , if it is found to be 5.1 times as great as a defined unit of length, namely, 1 metre (1 m). Units are treated as algebraic quantities, and may be multiplied and divided. Thus, the same length could be reported as  $l/m = 5.1$ . The symbols for physical properties are always italic (sloping; thus  $V$  for volume, not  $V$ ), including Greek symbols (thus,  $\mu$  for electric dipole moment, not  $\mu$ ), but available typefaces are not always so obliging.

In the **International System** of units (SI, from the French *Système International d’Unités*), the units are formed from seven **base units** listed in Table F.1. All other physical quantities may be expressed as combinations of these physical quantities and

**Fig. F.9** The regions of the electromagnetic spectrum. The boundaries are only approximate.

**Fig. F.10** Electromagnetic radiation consists of a wave of electric and magnetic fields perpendicular to the direction of propagation (in this case the  $x$ -direction), and mutually perpendicular to each other. This illustration shows a plane-polarized wave, with the electric and magnetic fields oscillating in the  $xz$ - and  $xy$ -planes, respectively.

**Table F.1** The SI base units

| Physical quantity         | Symbol for quantity | Base unit    |
|---------------------------|---------------------|--------------|
| Length                    | $l$                 | metre, m     |
| Mass                      | $m$                 | kilogram, kg |
| Time                      | $t$                 | second, s    |
| Electric current          | $I$                 | ampere, A    |
| Thermodynamic temperature | $T$                 | kelvin, K    |
| Amount of substance       | $n$                 | mole, mol    |
| Luminous intensity        | $I_v$               | candela, cd  |

**Table F.2** A selection of derived units

| Physical quantity | Derived unit*                                                              | Name of derived unit |
|-------------------|----------------------------------------------------------------------------|----------------------|
| Force             | $1 \text{ kg m s}^{-2}$                                                    | newton, N            |
| Pressure          | $1 \text{ kg m}^{-1} \text{ s}^{-2}$<br>$1 \text{ N m}^{-2}$               | pascal, Pa           |
| Energy            | $1 \text{ kg m}^2 \text{ s}^{-2}$<br>$1 \text{ N m}$<br>$1 \text{ Pa m}^3$ | joule, J             |
| Power             | $1 \text{ kg m}^2 \text{ s}^{-3}$<br>$1 \text{ J s}^{-1}$                  | watt, W              |

\* Equivalent definitions in terms of derived units are given following the definition in terms of base units.

**Table F.3** Common SI prefixes

| Prefix | y          | z          | a          | f          | p          | n         | $\mu$     | m         | c         | d         |
|--------|------------|------------|------------|------------|------------|-----------|-----------|-----------|-----------|-----------|
| Name   | yocto      | zepto      | atto       | femto      | pico       | nano      | micro     | milli     | centi     | deci      |
| Factor | $10^{-24}$ | $10^{-21}$ | $10^{-18}$ | $10^{-15}$ | $10^{-12}$ | $10^{-9}$ | $10^{-6}$ | $10^{-3}$ | $10^{-2}$ | $10^{-1}$ |
| Prefix | da         | h          | k          | M          | G          | T         | P         | E         | Z         | Y         |
| Name   | deca       | hecto      | kilo       | mega       | giga       | tera      | peta      | exa       | zeta      | yotta     |
| Factor | 10         | $10^2$     | $10^3$     | $10^6$     | $10^9$     | $10^{12}$ | $10^{15}$ | $10^{18}$ | $10^{21}$ | $10^{24}$ |

reported in terms of **derived units**. Thus, volume is  $(\text{length})^3$  and may be reported as a multiple of 1 metre cubed ( $1 \text{ m}^3$ ), and density, which is mass/volume, may be reported as a multiple of 1 kilogram per metre cubed ( $1 \text{ kg m}^{-3}$ ).

A number of derived units have special names and symbols. The names of units derived from names of people are lower case (as in torr, joule, pascal, and kelvin), but their symbols are upper case (as in Torr, J, Pa, and K). The most important for our purposes are listed in Table F.2.

In all cases (both for base and derived quantities), the units may be modified by a prefix that denotes a factor of a power of 10. The Greek prefixes of units are upright (as in  $\mu\text{m}$ , not  $\mu\text{m}$ ). Among the most common prefixes are those listed in Table F.3. Examples of the use of these prefixes are

$$1 \text{ nm} = 10^{-9} \text{ m} \quad 1 \text{ ps} = 10^{-12} \text{ s} \quad 1 \mu\text{mol} = 10^{-6} \text{ mol}$$

The kilogram (kg) is anomalous: although it is a base unit, it is interpreted as  $10^3 \text{ g}$ , and prefixes are attached to the gram (as in  $1 \text{ mg} = 10^{-3} \text{ g}$ ). Powers of units apply to the prefix as well as the unit they modify

$$1 \text{ cm}^3 = 1 (\text{cm})^3 = 1 (10^{-2} \text{ m})^3 = 10^{-6} \text{ m}^3$$

Note that  $1 \text{ cm}^3$  does not mean  $1 \text{ c}(\text{m}^3)$ . When carrying out numerical calculations, it is usually safest to write out the numerical value of an observable as a power of 10.

There are a number of units that are in wide use but are not a part of the International System. Some are exactly equal to multiples of SI units. These include the *litre* (L), which is exactly  $10^3 \text{ cm}^3$  (or  $1 \text{ dm}^3$ ) and the *atmosphere* (atm), which is exactly 101.325 kPa. Others rely on the values of fundamental constants, and hence are liable to change when the values of the fundamental constants are modified by more accurate

**Table F.4** Some common units

| Physical quantity | Name of unit | Symbol for unit | Value*                             |
|-------------------|--------------|-----------------|------------------------------------|
| Time              | minute       | min             | 60 s                               |
|                   | hour         | h               | 3600 s                             |
|                   | day          | d               | 86 400 s                           |
|                   | year         | a               | 31 556 952 s                       |
| Length            | ångström     | Å               | $10^{-10}$ m                       |
| Volume            | litre        | L, l            | 1 dm <sup>3</sup>                  |
| Mass              | tonne        | t               | $10^3$ kg                          |
| Pressure          | bar          | bar             | $10^5$ Pa                          |
|                   | atmosphere   | atm             | 101.325 kPa                        |
| Energy            | electronvolt | eV              | $1.602\,176\,53 \times 10^{-19}$ J |
|                   |              |                 | 96.485 31 kJ mol <sup>-1</sup>     |

\* All values in the final column are exact, except for the definition of 1 eV, which depends on the measured value of  $e$ , and the year, which is not a constant and depends on a variety of astronomical assumptions.

or more precise measurements. Thus, the size of the energy unit *electronvolt* (eV), the energy acquired by an electron that is accelerated through a potential difference of exactly 1 V, depends on the value of the charge of the electron, and the present (2008) conversion factor is  $1\text{ eV} = 1.602\,176\,53 \times 10^{-19}\text{ J}$ . Table F.4 gives the conversion factors for a number of these convenient units.

## Exercises

### F.1 Atoms

**F1.1(a)** Summarize the nuclear model of the atom.

**F1.1(b)** Define the terms atomic number, nucleon number, mass number.

**F1.2(a)** Express the typical ground-state electron configuration of an atom of an element in (a) Group 2, (b) Group 7, (c) Group 15 of the periodic table.

**F1.2(b)** Express the typical ground-state electron configuration of an atom of an element in (a) Group 3, (b) Group 5, (c) Group 13 of the periodic table.

**F1.3(a)** Identify the oxidation numbers of the elements in (a)  $\text{MgCl}_2$ , (b)  $\text{FeO}$ , (c)  $\text{Hg}_2\text{Cl}_2$ .

**F1.3(b)** Identify the oxidation numbers of the elements in (a)  $\text{CaH}_2$ , (b)  $\text{CaC}_2$ , (c)  $\text{LiN}_3$ .

**F1.4(a)** Where in the periodic table are metals and nonmetals found?

**F1.4(b)** Where in the periodic table are transition metals, lanthanoids, and actinoids found?

### F.2 Molecules

**F2.1(a)** Summarize what is meant by a single and multiple bond.

**F2.1(b)** Identify a molecule with (a) one, (b) two, (c) three lone pairs on the central atom.

**F2.2(a)** Draw the Lewis (electron dot) structures of (a)  $\text{SO}_3^{2-}$ , (b)  $\text{XeF}_4$ , (c)  $\text{P}_4$ .

**F2.2(b)** Draw the Lewis (electron dot) structures of (a)  $\text{O}_3$ , (b)  $\text{ClF}_3^+$ , (c)  $\text{N}_3^-$ .

**F2.3(a)** Summarize the principal concepts of the VSEPR theory of molecular shape.

**F2.3(b)** Identify four hypervalent compounds.

**F2.4(a)** Use VSEPR theory to predict the structures of (a)  $\text{PCl}_3$ , (b)  $\text{PCl}_5$ , (c)  $\text{XeF}_2$ , (d)  $\text{XeF}_4$ .

**F2.4(b)** Use VSEPR theory to predict the structures of (a)  $\text{H}_2\text{O}_2$ , (b)  $\text{FSO}_3^-$ , (c)  $\text{KrF}_2$ , (d)  $\text{PCl}_4^+$ .

**F2.5(a)** Identify the polarities (by attaching partial charges  $\delta^+$  and  $\delta^-$ ) of the bonds (a) C–Cl, (b) P–H, (c) N–O.

**F2.5(b)** Identify the polarities (by attaching partial charges  $\delta^+$  and  $\delta^-$ ) of the bonds (a) C–H, (b) P–S, (c) N–Cl.

**F2.6(a)** State whether you expect the following molecules to be polar or nonpolar: (a)  $\text{CO}_2$ , (b)  $\text{SO}_2$ , (c)  $\text{N}_2\text{O}$ , (d)  $\text{SF}_4$ .

**F2.6(b)** State whether you expect the following molecules to be polar or nonpolar: (a)  $\text{O}_3$ , (b)  $\text{XeF}_2$ , (c)  $\text{NO}_2$ , (d)  $\text{C}_6\text{H}_{14}$ .

**F2.7(a)** Arrange the molecules in Exercise F2.6a by increasing dipole moment.

**F2.7(b)** Arrange the molecules in Exercise F2.6b by increasing dipole moment.

## F.3 Bulk matter

**F3.1(a)** Compare and contrast the properties of the solid, liquid, and gas states of matter.

**F3.1(b)** Compare and contrast the properties of the condensed and gaseous states of matter.

**F3.2(a)** Classify the following properties as extensive or intensive: (a) mass, (b) mass density, (c) temperature, (d) number density.

**F3.2(b)** Classify the following properties as extensive or intensive: (a) pressure, (b) specific heat capacity, (c) weight, (d) molality.

**F3.3(a)** Calculate (a) the amount of  $\text{C}_2\text{H}_5\text{OH}$  (in moles) and (b) the number of molecules present in 25.0 g of ethanol.

**F3.3(b)** Calculate (a) the amount of  $\text{C}_6\text{H}_{12}\text{O}_6$  (in moles) and (b) the number of molecules present in 5.0 g of glucose.

**F3.4(a)** Express a pressure of 1.45 atm in (a) pascal, (b) bar.

**F3.4(b)** Express a pressure of 222 atm in (a) pascal, (b) bar.

**F3.5(a)** Convert blood temperature,  $37.0^\circ\text{C}$ , to the Kelvin scale.

**F3.5(b)** Convert the boiling point of oxygen, 90.18 K, to the Celsius scale.

**F3.6(a)** Equation F.2 is a relation between the Kelvin and Celsius scales. Devise the corresponding equation relating the Fahrenheit and Celsius scales and use it to express the boiling point of ethanol ( $78.5^\circ\text{C}$ ) in degrees Fahrenheit.

**F3.6(b)** The Rankine scale is a version of the thermodynamic temperature scale in which the degrees ( $^\circ\text{R}$ ) are the same size as degrees Fahrenheit. Derive an expression relating the Rankine and Kelvin scales and express the freezing point of water in degrees Rankine.

**F3.7(a)** A sample of hydrogen gas was found to have a pressure of 110 kPa when the temperature was  $20.0^\circ\text{C}$ . What is its pressure expected to be when the temperature is  $7.0^\circ\text{C}$ ?

**F3.7(b)** A sample of 325 mg of neon occupies  $2.00\text{ dm}^3$  at  $20.0^\circ\text{C}$ . Use the perfect gas law to calculate the pressure of the gas.

## F.4 Energy

**F4.1(a)** Define energy and work.

**F4.1(b)** Distinguish between kinetic and potential energy.

**F4.2(a)** Consider a region of the atmosphere of volume  $25\text{ dm}^3$  that at  $20^\circ\text{C}$  contains about 1.0 mol of molecules. Take the average molar mass of the molecules as  $29\text{ g mol}^{-1}$  and their average speed as about  $400\text{ m s}^{-1}$ . Estimate the energy stored as molecular kinetic energy in this volume of air.

**F4.2(b)** Calculate the minimum energy that a bird of mass 25 g must expend in order to reach a height of 50 m.

**F4.3(a)** The potential energy of a charge  $Q_1$  in the presence of another charge  $Q_2$  can be expressed in terms of the *Coulomb potential*,  $\phi$  (phi):

$$V = Q_1\phi \quad \phi = \frac{Q_2}{4\pi\epsilon_0 r}$$

The units of potential are joules per coulomb,  $\text{J C}^{-1}$  so, when  $\phi$  is multiplied by a charge in coulombs, the result is in joules. The combination joules per coulomb occurs widely and is called a volt (V), with  $1\text{ V} = 1\text{ J C}^{-1}$ . Calculate the Coulomb potential due to the nuclei at a point in a LiH molecule located at 200 pm from the Li nucleus and 150 pm from the H nucleus.

**F4.3(b)** Plot the Coulomb potential due to the nuclei at a point in a  $\text{Na}^+\text{Cl}^-$  ion pair located on a line halfway between the nuclei (the internuclear

separation is 283 pm) as the point approaches from infinity and ends at the midpoint between the nuclei.

## F.5 The relation between molecular and bulk properties

**F5.1(a)** What is meant by quantization of energy?

**F5.1(b)** In what circumstances are the effects of quantization most important for microscopic systems?

**F5.2(a)** The unit 1 electronvolt (1 eV) is defined as the energy acquired by an electron as it moves through a potential difference of 1 V. Suppose two states differ in energy by 1.0 eV. What is the ratio of their populations at (a) 300 K, (b) 3000 K?

**F5.2(b)** Suppose two states differ in energy by 1.0 eV, what can be said about their populations when  $T = 0$  and when the temperature is infinite?

**F5.3(a)** What are the assumptions of the kinetic molecular theory?

**F5.3(b)** What are the main features of the Maxwell distribution of speeds?

**F5.4(a)** Suggest a reason why most molecules survive for long periods at room temperature.

**F5.4(b)** Suggest a reason why the rates of chemical reactions typically increase with increasing temperature.

**F5.5(a)** Calculate the relative mean speeds of  $\text{N}_2$  molecules in air at  $0^\circ\text{C}$  and  $40^\circ\text{C}$ .

**F5.5(b)** Calculate the relative mean speeds of  $\text{CO}_2$  molecules in air at  $20^\circ\text{C}$  and  $30^\circ\text{C}$ .

**F5.6(a)** Use the equipartition theorem to calculate the contribution of translational motion to the total energy of 5.0 g of argon at  $25^\circ\text{C}$ .

**F5.6(b)** Use the equipartition theorem to calculate the contribution of translational motion to the total energy of 10.0 g of helium at  $30^\circ\text{C}$ .

**F5.7(a)** Use the equipartition theorem to calculate the contribution to the total energy of a sample of 10.0 g of (a) carbon dioxide, (b) methane at  $20^\circ\text{C}$ ; take into account translation and rotation but not vibration.

**F5.7(b)** Use the equipartition theorem to calculate the contribution to the total internal energy of a sample of 10.0 g of lead at  $20^\circ\text{C}$ , taking into account the vibrations of the atoms.

## F.6 The electromagnetic field

**F6.1(a)** Express a wavelength of 230 nm as a frequency.

**F6.1(b)** Express a wavelength of 720 nm as a frequency.

**F6.2(a)** Express a frequency of 560 THz as a wavenumber.

**F6.2(b)** Express a frequency of 160 MHz as a wavenumber.

**F6.3(a)** A radio station broadcasts at a frequency of 91.7 MHz. What is (a) the wavelength, (b) the wavenumber of the radiation?

**F6.3(b)** A spectroscopic technique uses microwave radiation of wavelength 3.0 cm. What is (a) the wavenumber, (b) the frequency of the radiation?

## F.7 Units

**F7.1(a)** Express a volume of  $1.45\text{ cm}^3$  in cubic metres.

**F7.1(b)** Express a volume of  $1.45\text{ dm}^3$  in cubic centimetres.

**F7.2(a)** Express a mass density of  $11.2\text{ g cm}^{-3}$  in kilograms per cubic metre.

**F7.2(b)** Express a mass density of  $1.12 \text{ g dm}^{-3}$  in kilograms per cubic metre.

**F7.3(a)** Express pascal per joule in base units.

**F7.3(b)** Express  $(\text{joule})^2$  per  $(\text{newton})^3$  in base units.

**F7.4(a)** The expression  $kT/hc$  sometimes appears in physical chemistry. Evaluate this expression at 298 K in reciprocal centimetres ( $\text{cm}^{-1}$ ).

**F7.4(b)** The expression  $kT/e$  sometimes appears in physical chemistry. Evaluate this expression at 298 K in millielectronvolts (meV).

**F7.5(a)** Given that  $R = 8.3144 \text{ J K}^{-1} \text{ mol}^{-1}$ , express  $R$  in decimetre cubed atmospheres per kelvin per mole.

**F7.5(b)** Given that  $R = 8.3144 \text{ J K}^{-1} \text{ mol}^{-1}$ , express  $R$  in pascal centimetre cubed per kelvin per molecule.

**F7.6(a)** Convert  $1 \text{ dm}^3 \text{ atm}$  into joules.

**F7.6(b)** Convert 1 J into litre-atmospheres.

**F7.7(a)** Determine the SI units of  $e^2/\epsilon_0 r^2$ . Express them in (a) base units, (b) units containing newtons.

**F7.7(b)** Determine the SI units of  $\mu_B^2/\mu_0 r^3$ , where  $\mu_B$  is the Bohr magneton ( $\mu_B = e\hbar/2m_e$ ) and  $\mu_0$  is the vacuum permeability (see inside front cover). Express them in (a) base units, (b) units containing joules.

*This page intentionally left blank*

# PART 1 Equilibrium

Part 1 of the text develops the concepts that are needed for the discussion of equilibria in chemistry. Equilibria include physical change, such as fusion and vaporization, and chemical change, including electrochemistry. The discussion is in terms of thermodynamics, and particularly in terms of enthalpy and entropy. We see that we can obtain a unified view of equilibrium and the direction of spontaneous change in terms of the chemical potentials of substances. The chapters in Part 1 deal with the bulk properties of matter; those of Part 2 will show how these properties stem from the behaviour of individual atoms.

## 1 The properties of gases

Mathematical background 1: Differentiation and integration

## 2 The First Law

Mathematical background 2: Multivariate calculus

## 3 The Second Law

## 4 Physical transformations of pure substances

## 5 Simple mixtures

## 6 Chemical equilibrium

*This page intentionally left blank*

# The properties of gases

This chapter establishes the properties of gases that will be used throughout the text. It begins with an account of an idealized version of a gas, a perfect gas, and shows how its equation of state may be assembled experimentally. We then see how the properties of real gases differ from those of a perfect gas, and construct an approximate equation of state that describes their properties.

The simplest state of matter is a **gas**, a form of matter that fills any container it occupies. Initially we consider only pure gases, but later in the chapter we see that the same ideas and equations apply to mixtures of gases too.

## The perfect gas

We shall find it helpful to picture a gas as a collection of molecules (or atoms) in continuous random motion, with average speeds that increase as the temperature is raised. A gas differs from a liquid in that, except during collisions, the molecules of a gas are widely separated from one another and move in paths that are largely unaffected by intermolecular forces.

### 1.1 The states of gases

**Key points** Each substance is described by an equation of state. (a) Pressure, force divided by area, provides a criterion of mechanical equilibrium for systems free to change their volume. (b) Pressure is measured with a barometer. (c) Through the Zeroth Law of thermodynamics, temperature provides a criterion of thermal equilibrium.

The **physical state** of a sample of a substance, its physical condition, is defined by its physical properties. Two samples of a substance that have the same physical properties are in the same state. The state of a pure gas, for example, is specified by giving its volume,  $V$ , amount of substance (number of moles),  $n$ , pressure,  $p$ , and temperature,  $T$ . However, it has been established experimentally that it is sufficient to specify only three of these variables, for then the fourth variable is fixed. That is, it is an experimental fact that each substance is described by an **equation of state**, an equation that interrelates these four variables.

The general form of an equation of state is

$$p = f(T, V, n)$$

Problems

This equation tells us that, if we know the values of  $n$ ,  $T$ , and  $V$  for a particular substance, then the pressure has a fixed value. Each substance is described by its own equation of state, but we know the explicit form of the equation in only a few special cases. One very important example is the equation of state of a ‘perfect gas’, which has the form  $p = nRT/V$ , where  $R$  is a constant (Section F.3). Much of the rest of this chapter will examine the origin of this equation of state and its applications.

### (a) Pressure

**Pressure**,  $p$ , is defined as force,  $F$ , divided by the area,  $A$ , to which the force is applied:

$$p = \frac{F}{A} \quad \text{Definition of pressure} \quad [1.2]$$

**Fig. 1.1** When a region of high pressure is separated from a region of low pressure by a movable wall, the wall will be pushed into one region or the other, as in (a) and (c). However, if the two pressures are identical, the wall will not move (b). The latter condition is one of mechanical equilibrium between the two regions.

That is, the greater the force acting on a given area, the greater the pressure. The origin of the force exerted by a gas is the incessant battering of the molecules on the walls of its container. The collisions are so numerous that they exert an effectively steady force, which is experienced as a steady pressure. The SI unit of pressure, the *pascal* (Pa,  $1 \text{ Pa} = 1 \text{ N m}^{-2}$ ) was introduced in Section F.7. As we saw there, several other units are still widely used (Table 1.1). A pressure of 1 bar is the **standard pressure** for reporting data; we denote it  $p^\ominus$ .

**Self-test 1.1** Calculate the pressure (in pascals and atmospheres) exerted by a mass of 1.0 kg pressing through the point of a pin of area  $1.0 \times 10^{-2} \text{ mm}^2$  at the surface of the Earth. *Hint.* The force exerted by a mass  $m$  due to gravity at the surface of the Earth is  $mg$ , where  $g$  is the acceleration of free fall (see inside the front cover for its standard value).  
[0.98 GPa,  $9.7 \times 10^3 \text{ atm}$ ]

If two gases are in separate containers that share a common movable wall (a ‘piston’, Fig. 1.1), the gas that has the higher pressure will tend to compress (reduce the volume of) the gas that has lower pressure. The pressure of the high-pressure gas will fall as it expands and that of the low-pressure gas will rise as it is compressed. There will come a stage when the two pressures are equal and the wall has no further tendency to move. This condition of equality of pressure on either side of a movable wall is a state of **mechanical equilibrium** between the two gases. The pressure of a gas is therefore an indication of whether a container that contains the gas will be in mechanical equilibrium with another gas with which it shares a movable wall.

**Table 1.1** Pressure units

| Name                   | Symbol | Value                                                       |
|------------------------|--------|-------------------------------------------------------------|
| pascal                 | 1 Pa   | $1 \text{ N m}^{-2}$ , $1 \text{ kg m}^{-1} \text{ s}^{-2}$ |
| bar                    | 1 bar  | $10^5 \text{ Pa}$                                           |
| atmosphere             | 1 atm  | 101.325 kPa                                                 |
| torr                   | 1 Torr | $(101\,325/760) \text{ Pa} = 133.32 \dots \text{ Pa}$       |
| millimetres of mercury | 1 mmHg | $133.322 \dots \text{ Pa}$                                  |
| pound per square inch  | 1 psi  | $6.894\,757 \dots \text{ kPa}$                              |

**(b) The measurement of pressure**

The pressure exerted by the atmosphere is measured with a **barometer**. The original version of a barometer (which was invented by Torricelli, a student of Galileo) was an inverted tube of mercury sealed at the upper end. When the column of mercury is in mechanical equilibrium with the atmosphere, the pressure at its base is equal to that exerted by the atmosphere. It follows that the height of the mercury column is proportional to the external pressure.

**Example 1.1** Calculating the pressure exerted by a column of liquid

Derive an equation for the pressure at the base of a column of liquid of mass density  $\rho$  (rho) and height  $h$  at the surface of the Earth. The pressure exerted by a column of liquid is commonly called the ‘hydrostatic pressure’.

**Method** Use the definition of pressure in eqn 1.2 with  $F = mg$ . To calculate  $F$  we need to know the mass  $m$  of the column of liquid, which is its mass density,  $\rho$ , multiplied by its volume,  $V$ :  $m = \rho V$ . The first step, therefore, is to calculate the volume of a cylindrical column of liquid.

**Answer** Let the column have cross-sectional area  $A$ ; then its volume is  $Ah$  and its mass is  $m = \rho Ah$ . The force the column of this mass exerts at its base is

$$F = mg = \rho Ahg$$

The pressure at the base of the column is therefore

$$p = \frac{F}{A} = \frac{\rho Ahg}{A} = \rho gh \quad \boxed{\text{Hydrostatic pressure}} \quad (1.3)$$

Note that the hydrostatic pressure is independent of the shape and cross-sectional area of the column. The mass of the column of a given height increases as the area, but so does the area on which the force acts, so the two cancel.

**Self-test 1.2** Derive an expression for the pressure at the base of a column of liquid of length  $l$  held at an angle  $\theta$  (theta) to the vertical (1).  $[p = \rho gl \cos \theta]$

The pressure of a sample of gas inside a container is measured by using a pressure gauge, which is a device with electrical properties that depend on the pressure. For instance, a *Bayard–Alpert pressure gauge* is based on the ionization of the molecules present in the gas and the resulting current of ions is interpreted in terms of the pressure. In a *capacitance manometer*, the deflection of a diaphragm relative to a fixed electrode is monitored through its effect on the capacitance of the arrangement. Certain semiconductors also respond to pressure and are used as transducers in solid-state pressure gauges.

**(c) Temperature**

The concept of temperature springs from the observation that a change in physical state (for example, a change of volume) can occur when two objects are in contact with one another, as when a red-hot metal is plunged into water. Later (Section 2.1) we shall see that the change in state can be interpreted as arising from a flow of energy as heat from one object to another. The **temperature**,  $T$ , is the property that indicates the direction of the flow of energy through a thermally conducting, rigid wall. If energy flows from A to B when they are in contact, then we say that A has a higher temperature than B (Fig. 1.2).

1

**Fig. 1.2** Energy flows as heat from a region at a higher temperature to one at a lower temperature if the two are in contact through a diathermic wall, as in (a) and (c). However, if the two regions have identical temperatures, there is no net transfer of energy as heat even though the two regions are separated by a diathermic wall (b). The latter condition corresponds to the two regions being at thermal equilibrium.

**Fig. 1.3** The experience summarized by the Zeroth Law of thermodynamics is that, if an object A is in thermal equilibrium with B and B is in thermal equilibrium with C, then C is in thermal equilibrium with A.

It will prove useful to distinguish between two types of boundary that can separate the objects. A boundary is **diathermic** (thermally conducting; ‘dia’ is from the Greek word for ‘through’) if a change of state is observed when two objects at different temperatures are brought into contact. A metal container has diathermic walls. A boundary is **adiabatic** (thermally insulating) if no change occurs even though the two objects have different temperatures. A vacuum flask is an approximation to an adiabatic container.

The temperature is a property that indicates whether two objects would be in ‘thermal equilibrium’ if they were in contact through a diathermic boundary. **Thermal equilibrium** is established if no change of state occurs when two objects A to B are in contact through a diathermic boundary. Suppose an object A (which we can think of as a block of iron) is in thermal equilibrium with an object B (a block of copper), and that B is also in thermal equilibrium with another object C (a flask of water). Then it has been found experimentally that A and C will also be in thermal equilibrium when they are put in contact (Fig. 1.3). This observation is summarized by the **Zeroth Law of thermodynamics**:

If A is in thermal equilibrium with B, and B is in thermal equilibrium with C, then C is also in thermal equilibrium with A.

Zeroth Law of thermodynamics

The Zeroth Law justifies the concept of temperature and the use of a **thermometer**, a device for measuring the temperature. Thus, suppose that B is a glass capillary containing a liquid, such as mercury, that expands significantly as the temperature increases. Then, when A is in contact with B, the mercury column in the latter has a certain length. According to the Zeroth Law, if the mercury column in B has the same length when it is placed in thermal contact with another object C, then we can predict that no change of state of A and C will occur when they are in thermal contact. Moreover, we can use the length of the mercury column as a measure of the temperatures of A and C.

In the early days of thermometry (and still in laboratory practice today), temperatures were related to the length of a column of liquid, and the difference in lengths shown when the thermometer was first in contact with melting ice and then with boiling water was divided into 100 steps called ‘degrees’, the lower point being labelled 0. This procedure led to the **Celsius scale** of temperature. In this text, temperatures on the Celsius scale are denoted  $\theta$  (theta) and expressed in *degrees Celsius* ( $^{\circ}\text{C}$ ). However, because different liquids expand to different extents, and do not always expand uniformly over a given range, thermometers constructed from different materials showed different numerical values of the temperature between their fixed points. The pressure of a gas, however, can be used to construct a **perfect-gas temperature scale** that is independent of the identity of the gas. The perfect-gas scale turns out to be identical to the **thermodynamic temperature scale** to be introduced in Section 3.2d, so we shall use the latter term from now on to avoid a proliferation of names. On the thermodynamic temperature scale, temperatures are denoted  $T$  and are normally reported in *kelvins* (K; not  $^{\circ}\text{K}$ ). Thermodynamic and Celsius temperatures are related by the exact expression

$$T/\text{K} = \theta/^{\circ}\text{C} + 273.15$$

Definition of Celsius scale

(1.4)

This relation is the current definition of the Celsius scale in terms of the more fundamental Kelvin scale. It implies that a difference in temperature of  $1^{\circ}\text{C}$  is equivalent to a difference of 1 K.

**A note on good practice** We write  $T = 0$ , not  $T = 0\text{ K}$  for the zero temperature on the thermodynamic temperature scale. This scale is absolute, and the lowest temperature is 0 regardless of the size of the divisions on the scale (just as we write  $p = 0$  for zero pressure, regardless of the size of the units we adopt, such as bar or pascal). However, we write  $0^{\circ}\text{C}$  because the Celsius scale is not absolute.

### • A brief illustration

To express 25.00°C as a temperature in kelvins, we use eqn 1.4 to write

$$T/\text{K} = (25.00^\circ\text{C})/^\circ\text{C} + 273.15 = 25.00 + 273.15 = 298.15$$

Note how the units (in this case, °C) are cancelled like numbers. This is the procedure called ‘quantity calculus’ in which a physical quantity (such as the temperature) is the product of a numerical value (25.00) and a unit (1°C); see Section F.7. Multiplication of both sides by the unit K then gives  $T = 298.15 \text{ K}$ . •

**A note on good practice** When the units need to be specified in an equation, the approved procedure, which avoids any ambiguity, is to write (physical quantity)/units, which is a dimensionless number, just as  $(25.00^\circ\text{C})/^\circ\text{C} = 25.00$  in this *brief illustration*. Units may be multiplied and cancelled just like numbers.

## 1.2 The gas laws

**Key points** (a) The perfect gas law, a limiting law valid in the limit of zero pressure, summarizes Boyle’s and Charles’s laws and Avogadro’s principle. (b) The kinetic theory of gases, in which molecules are in ceaseless random motion, provides a model that accounts for the gas laws and a relation between average speed and temperature. (c) A mixture of perfect gases behaves like a single perfect gas; its components each contribute their partial pressure to the total pressure.

The equation of state of a gas at low pressure was established by combining a series of empirical laws.

### (a) The perfect gas law

We assume that the following individual gas laws are familiar:

Boyle’s law:  $pV = \text{constant}$ , at constant  $n$ ,  $T$  (1.5)<sup>o</sup>

Charles’s law:  $V = \text{constant} \times T$ , at constant  $n$ ,  $p$  (1.6a)<sup>o</sup>

$p = \text{constant} \times T$ , at constant  $n$ ,  $V$  (1.6b)<sup>o</sup>

Avogadro’s principle:  $V = \text{constant} \times n$  at constant  $p$ ,  $T$  (1.7)<sup>o</sup>

Boyle’s and Charles’s laws are examples of a **limiting law**, a law that is strictly true only in a certain limit, in this case  $p \rightarrow 0$ . Equations valid in this limiting sense will be signalled by a <sup>o</sup> on the equation number, as in these expressions. Avogadro’s principle is commonly expressed in the form ‘equal volumes of gases at the same temperature and pressure contain the same numbers of molecules’. In this form, it is increasingly true as  $p \rightarrow 0$ . Although these relations are strictly true only at  $p = 0$ , they are reasonably reliable at normal pressures ( $p \approx 1 \text{ bar}$ ) and are used widely throughout chemistry.

Figure 1.4 depicts the variation of the pressure of a sample of gas as the volume is changed. Each of the curves in the graph corresponds to a single temperature and hence is called an **isotherm**. According to Boyle’s law, the isotherms of gases are hyperbolas (a curve obtained by plotting  $y$  against  $x$  with  $xy = \text{constant}$ ). An alternative depiction, a plot of pressure against  $1/\text{volume}$ , is shown in Fig. 1.5. The linear variation of volume with temperature summarized by Charles’s law is illustrated in Fig. 1.6. The lines in this illustration are examples of **isobars**, or lines showing the variation of properties at constant pressure. Figure 1.7 illustrates the linear variation of pressure with temperature. The lines in this diagram are **isochores**, or lines showing the variation of properties at constant volume.

The empirical observations summarized by eqns 1.5–7 can be combined into a single expression

$$pV = \text{constant} \times nT$$

### A brief comment

Avogadro’s principle is a principle rather than a law (a summary of experience) because it depends on the validity of a model, in this case the existence of molecules. Despite there now being no doubt about the existence of molecules, it is still a model-based principle rather than a law.

**Fig. 1.4** The pressure–volume dependence of a fixed amount of perfect gas at different temperatures. Each curve is a hyperbola ( $pV = \text{constant}$ ) and is called an isotherm.

**interActivity** Explore how the pressure of 1.5 mol  $\text{CO}_2(\text{g})$  varies with volume as it is compressed at (a) 273 K, (b) 373 K from 30  $\text{dm}^3$  to 15  $\text{dm}^3$ .

**Fig. 1.5** Straight lines are obtained when the pressure is plotted against  $1/V$  at constant temperature.

 **interActivity** Repeat *interActivity 1.4*, but plot the data as  $p$  against  $1/V$ .

**Fig. 1.6** The variation of the volume of a fixed amount of gas with the temperature at constant pressure. Note that in each case the isobars extrapolate to zero volume at  $T = 0$  or  $\theta = -273^\circ\text{C}$ .

 **interActivity** Explore how the volume of 1.5 mol  $\text{CO}_2(\text{g})$  in a container maintained at (a) 1.00 bar, (b) 0.50 bar varies with temperature as it is cooled from 373 K to 273 K.

**Fig. 1.7** The pressure also varies linearly with the temperature at constant volume, and extrapolates to zero at  $T = 0$  ( $-273^\circ\text{C}$ ).

 **interActivity** Explore how the pressure of 1.5 mol  $\text{CO}_2(\text{g})$  in a container of volume (a)  $30\text{ dm}^3$ , (b)  $15\text{ dm}^3$  varies with temperature as it is cooled from 373 K to 273 K.

**A note on good practice** To test the validity of a relation between two quantities, it is best to plot them in such a way that they should give a straight line, for deviations from a straight line are much easier to detect than deviations from a curve.

This expression is consistent with Boyle's law ( $pV = \text{constant}$ ) when  $n$  and  $T$  are constant, with both forms of Charles's law ( $p \propto T$ ,  $V \propto T$ ) when  $n$  and either  $V$  or  $p$  are held constant, and with Avogadro's principle ( $V \propto n$ ) when  $p$  and  $T$  are constant. The constant of proportionality, which is found experimentally to be the same for all gases, is denoted  $R$  and called the **gas constant**. The resulting expression

$$pV = nRT$$

Perfect gas law (1.8)<sup>o</sup>

is the **perfect gas law** (or *perfect gas equation of state*). It is the approximate equation of state of any gas, and becomes increasingly exact as the pressure of the gas approaches zero. A gas that obeys eqn 1.8 exactly under all conditions is called a **perfect gas** (or *ideal gas*). A **real gas**, an actual gas, behaves more like a perfect gas the lower the pressure, and is described exactly by eqn 1.8 in the limit of  $p \rightarrow 0$ . The gas constant  $R$  can be determined by evaluating  $R = pV/nT$  for a gas in the limit of zero pressure (to guarantee that it is behaving perfectly). However, a more accurate value can be obtained by measuring the speed of sound in a low-pressure gas (argon is used in practice) and extrapolating its value to zero pressure. Table 1.2 lists the values of  $R$  in a variety of units.

The surface in Fig. 1.8 is a plot of the pressure of a fixed amount of perfect gas against its volume and thermodynamic temperature as given by eqn 1.8. The surface depicts the only possible states of a perfect gas: the gas cannot exist in states that do not correspond to points on the surface. The graphs in Figs. 1.4, 1.6, and 1.7 correspond to the sections through the surface (Fig. 1.9).

**Table 1.2** The gas constant

| $R$                        |                                                    |
|----------------------------|----------------------------------------------------|
| 8.314 47                   | $\text{J K}^{-1} \text{ mol}^{-1}$                 |
| $8.205\,74 \times 10^{-2}$ | $\text{dm}^3 \text{ atm K}^{-1} \text{ mol}^{-1}$  |
| $8.314\,47 \times 10^{-2}$ | $\text{dm}^3 \text{ bar K}^{-1} \text{ mol}^{-1}$  |
| 8.314 47                   | $\text{Pa m}^3 \text{ K}^{-1} \text{ mol}^{-1}$    |
| 62.364                     | $\text{dm}^3 \text{ Torr K}^{-1} \text{ mol}^{-1}$ |
| 1.987 21                   | $\text{cal K}^{-1} \text{ mol}^{-1}$               |

**Example 1.2** Using the perfect gas law

In an industrial process, nitrogen is heated to 500 K in a vessel of constant volume. If it enters the vessel at 100 atm and 300 K, what pressure would it exert at the working temperature if it behaved as a perfect gas?

**Method** We expect the pressure to be greater on account of the increase in temperature. The perfect gas law in the form  $pV/nT = R$  implies that, if the conditions are changed from one set of values to another, then, because  $pV/nT$  is equal to a constant, the two sets of values are related by the ‘combined gas law’

$$\frac{p_1 V_1}{n_1 T_1} = \frac{p_2 V_2}{n_2 T_2} \quad \text{Combined gas law} \quad (1.9)^\circ$$

This expression is easily rearranged to give the unknown quantity (in this case  $p_2$ ) in terms of the known. The known and unknown data are summarized in (2).

**Answer** Cancellation of the volumes (because  $V_1 = V_2$ ) and amounts (because  $n_1 = n_2$ ) on each side of the combined gas law results in

$$\frac{p_1}{T_1} = \frac{p_2}{T_2}$$

which can be rearranged into

$$p_2 = \frac{T_2}{T_1} \times p_1$$

Substitution of the data then gives

$$p_2 = \frac{500 \text{ K}}{300 \text{ K}} \times (100 \text{ atm}) = 167 \text{ atm}$$

Experiment shows that the pressure is actually 183 atm under these conditions, so the assumption that the gas is perfect leads to a 10 per cent error.

**Self-test 1.3** What temperature would result in the same sample exerting a pressure of 300 atm? [900 K]

The perfect gas law is of the greatest importance in physical chemistry because it is used to derive a wide range of relations that are used throughout thermodynamics. However, it is also of considerable practical utility for calculating the properties of a gas under a variety of conditions. For instance, the molar volume,  $V_m = V/n$ , of a perfect gas under the conditions called **standard ambient temperature and pressure** (SATP), which means 298.15 K and 1 bar (that is, exactly  $10^5$  Pa), is easily calculated from  $V_m = RT/p$  to be  $24.789 \text{ dm}^3 \text{ mol}^{-1}$ . An earlier definition, **standard temperature and pressure** (STP), was  $0^\circ\text{C}$  and 1 atm; at STP, the molar volume of a perfect gas is  $22.414 \text{ dm}^3 \text{ mol}^{-1}$ .

**(b) The kinetic model of gases**

The molecular explanation of Boyle’s law is that, if a sample of gas is compressed to half its volume, then twice as many molecules strike the walls in a given period of time than before it was compressed. As a result, the average force exerted on the walls is

**Fig. 1.8** A region of the  $p, V, T$  surface of a fixed amount of perfect gas. The points forming the surface represent the only states of the gas that can exist.

**Fig. 1.9** Sections through the surface shown in Fig. 1.8 at constant temperature give the isotherms shown in Fig. 1.4 and the isobars shown in Fig. 1.6.

|         | $n$  | $p$ | $V$  | $T$ |
|---------|------|-----|------|-----|
| Initial | Same | 100 | Same | 300 |
| Final   | Same | ?   | Same | 500 |

doubled. Hence, when the volume is halved the pressure of the gas is doubled, and  $p \times V$  is a constant. Boyle's law applies to all gases regardless of their chemical identity (provided the pressure is low) because at low pressures the average separation of molecules is so great that they exert no influence on one another and hence travel independently. The molecular explanation of Charles's law lies in the fact that raising the temperature of a gas increases the average speed of its molecules. The molecules collide with the walls more frequently and with greater impact. Therefore they exert a greater pressure on the walls of the container.

These qualitative concepts are expressed quantitatively in terms of the kinetic model of gases, which is described more fully in Chapter 20. Briefly, the kinetic model is based on three assumptions:

1. The gas consists of molecules of mass  $m$  in ceaseless random motion.
2. The size of the molecules is negligible, in the sense that their diameters are much smaller than the average distance travelled between collisions.
3. The molecules interact only through brief, infrequent, and elastic collisions.

An *elastic collision* is a collision in which the total translational kinetic energy of the molecules is conserved. From the very economical assumptions of the kinetic model, it can be deduced (as we show in detail in Chapter 20) that the pressure and volume of the gas are related by

$$pV = \frac{1}{3}nMc^2 \quad (1.10)^\circ$$

where  $M = mN_A$ , the molar mass of the molecules, and  $c$  is the *root mean square speed* of the molecules, the square root of the mean of the squares of the speeds,  $v$ , of the molecules:

$$c = \langle v^2 \rangle^{1/2} \quad (1.11)$$

We see that, if the root mean square speed of the molecules depends only on the temperature, then at constant temperature  $pV = \text{constant}$ , which is the content of Boyle's law. Moreover, for eqn 1.10 to be the equation of state of a perfect gas, its right-hand side must be equal to  $nRT$ . It follows that the root mean square speed of the molecules in a gas at a temperature  $T$  must be

$$c = \left( \frac{3RT}{M} \right)^{1/2} \quad \text{Relation between molecular speed and temperature} \quad (1.12)^\circ$$

We can conclude that *the root mean square speed of the molecules of a gas is proportional to the square root of the temperature and inversely proportional to the square root of the molar mass*. That is, the higher the temperature, the higher the root mean square speed of the molecules, and, at a given temperature, heavy molecules travel more slowly than light molecules. The root mean square speed of  $N_2$  molecules, for instance, is found from eqn 1.12 to be  $515 \text{ m s}^{-1}$  at  $298 \text{ K}$ .

### (c) Mixtures of gases

When dealing with gaseous mixtures, we often need to know the contribution that each component makes to the total pressure of the sample. The **partial pressure**,  $p_j$ , of a gas  $J$  in a mixture (any gas, not just a perfect gas), is defined as

$$p_j = x_j p \quad \text{Definition of partial pressure} \quad [1.13]$$

where  $x_J$  is the **mole fraction** of the component J, the amount of J expressed as a fraction of the total amount of molecules,  $n$ , in the sample:

$$x_J = \frac{n_J}{n} \quad n = n_A + n_B + \dots \quad \text{Definition of mole fraction} \quad [1.14]$$

When no J molecules are present,  $x_J = 0$ ; when only J molecules are present,  $x_J = 1$ . It follows from the definition of  $x_J$  that, whatever the composition of the mixture,  $x_A + x_B + \dots = 1$  and therefore that the sum of the partial pressures is equal to the total pressure

$$p_A + p_B + \dots = (x_A + x_B + \dots)p = p \quad (1.15)$$

This relation is true for both real and perfect gases.

When all the gases are perfect, the partial pressure as defined in eqn 1.13 is also the pressure that each gas would exert if it occupied the same container alone at the same temperature. The latter is the original meaning of ‘partial pressure’. That identification was the basis of the original formulation of **Dalton’s law**:

The pressure exerted by a mixture of gases is the sum of the pressures that each one would exert if it occupied the container alone.

Dalton's law

Now, however, the relation between partial pressure (as defined in eqn 1.13) and total pressure (as given by eqn 1.15) is true for all gases and the identification of partial pressure with the pressure that the gas would exert on its own is valid only for a perfect gas.

### Example 1.3 Calculating partial pressures

The mass percentage composition of dry air at sea level is approximately  $N_2$ : 75.5;  $O_2$ : 23.2; Ar: 1.3. What is the partial pressure of each component when the total pressure is 1.20 atm?

**Method** We expect species with a high mole fraction to have a proportionally high partial pressure. Partial pressures are defined by eqn 1.13. To use the equation, we need the mole fractions of the components. To calculate mole fractions, which are defined by eqn 1.14, we use the fact that the amount of molecules J of molar mass  $M_J$  in a sample of mass  $m_J$  is  $n_J = m_J/M_J$ . The mole fractions are independent of the total mass of the sample, so we can choose the latter to be exactly 100 g (which makes the conversion from mass percentages very easy). Thus, the mass of  $N_2$  present is 75.5 per cent of 100 g, which is 75.5 g.

**Answer** The amounts of each type of molecule present in 100 g of air, in which the masses of  $N_2$ ,  $O_2$ , and Ar are 75.5 g, 23.2 g, and 1.3 g, respectively, are

$$n(N_2) = \frac{75.5 \text{ g}}{28.02 \text{ g mol}^{-1}} = \frac{75.5}{28.02} \text{ mol}$$

$$n(O_2) = \frac{23.2 \text{ g}}{32.00 \text{ g mol}^{-1}} = \frac{23.2}{32.00} \text{ mol}$$

$$n(\text{Ar}) = \frac{1.3 \text{ g}}{39.95 \text{ g mol}^{-1}} = \frac{1.3}{39.95} \text{ mol}$$

These three amounts work out as 2.69 mol, 0.725 mol, and 0.033 mol, respectively, for a total of 3.45 mol. The mole fractions are obtained by dividing each of the above amounts by 3.45 mol and the partial pressures are then obtained by multiplying the mole fraction by the total pressure (1.20 atm):

|                       | N <sub>2</sub> | O <sub>2</sub> | Ar     |
|-----------------------|----------------|----------------|--------|
| Mole fraction:        | 0.780          | 0.210          | 0.0096 |
| Partial pressure/atm: | 0.936          | 0.252          | 0.012  |

We have not had to assume that the gases are perfect: partial pressures are defined as  $p_i = x_i p$  for any kind of gas.

**Self-test 1.4** When carbon dioxide is taken into account, the mass percentages are 75.52 (N<sub>2</sub>), 23.15 (O<sub>2</sub>), 1.28 (Ar), and 0.046 (CO<sub>2</sub>). What are the partial pressures when the total pressure is 0.900 atm? [0.703, 0.189, 0.0084, 0.00027 atm]

## IMPACT ON ENVIRONMENTAL SCIENCE

### 11.1 The gas laws and the weather

The biggest sample of gas readily accessible to us is the atmosphere, a mixture of gases with the composition summarized in Table 1.3. The composition is maintained moderately constant by diffusion and convection (winds, particularly the local turbulence called *eddies*) but the pressure and temperature vary with altitude and with the local conditions, particularly in the troposphere (the ‘sphere of change’), the layer extending up to about 11 km.

In the troposphere the average temperature is 15°C at sea level, falling to –57°C at the bottom of the tropopause at 11 km. This variation is much less pronounced when expressed on the Kelvin scale, ranging from 288 K to 216 K, an average of 268 K. If we suppose that the temperature has its average value all the way up to the tropopause, then the pressure varies with altitude,  $h$ , according to the *barometric formula*

**Table 1.3** The composition of dry air at sea level

| Component                       | Percentage           |                      |
|---------------------------------|----------------------|----------------------|
|                                 | By volume            | By mass              |
| Nitrogen, N <sub>2</sub>        | 78.08                | 75.53                |
| Oxygen, O <sub>2</sub>          | 20.95                | 23.14                |
| Argon, Ar                       | 0.93                 | 1.28                 |
| Carbon dioxide, CO <sub>2</sub> | 0.031                | 0.047                |
| Hydrogen, H <sub>2</sub>        | $5.0 \times 10^{-3}$ | $2.0 \times 10^{-4}$ |
| Neon, Ne                        | $1.8 \times 10^{-3}$ | $1.3 \times 10^{-3}$ |
| Helium, He                      | $5.2 \times 10^{-4}$ | $7.2 \times 10^{-5}$ |
| Methane, CH <sub>4</sub>        | $2.0 \times 10^{-4}$ | $1.1 \times 10^{-4}$ |
| Krypton, Kr                     | $1.1 \times 10^{-4}$ | $3.2 \times 10^{-4}$ |
| Nitric oxide, NO                | $5.0 \times 10^{-5}$ | $1.7 \times 10^{-6}$ |
| Xenon, Xe                       | $8.7 \times 10^{-6}$ | $1.2 \times 10^{-5}$ |
| Ozone, O <sub>3</sub> : summer  | $7.0 \times 10^{-6}$ | $1.2 \times 10^{-5}$ |
| winter                          | $2.0 \times 10^{-6}$ | $3.3 \times 10^{-6}$ |

$$p = p_0 e^{-h/H} \quad (1.16)$$

where  $p_0$  is the pressure at sea level and  $H$  is a constant approximately equal to 8 km. More specifically,  $H = RT/Mg$ , where  $M$  is the average molar mass of air and  $T$  is the temperature. This formula represents the outcome of the competition between the potential energy of the molecules in the gravitational field of the Earth and the stirring effects of thermal motion; it is derived on the basis of the Boltzmann distribution (Section F.5a). The barometric formula fits the observed pressure distribution quite well even for regions well above the troposphere (Fig. 1.10). It implies that the pressure of the air falls to half its sea-level value at  $h = H \ln 2$ , or 6 km.

Local variations of pressure, temperature, and composition in the troposphere are manifest as ‘weather’. A small region of air is termed a *parcel*. First, we note that a parcel of warm air is less dense than the same parcel of cool air. As a parcel rises, it expands adiabatically (that is, without transfer of heat from its surroundings), so it cools. Cool air can absorb lower concentrations of water vapour than warm air, so the moisture forms clouds. Cloudy skies can therefore be associated with rising air and clear skies are often associated with descending air.

The motion of air in the upper altitudes may lead to an accumulation in some regions and a loss of molecules from other regions. The former result in the formation of regions of high pressure (‘highs’ or anticyclones) and the latter result in regions of low pressure (‘lows’, depressions, or cyclones). On a weather map, such as that shown in Fig. 1.11, the lines of constant pressure marked on it are called *isobars*. Elongated regions of high and low pressure are known, respectively, as *ridges* and *troughs*.

Horizontal pressure differentials result in the flow of air that we call *wind* (Fig. 1.12). Winds coming from the north in the Northern hemisphere and from the south in the Southern hemisphere are deflected towards the west as they migrate from a region where the Earth is rotating slowly (at the poles) to where it is rotating most rapidly (at the equator). Winds travel nearly parallel to the isobars, with low pressure to their left in the Northern hemisphere and to the right in the Southern hemisphere. At the surface, where wind speeds are lower, the winds tend to travel perpendicular to the isobars from high to low pressure. This differential motion results in a spiral outward flow of air clockwise in the Northern hemisphere around a high and an inward counterclockwise flow around a low.

The air lost from regions of high pressure is restored as an influx of air converges into the region and descends. As we have seen, descending air is associated with clear skies. It also becomes warmer by compression as it descends, so regions of high pressure are associated with high surface temperatures. In winter, the cold surface air may prevent the complete fall of air, and result in a temperature *inversion*, with a layer of warm air over a layer of cold air. Geographical conditions may also trap cool air, as in Los Angeles, and the photochemical pollutants we know as *smog* may be trapped under the warm layer.

## Real gases

Real gases do not obey the perfect gas law exactly except in the limit of  $p \rightarrow 0$ . Deviations from the law are particularly important at high pressures and low temperatures, especially when a gas is on the point of condensing to liquid.

**Fig. 1.10** The variation of atmospheric pressure with altitude, as predicted by the barometric formula and as suggested by the ‘US Standard Atmosphere’, which takes into account the variation of temperature with altitude.

**interActivity** How would the graph shown in the illustration change if the temperature variation with altitude were taken into account? Construct a graph allowing for a linear decrease in temperature with altitude.

**Fig. 1.12** The flow of air ('wind') around regions of high and low pressure in the Northern and Southern hemispheres.

**Fig. 1.13** The variation of the potential energy of two molecules on their separation. High positive potential energy (at very small separations) indicates that the interactions between them are strongly repulsive at these distances. At intermediate separations, where the potential energy is negative, the attractive interactions dominate. At large separations (on the right) the potential energy is zero and there is no interaction between the molecules.

### 1.3 Molecular interactions

**Key points** (a) The extent of deviations from perfect behaviour is summarized by introducing the compression factor. (b) The virial equation is an empirical extension of the perfect gas equation that summarizes the behaviour of real gases over a range of conditions. (c) The isotherms of a real gas introduce the concept of vapour pressure and critical behaviour. (d) A gas can be liquefied by pressure alone only if its temperature is at or below its critical temperature.

Real gases show deviations from the perfect gas law because molecules interact with one another. A point to keep in mind is that repulsive forces between molecules assist expansion and attractive forces assist compression.

Repulsive forces are significant only when molecules are almost in contact: they are short-range interactions, even on a scale measured in molecular diameters (Fig. 1.13). Because they are short-range interactions, repulsions can be expected to be important only when the average separation of the molecules is small. This is the case at high pressure, when many molecules occupy a small volume. On the other hand, attractive intermolecular forces have a relatively long range and are effective over several molecular diameters. They are important when the molecules are fairly close together but not necessarily touching (at the intermediate separations in Fig. 1.13). Attractive forces are ineffective when the molecules are far apart (well to the right in Fig. 1.13). Intermolecular forces are also important when the temperature is so low that the molecules travel with such low mean speeds that they can be captured by one another.

At low pressures, when the sample occupies a large volume, the molecules are so far apart for most of the time that the intermolecular forces play no significant role, and the gas behaves virtually perfectly. At moderate pressures, when the average separation of the molecules is only a few molecular diameters, the attractive forces dominate the repulsive forces. In this case, the gas can be expected to be more compressible than a perfect gas because the forces help to draw the molecules together. At high pressures, when the average separation of the molecules is small, the repulsive forces dominate and the gas can be expected to be less compressible because now the forces help to drive the molecules apart.

#### (a) The compression factor

The **compression factor**,  $Z$ , of a gas is the ratio of its measured molar volume,  $V_m = V/n$ , to the molar volume of a perfect gas,  $V_m^\circ$ , at the same pressure and temperature:

$$Z = \frac{V_m}{V_m^\circ} \quad \text{Definition of compression factor} \quad [1.17]$$

Because the molar volume of a perfect gas is equal to  $RT/p$ , an equivalent expression is  $Z = pV_m/RT$ , which we can write as

$$pV_m = RTZ \quad (1.18)$$

Because, for a perfect gas  $Z = 1$  under all conditions, deviation of  $Z$  from 1 is a measure of departure from perfect behaviour.

Some experimental values of  $Z$  are plotted in Fig. 1.14. At very low pressures, all the gases shown have  $Z \approx 1$  and behave nearly perfectly. At high pressures, all the gases have  $Z > 1$ , signifying that they have a larger molar volume than a perfect gas. Repulsive forces are now dominant. At intermediate pressures, most gases have  $Z < 1$ , indicating that the attractive forces are reducing the molar volume relative to that of a perfect gas.

**(b) Virial coefficients**

Figure 1.15 shows the experimental isotherms for carbon dioxide. At large molar volumes and high temperatures the real-gas isotherms do not differ greatly from perfect-gas isotherms. The small differences suggest that the perfect gas law is in fact the first term in an expression of the form

$$pV_m = RT(1 + B'p + C'p^2 + \dots) \quad (1.19a)$$

This expression is an example of a common procedure in physical chemistry, in which a simple law that is known to be a good first approximation (in this case  $pV = nRT$ ) is treated as the first term in a series in powers of a variable (in this case  $p$ ). A more convenient expansion for many applications is

$$pV_m = RT \left( 1 + \frac{B}{V_m} + \frac{C}{V_m^2} + \dots \right) \quad \text{Virial equation of state} \quad (1.19b)$$

These two expressions are two versions of the **virial equation of state**.<sup>1</sup> By comparing the expression with eqn 1.18 we see that the term in parentheses in eqn 1.19b is just the compression factor,  $Z$ .

The coefficients  $B, C, \dots$ , which depend on the temperature, are the second, third,  $\dots$  **virial coefficients** (Table 1.4); the first virial coefficient is 1. The third virial coefficient,  $C$ , is usually less important than the second coefficient,  $B$ , in the sense that at typical molar volumes  $C/V_m^2 \ll B/V_m$ . The values of the virial coefficients of a gas are determined from measurements of its compression factor.

An important point is that, although the equation of state of a real gas may coincide with the perfect gas law as  $p \rightarrow 0$ , not all its properties necessarily coincide with those of a perfect gas in that limit. Consider, for example, the value of  $dZ/dp$ , the slope of the graph of compression factor against pressure. For a perfect gas  $dZ/dp = 0$  (because  $Z = 1$  at all pressures), but for a real gas from eqn 1.19a we obtain

$$\frac{dZ}{dp} = B' + 2pC' + \dots \rightarrow B' \quad \text{as} \quad p \rightarrow 0 \quad (1.20a)$$

However,  $B'$  is not necessarily zero, so the slope of  $Z$  with respect to  $p$  does not necessarily approach 0 (the perfect gas value), as we can see in Fig. 1.14. Because several physical properties of gases depend on derivatives, the properties of real gases do not always coincide with the perfect gas values at low pressures. By a similar argument

$$\frac{dZ}{d\left(\frac{1}{V_m}\right)} \rightarrow B \quad \text{as} \quad V_m \rightarrow \infty \quad (1.20b)$$

Because the virial coefficients depend on the temperature, there may be a temperature at which  $Z \rightarrow 1$  with zero slope at low pressure or high molar volume (Fig. 1.16). At this temperature, which is called the **Boyle temperature**,  $T_B$ , the properties of the real gas do coincide with those of a perfect gas as  $p \rightarrow 0$ . According to eqn 1.20a,  $Z$  has zero slope as  $p \rightarrow 0$  if  $B = 0$ , so we can conclude that  $B = 0$  at the Boyle temperature. It then follows from eqn 1.18 that  $pV_m \approx RT_B$  over a more extended range of pressures than at other temperatures because the first term after 1 (that is,  $B/V_m$ ) in the virial equation is zero and  $C/V_m^2$  and higher terms are negligibly small. For helium  $T_B = 22.64$  K; for air  $T_B = 346.8$  K; more values are given in Table 1.5.

**Fig. 1.14** The variation of the compression factor,  $Z$ , with pressure for several gases at 0°C. A perfect gas has  $Z = 1$  at all pressures. Notice that, although the curves approach 1 as  $p \rightarrow 0$ , they do so with different slopes.

**Fig. 1.15** Experimental isotherms of carbon dioxide at several temperatures. The ‘critical isotherm’, the isotherm at the critical temperature, is at 31.04°C. The critical point is marked with a star.

<sup>1</sup> The name comes from the Latin word for force. The coefficients are sometimes denoted  $B_2, B_3, \dots$

**Table 1.4\*** Second virial coefficients,  $B/(\text{cm}^3 \text{mol}^{-1})$ 

|                 | Temperature |       |
|-----------------|-------------|-------|
|                 | 273 K       | 600 K |
| Ar              | −21.7       | 11.9  |

\* More values are given in the *Data section*.**(c) Condensation**

Now consider what happens when we compress (reduce the volume of) a sample of gas initially in the state marked A in Fig. 1.15 at constant temperature by pushing in a piston. Near A, the pressure of the gas rises in approximate agreement with Boyle's law. Serious deviations from that law begin to appear when the volume has been reduced to B.

At C (which corresponds to about 60 atm for carbon dioxide), all similarity to perfect behaviour is lost, for suddenly the piston slides in without any further rise in pressure: this stage is represented by the horizontal line CDE. Examination of the contents of the vessel shows that just to the left of C a liquid appears, and there are two phases separated by a sharply defined surface. As the volume is decreased from C through D to E, the amount of liquid increases. There is no additional resistance to the piston because the gas can respond by condensing. The pressure corresponding to the line CDE, when both liquid and vapour are present in equilibrium, is called the **vapour pressure** of the liquid at the temperature of the experiment.

At E, the sample is entirely liquid and the piston rests on its surface. Any further reduction of volume requires the exertion of considerable pressure, as is indicated by the sharply rising line to the left of E. Even a small reduction of volume from E to F requires a great increase in pressure.

**(d) Critical constants**

The isotherm at the temperature  $T_c$  (304.19 K, or 31.04°C for CO<sub>2</sub>) plays a special role in the theory of the states of matter. An isotherm slightly below  $T_c$  behaves as we have already described: at a certain pressure, a liquid condenses from the gas and is distinguishable from it by the presence of a visible surface. If, however, the compression takes place at  $T_c$  itself, then a surface separating two phases does not appear and the volumes at each end of the horizontal part of the isotherm have merged to a single point, the **critical point** of the gas. The temperature, pressure, and molar volume at the critical point are called, respectively, the **critical temperature**,  $T_c$ , **critical pressure**,  $p_c$ , and **critical molar volume**,  $V_c$ , of the substance. Collectively,  $p_c$ ,  $V_c$ , and  $T_c$  are the **critical constants** of a substance (Table 1.5).

At and above  $T_c$ , the sample has a single phase that occupies the entire volume of the container. Such a phase is, by definition, a gas. Hence, the liquid phase of a substance does not form above the critical temperature. The critical temperature of oxygen, for instance, signifies that it is impossible to produce liquid oxygen by compression alone if its temperature is greater than 155 K: to liquefy oxygen—to obtain a fluid phase that does not occupy the entire volume—the temperature must first be lowered to below 155 K, and then the gas compressed isothermally. The single phase that fills the entire volume when  $T > T_c$  may be much denser than we normally consider typical of gases, and the name **supercritical fluid** is preferred.

## 1.4 The van der Waals equation

**Key points** (a) The van der Waals equation is a model equation of state for a real gas expressed in terms of two parameters, one corresponding to molecular attractions and the other to molecular repulsions. (b) The van der Waals equation captures the general features of the behaviour of real gases, including their critical behaviour. (c) The properties of real gases are coordinated by expressing their equations of state in terms of reduced variables.

We can draw conclusions from the virial equations of state only by inserting specific values of the coefficients. It is often useful to have a broader, if less precise, view of all gases. Therefore, we introduce the approximate equation of state suggested by J.D. van der Waals in 1873. This equation is an excellent example of an expression that can be obtained by thinking scientifically about a mathematically complicated but physically simple problem; that is, it is a good example of ‘model building’.

### (a) Formulation of the equation

The van der Waals equation is

$$p = \frac{nRT}{V - nb} - a \frac{n^2}{V^2} \quad \text{van der Waals equation of state} \quad (1.21a)$$

and a derivation is given in the following *Justification*. The equation is often written in terms of the molar volume  $V_m = V/n$  as

$$p = \frac{RT}{V_m - b} - \frac{a}{V_m^2} \quad (1.21b)$$

The constants  $a$  and  $b$  are called the **van der Waals coefficients**. As can be understood from the following *Justification*,  $a$  represents the strength of attractive interactions and  $b$  that of the repulsive interactions between the molecules. They are characteristic of each gas but independent of the temperature (Table 1.6). Although  $a$  and  $b$  are not precisely defined molecular properties, they correlate with physical properties such as critical temperature, vapor pressure, and enthalpy of vaporization that reflect the strength of intermolecular interactions. Correlations have also been sought where intermolecular forces might play a role. For example, the potencies of certain general anaesthetics show a correlation in the sense that a higher activity is observed with lower values of  $a$  (Fig. 1.17).

#### Justification 1.1 The van der Waals equation of state

The repulsive interactions between molecules are taken into account by supposing that they cause the molecules to behave as small but impenetrable spheres. The non-zero volume of the molecules implies that instead of moving in a volume  $V$  they are restricted to a smaller volume  $V - nb$ , where  $nb$  is approximately the total volume taken up by the molecules themselves. This argument suggests that the perfect gas law  $p = nRT/V$  should be replaced by

$$p = \frac{nRT}{V - nb}$$

when repulsions are significant. To calculate the excluded volume we note that the closest distance of two hard-sphere molecules of radius  $r$ , and volume  $V_{\text{molecule}} = \frac{4}{3}\pi r^3$ , is  $2r$ , so the volume excluded is  $\frac{4}{3}\pi(2r)^3$ , or  $8V_{\text{molecule}}$ . The volume excluded per molecule is one-half this volume, or  $4V_{\text{molecule}}$ , so  $b \approx 4V_{\text{molecule}}N_A$ .

**Table 1.6\*** van der Waals coefficients

|                 | $a/(\text{atm dm}^6 \text{ mol}^{-2})$ | $b/(10^{-2} \text{ dm}^3 \text{ mol}^{-1})$ |

\* More values are given in the Data section.

**Fig. 1.17** The correlation of the effectiveness of a gas as an anaesthetic and the van der Waals parameter  $a$ . (Based on R.J. Wulff and R.M. Featherstone, *Anesthesiology*, 18, 97 (1957).) The isonarcotic pressure is the pressure required to bring about the same degree of anaesthesia.

The pressure depends on both the frequency of collisions with the walls and the force of each collision. Both the frequency of the collisions and their force are reduced by the attractive interactions, which act with a strength proportional to the molar concentration,  $n/V$ , of molecules in the sample. Therefore, because both the frequency and the force of the collisions are reduced by the attractive interactions, the pressure is reduced in proportion to the square of this concentration. If the reduction of pressure is written as  $-a(n/V)^2$ , where  $a$  is a positive constant characteristic of each gas, the combined effect of the repulsive and attractive forces is the van der Waals equation of state as expressed in eqn 1.21.

In this *Justification* we have built the van der Waals equation using vague arguments about the volumes of molecules and the effects of forces. The equation can be derived in other ways, but the present method has the advantage that it shows how to derive the form of an equation from general ideas. The derivation also has the advantage of keeping imprecise the significance of the coefficients  $a$  and  $b$ : they are much better regarded as empirical parameters that represent attractions and repulsions, respectively, rather than as precisely defined molecular properties.

**Example 1.4** Using the van der Waals equation to estimate a molar volume

Estimate the molar volume of  $\text{CO}_2$  at 500 K and 100 atm by treating it as a van der Waals gas.

**Method** We need to find an expression for the molar volume by solving the van der Waals equation, eqn 1.21b. To do so, we multiply both sides of the equation by  $(V_m - b)V_m^2$ , to obtain

$$(V_m - b)V_m^2 p = RTV_m^2 - (V_m - b)a$$

Then, after division by  $p$ , collect powers of  $V_m$  to obtain

$$V_m^3 - \left(b + \frac{RT}{p}\right)V_m^2 + \left(\frac{a}{p}\right)V_m - \frac{ab}{p} = 0$$

Although closed expressions for the roots of a cubic equation can be given, they are very complicated. Unless analytical solutions are essential, it is usually more expedient to solve such equations with commercial software; graphing calculators can also be used to help identify the acceptable root.

**Answer** According to Table 1.6,  $a = 3.610 \text{ dm}^6 \text{ atm mol}^{-2}$  and  $b = 4.29 \times 10^{-2} \text{ dm}^3 \text{ mol}^{-1}$ . Under the stated conditions,  $RT/p = 0.410 \text{ dm}^3 \text{ mol}^{-1}$ . The coefficients in the equation for  $V_m$  are therefore

$$b + RT/p = 0.453 \text{ dm}^3 \text{ mol}^{-1}$$

$$a/p = 3.61 \times 10^{-2} (\text{dm}^3 \text{ mol}^{-1})^2$$

$$ab/p = 1.55 \times 10^{-3} (\text{dm}^3 \text{ mol}^{-1})^3$$

Therefore, on writing  $x = V_m/(\text{dm}^3 \text{ mol}^{-1})$ , the equation to solve is

$$x^3 - 0.453x^2 + (3.61 \times 10^{-2})x - (1.55 \times 10^{-3}) = 0$$

The acceptable root is  $x = 0.366$  (Fig. 1.18), which implies that  $V_m = 0.366 \text{ dm}^3 \text{ mol}^{-1}$ . For a perfect gas under these conditions, the molar volume is  $0.410 \text{ dm}^3 \text{ mol}^{-1}$ .

\* Reduced variables are defined in Section 1.4c.

**(b) The features of the equation**

We now examine to what extent the van der Waals equation predicts the behaviour of real gases. It is too optimistic to expect a single, simple expression to be the true equation of state of all substances, and accurate work on gases must resort to the virial equation, use tabulated values of the coefficients at various temperatures, and analyse the systems numerically. The advantage of the van der Waals equation, however, is that it is analytical (that is, expressed symbolically) and allows us to draw some general conclusions about real gases. When the equation fails we must use one of the other equations of state that have been proposed (some are listed in Table 1.7), invent a new one, or go back to the virial equation.

That having been said, we can begin to judge the reliability of the equation by comparing the isotherms it predicts with the experimental isotherms in Fig. 1.15. Some calculated isotherms are shown in Fig. 1.19 and Fig. 1.20. Apart from the oscillations below the critical temperature, they do resemble experimental isotherms quite well. The oscillations, the **van der Waals loops**, are unrealistic because they suggest that under some conditions an increase of pressure results in an increase of volume. Therefore they are replaced by horizontal lines drawn so the loops define equal areas above and below the lines: this procedure is called the **Maxwell construction** (3). The van der Waals coefficients, such as those in Table 1.6, are found by fitting the calculated curves to the experimental curves.

The principal features of the van der Waals equation can be summarized as follows.

- (1) Perfect gas isotherms are obtained at high temperatures and large molar volumes.

When the temperature is high,  $RT$  may be so large that the first term in eqn 1.21b greatly exceeds the second. Furthermore, if the molar volume is large in the sense  $V_m \gg b$ , then the denominator  $V_m - b \approx V_m$ . Under these conditions, the equation reduces to  $p = RT/V_m$ , the perfect gas equation.

- (2) Liquids and gases coexist when cohesive and dispersing effects are in balance.

The van der Waals loops occur when both terms in eqn 1.21b have similar magnitudes. The first term arises from the kinetic energy of the molecules and their repulsive interactions; the second represents the effect of the attractive interactions.

**Fig. 1.19** The surface of possible states allowed by the van der Waals equation. Compare this surface with that shown in Fig. 1.8.

**Fig. 1.20** Van der Waals isotherms at several values of  $T/T_c$ . Compare these curves with those in Fig. 1.15. The van der Waals loops are normally replaced by horizontal straight lines. The critical isotherm is the isotherm for  $T/T_c = 1$ .

 **InterActivity** Calculate the molar volume of chlorine gas on the basis of the van der Waals equation of state at 250 K and 150 kPa and calculate the percentage difference from the value predicted by the perfect gas equation.

(3) The critical constants are related to the van der Waals coefficients.

For  $T < T_c$ , the calculated isotherms oscillate, and each one passes through a minimum followed by a maximum. These extrema converge as  $T \rightarrow T_c$  and coincide at  $T = T_c$ ; at the critical point the curve has a flat inflexion (4). From the properties of curves, we know that an inflexion of this type occurs when both the first and second derivatives are zero. Hence, we can find the critical constants by calculating these derivatives and setting them equal to zero

$$\frac{dp}{dV_m} = -\frac{RT}{(V_m - b)^2} + \frac{2a}{V_m^3} = 0$$

$$\frac{d^2p}{dV_m^2} = \frac{2RT}{(V_m - b)^3} - \frac{6a}{V_m^4} = 0$$

at the critical point. The solutions of these two equations (and using eqn 1.21b to calculate  $p_c$  from  $V_c$  and  $T_c$ ) are

$$V_c = 3b \quad p_c = \frac{a}{27b^2} \quad T_c = \frac{8a}{27Rb} \quad (1.22)$$

These relations provide an alternative route to the determination of  $a$  and  $b$  from the values of the critical constants. They can be tested by noting that the **critical compression factor**,  $Z_c$ , is predicted to be equal to

$$Z_c = \frac{p_c V_c}{RT_c} = \frac{3}{8} \quad (1.23)$$

for all gases that are described by the van der Waals equation near the critical point. We see from Table 1.5 that, although  $Z_c < \frac{3}{8} = 0.375$ , it is approximately constant (at 0.3) and the discrepancy is reasonably small.

### (c) The principle of corresponding states

An important general technique in science for comparing the properties of objects is to choose a related fundamental property of the same kind and to set up a relative scale on that basis. We have seen that the critical constants are characteristic properties of gases, so it may be that a scale can be set up by using them as yardsticks. We therefore introduce the dimensionless **reduced variables** of a gas by dividing the actual variable by the corresponding critical constant:

$$V_r = \frac{V_m}{V_c} \quad p_r = \frac{p}{p_c} \quad T_r = \frac{T}{T_c} \quad \text{Definition of reduced variables} \quad [1.24]$$

If the reduced pressure of a gas is given, we can easily calculate its actual pressure by using  $p = p_r p_c$ , and likewise for the volume and temperature. van der Waals, who first tried this procedure, hoped that gases confined to the same reduced volume,  $V_r$ , at the same reduced temperature,  $T_r$ , would exert the same reduced pressure,  $p_r$ . The hope was largely fulfilled (Fig. 1.21). The illustration shows the dependence of the compression factor on the reduced pressure for a variety of gases at various reduced temperatures. The success of the procedure is strikingly clear: compare this graph with Fig. 1.14, where similar data are plotted without using reduced variables. The observation that real gases at the same reduced volume and reduced temperature exert the same reduced pressure is called the **principle of corresponding states**. The principle is only an approximation. It works best for gases composed of spherical molecules; it fails, sometimes badly, when the molecules are non-spherical or polar.

The van der Waals equation sheds some light on the principle. First, we express eqn 1.21b in terms of the reduced variables, which gives

$$p_r p_c = \frac{RT_r T_c}{V_r V_c - b} - \frac{a}{V_r^2 V_c^2}$$

Then we express the critical constants in terms of  $a$  and  $b$  by using eqn 1.22:

$$\frac{ap_r}{27b^2} = \frac{8aT_r}{27b(3bV_r - b)} - \frac{a}{9b^2V_r^2}$$

which can be reorganized into

$$p_r = \frac{8T_r}{3V_r - 1} - \frac{3}{V_r^2} \quad (1.25)$$

This equation has the same form as the original, but the coefficients  $a$  and  $b$ , which differ from gas to gas, have disappeared. It follows that, if the isotherms are plotted in terms of the reduced variables (as we did in fact in Fig. 1.20 without drawing attention to the fact), then the same curves are obtained whatever the gas. This is precisely the content of the principle of corresponding states, so the van der Waals equation is compatible with it.

Looking for too much significance in this apparent triumph is mistaken, because other equations of state also accommodate the principle (Table 1.7). In fact, all we need are two parameters playing the roles of  $a$  and  $b$ , for then the equation can always be manipulated into reduced form. The observation that real gases obey the principle approximately amounts to saying that the effects of the attractive and repulsive interactions can each be approximated in terms of a single parameter. The importance of the principle is then not so much its theoretical interpretation but the way in which it enables the properties of a range of gases to be coordinated on to a single diagram (for example, Fig. 1.21 instead of Fig. 1.14).

**Fig. 1.21** The compression factors of four gases plotted using reduced variables. The curves are labelled with the reduced temperature  $T_r = T/T_c$ . The use of reduced variables organizes the data on to single curves.

**InterActivity** Is there a set of conditions at which the compression factor of a van der Waals gas passes through a minimum? If so, how do the location and value of the minimum value of  $Z$  depend on the coefficients  $a$  and  $b$ ?

## Checklist of key equations

| Property                            | Equation                                 | Comment                                                   |
|-------------------------------------|------------------------------------------|-----------------------------------------------------------|
| Equation of state                   | $p = f(n, V, T)$                         |                                                           |
| Perfect gas law                     | $pV = nRT$                               | Valid for real gases in the limit $p \rightarrow 0$       |
| Relation between temperature scales | $T/K = \theta/^{\circ}\text{C} + 273.15$ | 273.15 is exact temperature scales                        |
| Partial pressure                    | $p_j = x_j p$                            | Valid for all gases                                       |
| Virial equation of state            | $pV_m = RT(1 + B/V_m + C/V_m^2 + \dots)$ | $B, C$ depend on temperature                              |
| van der Waals equation of state     | $p = nRT/(V - nb) - a(n/V)^2$            | $a$ parametrizes attractions; $b$ parametrizes repulsions |

→ For a chart of the relations between principal equations, see the [Road map section](#) of the Resource section.

## Discussion questions

**1.1** Explain how the perfect gas equation of state arises by combination of Boyle's law, Charles's law, and Avogadro's principle.

**1.2** Explain the term 'partial pressure' and explain why Dalton's law is a limiting law.

**1.3** Explain how the compression factor varies with pressure and temperature and describe how it reveals information about intermolecular interactions in real gases.

**1.4** What is the significance of the critical constants?

**1.5** Describe the formulation of the van der Waals equation and suggest a rationale for one other equation of state in Table 1.7.

**1.6** Explain how the van der Waals equation accounts for critical behaviour.

## Exercises

**1.1(a)** (a) Could 131 g of xenon gas in a vessel of volume  $1.0 \text{ dm}^3$  exert a pressure of 20 atm at  $25^\circ\text{C}$  if it behaved as a perfect gas? If not, what pressure would it exert? (b) What pressure would it exert if it behaved as a van der Waals gas?

**1.1(b)** (a) Could 25 g of argon gas in a vessel of volume  $1.5 \text{ dm}^3$  exert a pressure of 2.0 bar at  $30^\circ\text{C}$  if it behaved as a perfect gas? If not, what pressure would it exert? (b) What pressure would it exert if it behaved as a van der Waals gas?

**1.2(a)** A perfect gas undergoes isothermal compression, which reduces its volume by  $2.20 \text{ dm}^3$ . The final pressure and volume of the gas are 5.04 bar and  $4.65 \text{ dm}^3$ , respectively. Calculate the original pressure of the gas in (a) bar, (b) atm.

**1.2(b)** A perfect gas undergoes isothermal compression, which reduces its volume by  $1.80 \text{ dm}^3$ . The final pressure and volume of the gas are 1.97 bar and  $2.14 \text{ dm}^3$ , respectively. Calculate the original pressure of the gas in (a) bar, (b) Torr.

**1.3(a)** A car tyre (i.e. an automobile tire) was inflated to a pressure of 24 lb in $^{-2}$  ( $1.00 \text{ atm} = 14.7 \text{ lb in}^{-2}$ ) on a winter's day when the temperature was  $-5^\circ\text{C}$ . What pressure will be found, assuming no leaks have occurred and that the volume is constant, on a subsequent summer's day when the temperature is  $35^\circ\text{C}$ ? What complications should be taken into account in practice?

**1.3(b)** A sample of hydrogen gas was found to have a pressure of 125 kPa when the temperature was  $23^\circ\text{C}$ . What can its pressure be expected to be when the temperature is  $11^\circ\text{C}$ ?

**1.4(a)** A sample of 255 mg of neon occupies  $3.00 \text{ dm}^3$  at 122 K. Use the perfect gas law to calculate the pressure of the gas.

**1.4(b)** A homeowner uses  $4.00 \times 10^3 \text{ m}^3$  of natural gas in a year to heat a home. Assume that natural gas is all methane,  $\text{CH}_4$ , and that methane is a perfect gas for the conditions of this problem, which are 1.00 atm and  $20^\circ\text{C}$ . What is the mass of gas used?

**1.5(a)** A diving bell has an air space of  $3.0 \text{ m}^3$  when on the deck of a boat. What is the volume of the air space when the bell has been lowered to a depth of 50 m? Take the mean density of sea water to be  $1.025 \text{ g cm}^{-3}$  and assume that the temperature is the same as on the surface.

**1.5(b)** What pressure difference must be generated across the length of a 15 cm vertical drinking straw in order to drink a water-like liquid of density  $1.0 \text{ g cm}^{-3}$ ?

**1.6(a)** A manometer consists of a U-shaped tube containing a liquid. One side is connected to the apparatus and the other is open to the atmosphere. The pressure inside the apparatus is then determined from the difference in heights of the liquid. Suppose the liquid is water, the external pressure is 770 Torr, and the open side is 10.0 cm lower than the side connected to the

apparatus. What is the pressure in the apparatus? (The density of water at  $25^\circ\text{C}$  is  $0.99707 \text{ g cm}^{-3}$ .)

**1.6(b)** A manometer like that described in Exercise 1.6a contained mercury in place of water. Suppose the external pressure is 760 Torr, and the open side is 10.0 cm higher than the side connected to the apparatus. What is the pressure in the apparatus? (The density of mercury at  $25^\circ\text{C}$  is  $13.55 \text{ g cm}^{-3}$ .)

**1.7(a)** In an attempt to determine an accurate value of the gas constant,  $R$ , a student heated a container of volume  $20.000 \text{ dm}^3$  filled with 0.251 32 g of helium gas to  $500^\circ\text{C}$  and measured the pressure as 206.402 cm of water in a manometer at  $25^\circ\text{C}$ . Calculate the value of  $R$  from these data. (The density of water at  $25^\circ\text{C}$  is  $0.99707 \text{ g cm}^{-3}$ ; the construction of a manometer is described in Exercise 1.6a.)

**1.7(b)** The following data have been obtained for oxygen gas at  $273.15 \text{ K}$ . Calculate the best value of the gas constant  $R$  from them and the best value of the molar mass of  $\text{O}_2$ .

|                                      |           |           |           |
|--------------------------------------|-----------|-----------|-----------|
| $p/\text{atm}$                       | 0.750 000 | 0.500 000 | 0.250 000 |
| $V_m/(\text{dm}^3 \text{ mol}^{-1})$ | 29.8649   | 44.8090   | 89.6384   |

**1.8(a)** At  $500^\circ\text{C}$  and 93.2 kPa, the mass density of sulfur vapour is  $3.710 \text{ kg m}^{-3}$ . What is the molecular formula of sulfur under these conditions?

**1.8(b)** At  $100^\circ\text{C}$  and 16.0 kPa, the mass density of phosphorus vapour is  $0.6388 \text{ kg m}^{-3}$ . What is the molecular formula of phosphorus under these conditions?

**1.9(a)** Calculate the mass of water vapour present in a room of volume  $400 \text{ m}^3$  that contains air at  $27^\circ\text{C}$  on a day when the relative humidity is 60 per cent.

**1.9(b)** Calculate the mass of water vapour present in a room of volume  $250 \text{ m}^3$  that contains air at  $23^\circ\text{C}$  on a day when the relative humidity is 53 per cent.

**1.10(a)** Given that the density of air at 0.987 bar and  $27^\circ\text{C}$  is  $1.146 \text{ kg m}^{-3}$ , calculate the mole fraction and partial pressure of nitrogen and oxygen assuming that (a) air consists only of these two gases, (b) air also contains 1.0 mole per cent Ar.

**1.10(b)** A gas mixture consists of 320 mg of methane, 175 mg of argon, and 225 mg of neon. The partial pressure of neon at 300 K is 8.87 kPa. Calculate (a) the volume and (b) the total pressure of the mixture.

**1.11(a)** The density of a gaseous compound was found to be  $1.23 \text{ kg m}^{-3}$  at 330 K and 20 kPa. What is the molar mass of the compound?

**1.11(b)** In an experiment to measure the molar mass of a gas,  $250 \text{ cm}^3$  of the gas was confined in a glass vessel. The pressure was 152 Torr at  $298 \text{ K}$  and, after correcting for buoyancy effects, the mass of the gas was 33.5 mg. What is the molar mass of the gas?

**1.12(a)** The densities of air at  $-85^{\circ}\text{C}$ ,  $0^{\circ}\text{C}$ , and  $100^{\circ}\text{C}$  are  $1.877\text{ g dm}^{-3}$ ,  $1.294\text{ g dm}^{-3}$ , and  $0.946\text{ g dm}^{-3}$ , respectively. From these data, and assuming that air obeys Charles's law, determine a value for the absolute zero of temperature in degrees Celsius.

**1.12(b)** A certain sample of a gas has a volume of  $20.00\text{ dm}^3$  at  $0^{\circ}\text{C}$  and  $1.000\text{ atm}$ . A plot of the experimental data of its volume against the Celsius temperature,  $\theta$ , at constant  $p$ , gives a straight line of slope  $0.0741\text{ dm}^3 (^{\circ}\text{C})^{-1}$ . From these data alone (without making use of the perfect gas law), determine the absolute zero of temperature in degrees Celsius.

**1.13(a)** Calculate the pressure exerted by  $1.0\text{ mol C}_2\text{H}_6$  behaving as (a) a perfect gas, (b) a van der Waals gas when it is confined under the following conditions: (i) at  $273.15\text{ K}$  in  $22.414\text{ dm}^3$ , (ii) at  $1000\text{ K}$  in  $100\text{ cm}^3$ . Use the data in Table 1.6.

**1.13(b)** Calculate the pressure exerted by  $1.0\text{ mol H}_2\text{S}$  behaving as (a) a perfect gas, (b) a van der Waals gas when it is confined under the following conditions: (i) at  $273.15\text{ K}$  in  $22.414\text{ dm}^3$ , (ii) at  $500\text{ K}$  in  $150\text{ cm}^3$ . Use the data in Table 1.6.

**1.14(a)** Express the van der Waals parameters  $a = 0.751\text{ atm dm}^6\text{ mol}^{-2}$  and  $b = 0.0226\text{ dm}^3\text{ mol}^{-1}$  in SI base units.

**1.14(b)** Express the van der Waals parameters  $a = 1.32\text{ atm dm}^6\text{ mol}^{-2}$  and  $b = 0.0436\text{ dm}^3\text{ mol}^{-1}$  in SI base units.

**1.15(a)** A gas at  $250\text{ K}$  and  $15\text{ atm}$  has a molar volume 12 per cent smaller than that calculated from the perfect gas law. Calculate (a) the compression factor under these conditions and (b) the molar volume of the gas. Which are dominating in the sample, the attractive or the repulsive forces?

**1.15(b)** A gas at  $350\text{ K}$  and  $12\text{ atm}$  has a molar volume 12 per cent larger than that calculated from the perfect gas law. Calculate (a) the compression factor under these conditions and (b) the molar volume of the gas. Which are dominating in the sample, the attractive or the repulsive forces?

**1.16(a)** In an industrial process, nitrogen is heated to  $500\text{ K}$  at a constant volume of  $1.000\text{ m}^3$ . The gas enters the container at  $300\text{ K}$  and  $100\text{ atm}$ . The mass of the gas is  $92.4\text{ kg}$ . Use the van der Waals equation to determine the approximate pressure of the gas at its working temperature of  $500\text{ K}$ . For nitrogen,  $a = 1.352\text{ dm}^6\text{ atm mol}^{-2}$ ,  $b = 0.0387\text{ dm}^3\text{ mol}^{-1}$ .

**1.16(b)** Cylinders of compressed gas are typically filled to a pressure of  $200\text{ bar}$ . For oxygen, what would be the molar volume at this pressure and  $25^{\circ}\text{C}$  based on (a) the perfect gas equation, (b) the van der Waals equation. For oxygen,  $a = 1.364\text{ dm}^6\text{ atm mol}^{-2}$ ,  $b = 3.19 \times 10^{-2}\text{ dm}^3\text{ mol}^{-1}$ .

**1.17(a)** Suppose that  $10.0\text{ mol C}_2\text{H}_6(\text{g})$  is confined to  $4.860\text{ dm}^3$  at  $27^{\circ}\text{C}$ . Predict the pressure exerted by the ethane from (a) the perfect gas and (b) the van der Waals equations of state. Calculate the compression factor based on these calculations. For ethane,  $a = 5.507\text{ dm}^6\text{ atm mol}^{-2}$ ,  $b = 0.0651\text{ dm}^3\text{ mol}^{-1}$ .

**1.17(b)** At  $300\text{ K}$  and  $20\text{ atm}$ , the compression factor of a gas is  $0.86$ . Calculate (a) the volume occupied by  $8.2\text{ mmol}$  of the gas under these conditions and (b) an approximate value of the second virial coefficient  $B$  at  $300\text{ K}$ .

**1.18(a)** A vessel of volume  $22.4\text{ dm}^3$  contains  $2.0\text{ mol H}_2$  and  $1.0\text{ mol N}_2$  at  $273.15\text{ K}$ . Calculate (a) the mole fractions of each component, (b) their partial pressures, and (c) their total pressure.

**1.18(b)** A vessel of volume  $22.4\text{ dm}^3$  contains  $1.5\text{ mol H}_2$  and  $2.5\text{ mol N}_2$  at  $273.15\text{ K}$ . Calculate (a) the mole fractions of each component, (b) their partial pressures, and (c) their total pressure.

**1.19(a)** The critical constants of methane are  $p_c = 45.6\text{ atm}$ ,  $V_c = 98.7\text{ cm}^3\text{ mol}^{-1}$ , and  $T_c = 190.6\text{ K}$ . Calculate the van der Waals parameters of the gas and estimate the radius of the molecules.

**1.19(b)** The critical constants of ethane are  $p_c = 48.20\text{ atm}$ ,  $V_c = 148\text{ cm}^3\text{ mol}^{-1}$ , and  $T_c = 305.4\text{ K}$ . Calculate the van der Waals parameters of the gas and estimate the radius of the molecules.

**1.20(a)** Use the van der Waals parameters for chlorine to calculate approximate values of (a) the Boyle temperature of chlorine and (b) the radius of a  $\text{Cl}_2$  molecule regarded as a sphere.

**1.20(b)** Use the van der Waals parameters for hydrogen sulfide (Table 1.6 in the Data section) to calculate approximate values of (a) the Boyle temperature of the gas and (b) the radius of a  $\text{H}_2\text{S}$  molecule regarded as a sphere.

**1.21(a)** Suggest the pressure and temperature at which  $1.0\text{ mol}$  of (a)  $\text{NH}_3$ , (b)  $\text{Xe}$ , (c)  $\text{He}$  will be in states that correspond to  $1.0\text{ mol H}_2$  at  $1.0\text{ atm}$  and  $25^{\circ}\text{C}$ .

**1.21(b)** Suggest the pressure and temperature at which  $1.0\text{ mol}$  of (a)  $\text{H}_2\text{S}$ , (b)  $\text{CO}_2$ , (c)  $\text{Ar}$  will be in states that correspond to  $1.0\text{ mol N}_2$  at  $1.0\text{ atm}$  and  $25^{\circ}\text{C}$ .

**1.22(a)** A certain gas obeys the van der Waals equation with  $a = 0.50\text{ m}^6\text{ Pa mol}^{-2}$ . Its volume is found to be  $5.00 \times 10^{-4}\text{ m}^3\text{ mol}^{-1}$  at  $273\text{ K}$  and  $3.0\text{ MPa}$ . From this information calculate the van der Waals constant  $b$ . What is the compression factor for this gas at the prevailing temperature and pressure?

**1.22(b)** A certain gas obeys the van der Waals equation with  $a = 0.76\text{ m}^6\text{ Pa mol}^{-2}$ . Its volume is found to be  $4.00 \times 10^{-4}\text{ m}^3\text{ mol}^{-1}$  at  $288\text{ K}$  and  $4.0\text{ MPa}$ . From this information calculate the van der Waals constant  $b$ . What is the compression factor for this gas at the prevailing temperature and pressure?

## Problems\*

### Numerical problems

**1.1** Recent communication with the inhabitants of Neptune has revealed that they have a Celsius-type temperature scale, but based on the melting point ( $0^{\circ}\text{N}$ ) and boiling point ( $100^{\circ}\text{N}$ ) of their most common substance, hydrogen. Further communications have revealed that the Neptunians know about perfect gas behaviour and they find that, in the limit of zero pressure, the value of  $pV$  is  $28\text{ dm}^3\text{ atm}$  at  $0^{\circ}\text{N}$  and  $40\text{ dm}^3\text{ atm}$  at  $100^{\circ}\text{N}$ . What is the value of the absolute zero of temperature on their temperature scale?

**1.2** Deduce the relation between the pressure and mass density,  $\rho$ , of a perfect gas of molar mass  $M$ . Confirm graphically, using the following data on

dimethyl ether at  $25^{\circ}\text{C}$ , that perfect behaviour is reached at low pressures and find the molar mass of the gas.

|                           |        |       |       |       |       |       |
|---------------------------|--------|-------|-------|-------|-------|-------|
| $p/\text{kPa}$            | 12.223 | 25.20 | 36.97 | 60.37 | 85.23 | 101.3 |
| $\rho/(\text{kg m}^{-3})$ | 0.225  | 0.456 | 0.664 | 1.062 | 1.468 | 1.734 |

**1.3** Charles's law is sometimes expressed in the form  $V = V_0(1 + \alpha\theta)$ , where  $\theta$  is the Celsius temperature,  $\alpha$  is a constant, and  $V_0$  is the volume of the sample at  $0^{\circ}\text{C}$ . The following values for  $\alpha$  have been reported for nitrogen at  $0^{\circ}\text{C}$ :

|                                      |        |        |        |        |
|--------------------------------------|--------|--------|--------|--------|
| $p/\text{Torr}$                      | 749.7  | 599.6  | 333.1  | 98.6   |
| $10^3\alpha/(^{\circ}\text{C})^{-1}$ | 3.6717 | 3.6697 | 3.6665 | 3.6643 |

\* Problems denoted with the symbol \* were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

For these data calculate the best value for the absolute zero of temperature on the Celsius scale.

**1.4** The molar mass of a newly synthesized fluorocarbon was measured in a gas microbalance. This device consists of a glass bulb forming one end of a beam, the whole surrounded by a closed container. The beam is pivoted, and the balance point is attained by raising the pressure of gas in the container, so increasing the buoyancy of the enclosed bulb. In one experiment, the balance point was reached when the fluorocarbon pressure was 327.10 Torr; for the same setting of the pivot, a balance was reached when  $\text{CHF}_3$  ( $M = 70.014 \text{ g mol}^{-1}$ ) was introduced at 423.22 Torr. A repeat of the experiment with a different setting of the pivot required a pressure of 293.22 Torr of the fluorocarbon and 427.22 Torr of the  $\text{CHF}_3$ . What is the molar mass of the fluorocarbon? Suggest a molecular formula.

**1.5** A constant-volume perfect gas thermometer indicates a pressure of 6.69 kPa at the triple point temperature of water (273.16 K). (a) What change of pressure indicates a change of 1.00 K at this temperature? (b) What pressure indicates a temperature of 100.00°C? (c) What change of pressure indicates a change of 1.00 K at the latter temperature?

**1.6** A vessel of volume  $22.4 \text{ dm}^3$  contains 2.0 mol  $\text{H}_2$  and 1.0 mol  $\text{N}_2$  at 273.15 K initially. All the  $\text{H}_2$  reacted with sufficient  $\text{N}_2$  to form  $\text{NH}_3$ . Calculate the partial pressures and the total pressure of the final mixture.

**1.7** Calculate the molar volume of chlorine gas at 350 K and 2.30 atm using (a) the perfect gas law and (b) the van der Waals equation. Use the answer to (a) to calculate a first approximation to the correction term for attraction and then use successive approximations to obtain a numerical answer for part (b).

**1.8** At 273 K measurements on argon gave  $B = -21.7 \text{ cm}^3 \text{ mol}^{-1}$  and  $C = 1200 \text{ cm}^6 \text{ mol}^{-2}$ , where  $B$  and  $C$  are the second and third virial coefficients in the expansion of  $Z$  in powers of  $1/V_m$ . Assuming that the perfect gas law holds sufficiently well for the estimation of the second and third terms of the expansion, calculate the compression factor of argon at 100 atm and 273 K. From your result, estimate the molar volume of argon under these conditions.

**1.9** Calculate the volume occupied by 1.00 mol  $\text{N}_2$  using the van der Waals equation in the form of a virial expansion at (a) its critical temperature, (b) its Boyle temperature, and (c) its inversion temperature. Assume that the pressure is 10 atm throughout. At what temperature is the gas most perfect? Use the following data:  $T_c = 126.3 \text{ K}$ ,  $a = 1.390 \text{ dm}^6 \text{ atm mol}^{-2}$ ,  $b = 0.0391 \text{ dm}^3 \text{ mol}^{-1}$ .

**1.10†** The second virial coefficient of methane can be approximated by the empirical equation  $B'(T) = a + be^{-c/T^2}$ , where  $a = -0.1993 \text{ bar}^{-1}$ ,  $b = 0.2002 \text{ bar}^{-1}$ , and  $c = 1131 \text{ K}^2$  with  $300 \text{ K} < T < 600 \text{ K}$ . What is the Boyle temperature of methane?

**1.11** The mass density of water vapour at 327.6 atm and 776.4 K is  $133.2 \text{ kg m}^{-3}$ . Given that for water  $T_c = 647.4 \text{ K}$ ,  $p_c = 218.3 \text{ atm}$ ,  $a = 5.464 \text{ dm}^6 \text{ atm mol}^{-2}$ ,  $b = 0.03049 \text{ dm}^3 \text{ mol}^{-1}$ , and  $M = 18.02 \text{ g mol}^{-1}$ , calculate (a) the molar volume. Then calculate the compression factor (b) from the data, (c) from the virial expansion of the van der Waals equation.

**1.12** The critical volume and critical pressure of a certain gas are  $160 \text{ cm}^3 \text{ mol}^{-1}$  and 40 atm, respectively. Estimate the critical temperature by assuming that the gas obeys the Berthelot equation of state. Estimate the radii of the gas molecules on the assumption that they are spheres.

**1.13** Estimate the coefficients  $a$  and  $b$  in the Dieterici equation of state from the critical constants of xenon. Calculate the pressure exerted by 1.0 mol Xe when it is confined to  $1.0 \text{ dm}^3$  at 25°C.

### Theoretical problems

**1.14** Show that the van der Waals equation leads to values of  $Z < 1$  and  $Z > 1$ , and identify the conditions for which these values are obtained.

**1.15** Express the van der Waals equation of state as a virial expansion in powers of  $1/V_m$  and obtain expressions for  $B$  and  $C$  in terms of the parameters  $a$  and  $b$ . The expansion you will need is  $(1-x)^{-1} = 1 + x + x^2 + \dots$ . Measurements on argon gave  $B = -21.7 \text{ cm}^3 \text{ mol}^{-1}$  and  $C = 1200 \text{ cm}^6 \text{ mol}^{-2}$  for the virial coefficients at 273 K. What are the values of  $a$  and  $b$  in the corresponding van der Waals equation of state?

**1.16†** Derive the relation between the critical constants and the Dieterici equation parameters. Show that  $Z_c = 2e^{-2}$  and derive the reduced form of the Dieterici equation of state. Compare the van der Waals and Dieterici predictions of the critical compression factor. Which is closer to typical experimental values?

**1.17** A scientist proposed the following equation of state:

$$p = \frac{RT}{V_m} - \frac{B}{V_m^2} + \frac{C}{V_m^3}$$

Show that the equation leads to critical behaviour. Find the critical constants of the gas in terms of  $B$  and  $C$  and an expression for the critical compression factor.

**1.18** Equations 1.19a and 1.19b are expansions in  $p$  and  $1/V_m$ , respectively. Find the relation between  $B$ ,  $C$  and  $B'$ ,  $C'$ .

**1.19** The second virial coefficient  $B'$  can be obtained from measurements of the density  $\rho$  of a gas at a series of pressures. Show that the graph of  $p/\rho$  against  $p$  should be a straight line with slope proportional to  $B'$ . Use the data on dimethyl ether in Problem 1.2 to find the values of  $B'$  and  $B$  at 25°C.

**1.20** The equation of state of a certain gas is given by  $p = RT/V_m + (a + bT)/V_m^2$ , where  $a$  and  $b$  are constants. Find  $(\partial V/\partial T)_p$ .

**1.21** The following equations of state are occasionally used for approximate calculations on gases: (gas A)  $pV_m = RT(1 + b/V_m)$ , (gas B)  $p(V_m - b) = RT$ . Assuming that there were gases that actually obeyed these equations of state, would it be possible to liquefy either gas A or B? Would they have a critical temperature? Explain your answer.

**1.22** Derive an expression for the compression factor of a gas that obeys the equation of state  $p(V - nb) = nRT$ , where  $b$  and  $R$  are constants. If the pressure and temperature are such that  $V_m = 10b$ , what is the numerical value of the compression factor?

**1.23†** The discovery of the element argon by Lord Rayleigh and Sir William Ramsay had its origins in Rayleigh's measurements of the density of nitrogen with an eye toward accurate determination of its molar mass. Rayleigh prepared some samples of nitrogen by chemical reaction of nitrogen-containing compounds; under his standard conditions, a glass globe filled with this 'chemical nitrogen' had a mass of 2.2990 g. He prepared other samples by removing oxygen, carbon dioxide, and water vapour from atmospheric air; under the same conditions, this 'atmospheric nitrogen' had a mass of 2.3102 g (Lord Rayleigh, *Royal Institution Proceedings* 14, 524 (1895)). With the hindsight of knowing accurate values for the molar masses of nitrogen and argon, compute the mole fraction of argon in the latter sample on the assumption that the former was pure nitrogen and the latter a mixture of nitrogen and argon.

**1.24†** A substance as elementary and well known as argon still receives research attention. Stewart and Jacobsen have published a review of thermodynamic properties of argon (R.B. Stewart and R.T. Jacobsen, *J. Phys. Chem. Ref. Data* 18, 639 (1989)) which included the following 300 K isotherm.

|                                      |        |        |         |         |         |
|--------------------------------------|--------|--------|---------|---------|---------|
| $p/\text{MPa}$                       | 0.4000 | 0.5000 | 0.6000  | 0.8000  | 1.000   |
| $V_m/(\text{dm}^3 \text{ mol}^{-1})$ | 6.2208 | 4.9736 | 4.1423  | 3.1031  | 2.4795  |
| $p/\text{MPa}$                       | 1.500  | 2.000  | 2.500   | 3.000   | 4.000   |
| $V_m/(\text{dm}^3 \text{ mol}^{-1})$ | 1.6483 | 1.2328 | 0.98357 | 0.81746 | 0.60998 |

(a) Compute the second virial coefficient,  $B$ , at this temperature. (b) Use nonlinear curve-fitting software to compute the third virial coefficient,  $C$ , at this temperature.

### Applications: to atmospheric science

**1.25** Atmospheric pollution is a problem that has received much attention. Not all pollution, however, is from industrial sources. Volcanic eruptions can be a significant source of air pollution. The Kilauea volcano in Hawaii emits 200–300 t of  $\text{SO}_2$  per day. If this gas is emitted at  $800^\circ\text{C}$  and 1.0 atm, what volume of gas is emitted?

**1.26** Ozone is a trace atmospheric gas that plays an important role in screening the Earth from harmful ultraviolet radiation. The abundance of ozone is commonly reported in *Dobson units*. One Dobson unit is the thickness, in thousandths of a centimetre, of a column of gas if it were collected as a pure gas at 1.00 atm and  $0^\circ\text{C}$ . What amount of  $\text{O}_3$  (in moles) is found in a column of atmosphere with a cross-sectional area of  $1.00\text{ dm}^2$  if the abundance is 250 Dobson units (a typical mid-latitude value)? In the seasonal Antarctic ozone hole, the column abundance drops below 100 Dobson units; how many moles of ozone are found in such a column of air above a  $1.00\text{ dm}^2$  area? Most atmospheric ozone is found between 10 and 50 km above the surface of the Earth. If that ozone is spread uniformly through this portion of the atmosphere, what is the average molar concentration corresponding to (a) 250 Dobson units, (b) 100 Dobson units?

**1.27** The barometric formula relates the pressure of a gas of molar mass  $M$  at an altitude  $h$  to its pressure  $p_0$  at sea level. Derive this relation by showing that the change in pressure  $dp$  for an infinitesimal change in altitude  $dh$  where the density is  $\rho$  is  $dp = -\rho g dh$ . Remember that  $\rho$  depends on the pressure. Evaluate (a) the pressure difference between the top and bottom of a

laboratory vessel of height 15 cm, and (b) the external atmospheric pressure at a typical cruising altitude of an aircraft (11 km) when the pressure at ground level is 1.0 atm.

**1.28** Balloons are still used to deploy sensors that monitor meteorological phenomena and the chemistry of the atmosphere. It is possible to investigate some of the technicalities of ballooning by using the perfect gas law. Suppose your balloon has a radius of 3.0 m and that it is spherical. (a) What amount of  $\text{H}_2$  (in moles) is needed to inflate it to 1.0 atm in an ambient temperature of  $25^\circ\text{C}$  at sea level? (b) What mass can the balloon lift at sea level, where the density of air is  $1.22\text{ kg m}^{-3}$ ? (c) What would be the payload if He were used instead of  $\text{H}_2$ ?

**1.29†** The preceding problem is most readily solved (see the *Solutions manual*) with the use of Archimedes' principle, which states that the lifting force is equal to the difference between the weight of the displaced air and the weight of the balloon. Prove Archimedes' principle for the atmosphere from the barometric formula. *Hint.* Assume a simple shape for the balloon, perhaps a right circular cylinder of cross-sectional area  $A$  and height  $h$ .

**1.30†** Chlorofluorocarbons such as  $\text{CCl}_3\text{F}$  and  $\text{CCl}_2\text{F}_2$  have been linked to ozone depletion in Antarctica. As of 1994, these gases were found in quantities of 261 and 509 parts per trillion ( $10^{12}$ ) by volume (World Resources Institute, *World resources* 1996–97). Compute the molar concentration of these gases under conditions typical of (a) the mid-latitude troposphere ( $10^\circ\text{C}$  and 1.0 atm) and (b) the Antarctic stratosphere (200 K and 0.050 atm).

**1.31†** The composition of the atmosphere is approximately 80 per cent nitrogen and 20 per cent oxygen by mass. At what height above the surface of the Earth would the atmosphere become 90 per cent nitrogen and 10 per cent oxygen by mass? Assume that the temperature of the atmosphere is constant at  $25^\circ\text{C}$ . What is the pressure of the atmosphere at that height?

## MATHEMATICAL BACKGROUND 1

## Differentiation and integration

Rates of change of functions—slopes of their graphs—are best discussed in terms of infinitesimal calculus. The slope of a function, like the slope of a hill, is obtained by dividing the rise of the hill by the horizontal distance (Fig. MB1.1). However, because the slope may vary from point to point, we should make the horizontal distance between the points as small as possible. In fact, we let it become infinitesimally small—hence the name *infinitesimal* calculus. The values of a function  $f$  at two locations  $x$  and  $x + \delta x$  are  $f(x)$  and  $f(x + \delta x)$ , respectively. Therefore, the slope of the function  $f$  at  $x$  is the vertical distance, which we write  $\delta f$ , divided by the horizontal distance, which we write  $\delta x$ :

$$\text{Slope} = \frac{\text{rise in value}}{\text{horizontal distance}} = \frac{\delta f}{\delta x} = \frac{f(x + \delta x) - f(x)}{\delta x} \quad (\text{MB1.1})$$

The slope at  $x$  itself is obtained by letting the horizontal distance become zero, which we write  $\lim_{\delta x \rightarrow 0}$ . In this limit, the  $\delta$  is replaced by a  $d$ , and we write

$$\text{Slope at } x = \frac{df}{dx} = \lim_{\delta x \rightarrow 0} \left( \frac{f(x + \delta x) - f(x)}{\delta x} \right) \quad (\text{MB1.2})$$

To work out the slope of any function, we work out the expression on the right: this process is called **differentiation** and the expression for  $df/dx$  is the **derivative** of the function  $f$  with respect to the variable  $x$ . Some important derivatives are given inside the front cover of the text. Most of the functions encountered in chemistry can be differentiated by using the following rules (noting that in these expressions, derivatives  $df/dx$  are written as  $df$ ).

**Rule 1** For two functions  $f$  and  $g$ :

$$d(f + g) = df + dg \quad [\text{MB1.3}]$$

**Rule 2** (the product rule) For two functions  $f$  and  $g$ :

$$d(fg) = f dg + g df \quad [\text{MB1.4}]$$

**Rule 3** (the quotient rule) For two functions  $f$  and  $g$ :

$$d\left(\frac{f}{g}\right) = \frac{1}{g} df - \frac{f}{g^2} dg \quad [\text{MB1.5}]$$

**Rule no. 4** (the chain rule) For a function  $f = f(g)$ , where  $g = g(t)$ :

$$\frac{df}{dt} = \frac{df}{dg} \frac{dg}{dt} \quad [\text{MB1.6}]$$

The area under a graph of any function  $f$  is found by the techniques of **integration**. For instance, the area under the graph of the function  $f$  drawn in Fig. MB1.2 can be written as the value of  $f$  evaluated at a point multiplied by the width of the region,  $\delta x$ , and then all those products  $f(x)\delta x$  summed over all the regions:

$$\text{Area between } a \text{ and } b = \sum f(x)\delta x$$

When we allow  $\delta x$  to become infinitesimally small, written  $dx$ , and sum an infinite number of strips, we write

$$\text{Area between } a \text{ and } b = \int_a^b f(x) dx \quad [\text{MB1.7}]$$

The elongated S symbol on the right is called the **integral** of the function  $f$ . When written as  $\int$  alone, it is the **indefinite integral** of the function. When written with limits (as in eqn MB1.7), it is the **definite integral** of the function. The definite integral is the indefinite integral evaluated at the upper limit ( $b$ ) minus the indefinite integral evaluated at the lower limit ( $a$ ). The **average value** (or *mean value*) of a function  $f(x)$  in the range  $x = a$  to  $x = b$  is

$$\text{Average value of } f(x) \text{ from } a \text{ to } b = \frac{1}{b-a} \int_a^b f(x) dx \quad [\text{MB1.8}]$$

The **mean value theorem** states that a continuous function has its mean value at least once in the range.

Integration is the inverse of differentiation. That is, if we integrate a function and then differentiate the result, we get back the original function. Some important integrals are given inside the front cover of the text. Many other standard forms are found in tables and it is also possible to calculate definite and indefinite integrals with mathematical software. Two integration techniques are useful.

*Technique 1* (integration by parts) For two functions  $f$  and  $g$ :

$$\int f \frac{dg}{dx} dx = fg - \int g \frac{df}{dx} dx \quad [\text{MB1.9}]$$

*Technique 2* (method of partial fractions) To solve an integral of the form

$$\int \frac{1}{(a-x)(b-x)} dx$$

where  $a$  and  $b$  are constants, we write

$$\frac{1}{(a-x)(b-x)} = \frac{1}{b-a} \left( \frac{1}{a-x} - \frac{1}{b-x} \right)$$

and integrate the expression on the right. It follows that

$$\begin{aligned} \int \frac{dx}{(a-x)(b-x)} &= \frac{1}{b-a} \left[ \int \frac{dx}{a-x} - \int \frac{dx}{b-x} \right] \\ &= \frac{1}{b-a} \left( \ln \frac{1}{a-x} - \ln \frac{1}{b-x} \right) + \text{constant} \end{aligned} \quad [\text{MB1.10}]$$

Problems

This chapter introduces some of the basic concepts of thermodynamics. It concentrates on the conservation of energy—the experimental observation that energy can be neither created nor destroyed—and shows how the principle of the conservation of energy can be used to assess the energy changes that accompany physical and chemical processes. Much of this chapter examines the means by which a system can exchange energy with its surroundings in terms of the work it may do or have done on it or the heat that it may produce or absorb. The target concept of the chapter is enthalpy, which is a very useful bookkeeping property for keeping track of the heat output (or requirements) of physical processes and chemical reactions at constant pressure. We also begin to unfold some of the power of thermodynamics by showing how to establish relations between different properties of a system. We shall see that one very useful aspect of thermodynamics is that a property can be measured indirectly by measuring others and then combining their values. The relations we derive also enable us to discuss the liquefaction of gases and to establish the relation between the heat capacities of a substance under different conditions.

The release of energy can be used to provide heat when a fuel burns in a furnace, to produce mechanical work when a fuel burns in an engine, and to generate electrical work when a chemical reaction pumps electrons through a circuit. In chemistry, we encounter reactions that can be harnessed to provide heat and work, reactions that liberate energy that is released unused but which give products we require, and reactions that constitute the processes of life. **Thermodynamics**, the study of the transformations of energy, enables us to discuss all these matters quantitatively and to make useful predictions.

## The basic concepts

For the purposes of thermodynamics, the universe is divided into two parts, the system and its surroundings. The **system** is the part of the world in which we have a special interest. It may be a reaction vessel, an engine, an electrochemical cell, a biological cell, and so on. The **surroundings** comprise the region outside the system and are where we make our measurements. The type of system depends on the characteristics of the boundary that divides it from the surroundings (Fig. 2.1). If matter can be transferred through the boundary between the system and its surroundings the system is classified as **open**. If matter cannot pass through the boundary the system is classified as **closed**. Both open and closed systems can exchange energy with their surroundings. For example, a closed system can expand and thereby raise a weight in the surroundings; a closed system may also transfer energy to the surroundings if they are

at a lower temperature. An **isolated system** is a closed system that has neither mechanical nor thermal contact with its surroundings.

## 2.1 Work, heat, and energy

**Key points** (a) Work is done to achieve motion against an opposing force; energy is the capacity to do work. (b) Heating is the transfer of energy that makes use of disorderly molecular motion; work is the transfer of energy that makes use of organized motion.

Although thermodynamics deals with observations on bulk systems, it is immeasurably enriched by understanding the molecular origins of these observations. In each case we shall set out the bulk observations on which thermodynamics is based and then describe their molecular interpretations.

### (a) Operational definitions

The fundamental physical property in thermodynamics is work: **work** is done to achieve motion against an opposing force. A simple example is the process of raising a weight against the pull of gravity. A process does work if, in principle, it can be harnessed to raise a weight somewhere in the surroundings. An example of doing work is the expansion of a gas that pushes out a piston: the motion of the piston can in principle be used to raise a weight. A chemical reaction that drives an electric current through a resistance also does work, because the same current could be passed through a motor and used to raise a weight.

The **energy** of a system is its capacity to do work. When work is done on an otherwise isolated system (for instance, by compressing a gas or winding a spring), the capacity of the system to do work is increased; in other words, the energy of the system is increased. When the system does work (when the piston moves out or the spring unwinds), the energy of the system is reduced and it can do less work than before.

Experiments have shown that the energy of a system may be changed by means other than work itself. When the energy of a system changes as a result of a temperature difference between the system and its surroundings we say that energy has been transferred as **heat**. When a heater is immersed in a beaker of water (the system), the capacity of the system to do work increases because hot water can be used to do more work than the same amount of cold water. Not all boundaries permit the transfer of energy even though there is a temperature difference between the system and its surroundings. Boundaries that do permit the transfer of energy as heat are called **diathermic**; those that do not are called **adiabatic**.

An **exothermic process** is a process that releases energy as heat into its surroundings. All combustion reactions are exothermic. An **endothermic process** is a process in which energy is acquired from its surroundings as heat. An example of an endothermic process is the vaporization of water. To avoid a lot of awkward language, we say that in an exothermic process energy is transferred ‘as heat’ to the surroundings and in an endothermic process energy is transferred ‘as heat’ from the surroundings into the system. However, it must never be forgotten that heat is a process (the transfer of energy as a result of a temperature difference), not an entity. An endothermic process in a diathermic container results in energy flowing into the system as heat to restore the temperature to that of the surroundings. An exothermic process in a similar diathermic container results in a release of energy as heat into the surroundings. When an endothermic process takes place in an adiabatic container, it results in a lowering of temperature of the system; an exothermic process results in a rise of temperature. These features are summarized in Fig. 2.2.

**Fig. 2.1** (a) An open system can exchange matter and energy with its surroundings. (b) A closed system can exchange energy with its surroundings, but it cannot exchange matter. (c) An isolated system can exchange neither energy nor matter with its surroundings.

**Fig. 2.2** (a) When an endothermic process occurs in an adiabatic system, the temperature falls; (b) if the process is exothermic, the temperature rises. (c) When an endothermic process occurs in a diathermic container, energy enters as heat from the surroundings, and the system remains at the same temperature. (d) If the process is exothermic, energy leaves as heat, and the process is isothermal.

**Fig. 2.3** When energy is transferred to the surroundings as heat, the transfer stimulates random motion of the atoms in the surroundings. Transfer of energy from the surroundings to the system makes use of random motion (thermal motion) in the surroundings.

**Fig. 2.4** When a system does work, it stimulates orderly motion in the surroundings. For instance, the atoms shown here may be part of a weight that is being raised. The ordered motion of the atoms in a falling weight does work on the system.

### (b) The molecular interpretation of heat and work

In molecular terms, heating is the transfer of energy that makes use of disorderly molecular motion in the surroundings. The disorderly motion of molecules is called **thermal motion**. The thermal motion of the molecules in the hot surroundings stimulates the molecules in the cooler system to move more vigorously and, as a result, the energy of the system is increased. When a system heats its surroundings, molecules of the system stimulate the thermal motion of the molecules in the surroundings (Fig. 2.3).

In contrast, work is the transfer of energy that makes use of organized motion in the surroundings (Fig. 2.4). When a weight is raised or lowered, its atoms move in an organized way (up or down). The atoms in a spring move in an orderly way when it is wound; the electrons in an electric current move in an orderly direction. When a system does work it causes atoms or electrons in its surroundings to move in an organized way. Likewise, when work is done on a system, molecules in the surroundings are used to transfer energy to it in an organized way, as the atoms in a weight are lowered or a current of electrons is passed.

The distinction between work and heat is made in the surroundings. The fact that a falling weight may stimulate thermal motion in the system is irrelevant to the distinction between heat and work: work is identified as energy transfer making use of the organized motion of atoms in the surroundings, and heat is identified as energy transfer making use of thermal motion in the surroundings. In the adiabatic compression of a gas, for instance, work is done on the system as the atoms of the compressing weight descend in an orderly way, but the effect of the incoming piston is to accelerate the gas molecules to higher average speeds. Because collisions between molecules quickly randomize their directions, the orderly motion of the atoms of the weight is in effect stimulating thermal motion in the gas. We observe the falling weight, the orderly descent of its atoms, and report that work is being done even though it is stimulating thermal motion.

## 2.2 The internal energy

**Key points** Internal energy, the total energy of a system, is a state function. (a) The equipartition theorem can be used to estimate the contribution to the internal energy of classical modes of motion. (b) The First Law states that the internal energy of an isolated system is constant.

In thermodynamics, the total energy of a system is called its **internal energy**,  $U$ . The internal energy is the total kinetic and potential energy of the molecules in the system. We denote by  $\Delta U$  the change in internal energy when a system changes from an initial state  $i$  with internal energy  $U_i$  to a final state  $f$  of internal energy  $U_f$ :

$$\Delta U = U_f - U_i \quad [2.1]$$

Throughout thermodynamics, we use the convention that  $\Delta X = X_f - X_i$ , where  $X$  is a property (a ‘state function’) of the system.

The internal energy is a **state function** in the sense that its value depends only on the current state of the system and is independent of how that state has been prepared. In other words, internal energy is a function of the properties that determine the current state of the system. Changing any one of the state variables, such as the pressure, results in a change in internal energy. That the internal energy is a state function has consequences of the greatest importance, as we shall start to unfold in Section 2.10.

The internal energy is an extensive property of a system (Section F.3) and is measured in joules ( $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$ , Section F.4). The molar internal energy,  $U_m$ , is the internal energy divided by the amount of substance in a system,  $U_m = U/n$ ; it is an intensive property and commonly reported in kilojoules per mole ( $\text{kJ mol}^{-1}$ ).

### (a) Molecular interpretation of internal energy

A molecule has a certain number of motional degrees of freedom, such as the ability to translate (the motion of its centre of mass through space), rotate around its centre of mass, or vibrate (as its bond lengths and angles change, leaving its centre of mass unmoved). Many physical and chemical properties depend on the energy associated with each of these modes of motion. For example, a chemical bond might break if a lot of energy becomes concentrated in it, for instance as vigorous vibration.

The ‘equipartition theorem’ of classical mechanics was introduced in Section F.5. According to it, the average energy of each quadratic contribution to the energy is  $\frac{1}{2}kT$ . As we saw in Section F.5, the mean energy of the atoms free to move in three dimensions is  $\frac{3}{2}kT$  and the total energy of a monatomic perfect gas is  $\frac{3}{2}NkT$ , or  $\frac{3}{2}nRT$  (because  $N = nN_A$  and  $R = N_A k$ ). We can therefore write

$$U_m(T) = U_m(0) + \frac{3}{2}RT \quad (\text{monatomic gas; translation only}) \quad (2.2a)$$

where  $U_m(0)$  is the molar internal energy at  $T = 0$ , when all translational motion has ceased and the sole contribution to the internal energy arises from the internal structure of the atoms. This equation shows that the internal energy of a perfect gas increases linearly with temperature. At  $25^\circ\text{C}$ ,  $\frac{3}{2}RT = 3.7 \text{ kJ mol}^{-1}$ , so translational motion contributes about  $4 \text{ kJ mol}^{-1}$  to the molar internal energy of a gaseous sample of atoms or molecules.

When the gas consists of molecules, we need to take into account the effect of rotation and vibration. A linear molecule, such as  $\text{N}_2$  and  $\text{CO}_2$ , can rotate around two axes perpendicular to the line of the atoms (Fig. 2.5), so it has two rotational modes of motion, each contributing a term  $\frac{1}{2}kT$  to the internal energy. Therefore, the mean rotational energy is  $kT$  and the rotational contribution to the molar internal energy is  $RT$ . By adding the translational and rotational contributions, we obtain

### A brief comment

The internal energy does not include the kinetic energy arising from the motion of the system as a whole, such as its kinetic energy as it accompanies the Earth on its orbit round the Sun. That is, the internal energy is the energy ‘internal’ to the system.

**Fig. 2.5** The rotational modes of molecules and the corresponding average energies at a temperature  $T$ . (a) A linear molecule can rotate about two axes perpendicular to the line of the atoms. (b) A nonlinear molecule can rotate about three perpendicular axes.

$$U_m(T) = U_m(0) + \frac{5}{2}RT \quad (\text{linear molecule; translation and rotation only}) \quad (2.2b)$$

A nonlinear molecule, such as  $\text{CH}_4$  or  $\text{H}_2\text{O}$ , can rotate around three axes and, again, each mode of motion contributes a term  $\frac{1}{2}kT$  to the internal energy. Therefore, the mean rotational energy is  $\frac{3}{2}kT$  and there is a rotational contribution of  $\frac{3}{2}RT$  to the molar internal energy. That is,

$$U_m(T) = U_m(0) + 3RT \quad (\text{nonlinear molecule; translation and rotation only}) \quad (2.2c)$$

The internal energy now increases twice as rapidly with temperature compared with the monatomic gas. Put another way: for a gas consisting of 1 mol of nonlinear molecules to undergo the same rise in temperature as 1 mol of monatomic gas, twice as much energy must be supplied. Molecules do not vibrate significantly at room temperature and, as a first approximation, the contribution of molecular vibrations to the internal energy is negligible except for very large molecules such as polymers and biological macromolecules.

None of the expressions we have derived depends on the volume occupied by the molecules: there are no intermolecular interactions in a perfect gas, so the distance between the molecules has no effect on the energy. That is, *the internal energy of a perfect gas is independent of the volume it occupies*. The internal energy of interacting molecules in condensed phases also has a contribution from the potential energy of their interaction. However, no simple expressions can be written down in general. Nevertheless, the crucial molecular point is that, as the temperature of a system is raised, the internal energy increases as the various modes of motion become more highly excited.

### (b) The formulation of the First Law

It has been found experimentally that the internal energy of a system may be changed either by doing work on the system or by heating it. Whereas we may know how the energy transfer has occurred (because we can see if a weight has been raised or lowered in the surroundings, indicating transfer of energy by doing work, or if ice has melted in the surroundings, indicating transfer of energy as heat), the system is blind to the mode employed. *Heat and work are equivalent ways of changing a system's internal energy*. A system is like a bank: it accepts deposits in either currency, but stores its reserves as internal energy. It is also found experimentally that, if a system is isolated from its surroundings, then no change in internal energy takes place. This summary of observations is now known as the **First Law of thermodynamics** and is expressed as follows:

The internal energy of an isolated system is constant.

First Law of thermodynamics

We cannot use a system to do work, leave it isolated, and then come back expecting to find it restored to its original state with the same capacity for doing work. The experimental evidence for this observation is that no 'perpetual motion machine', a machine that does work without consuming fuel or using some other source of energy, has ever been built.

These remarks may be summarized as follows. If we write  $w$  for the work done on a system,  $q$  for the energy transferred as heat to a system, and  $\Delta U$  for the resulting change in internal energy, then it follows that

$$\Delta U = q + w$$

Mathematical statement  
of the First Law

(2.3)

Equation 2.3 summarizes the equivalence of heat and work and the fact that the internal energy is constant in an isolated system (for which  $q = 0$  and  $w = 0$ ). The equation states that the change in internal energy of a closed system is equal to the energy that passes through its boundary as heat or work. It employs the ‘acquisitive convention’, in which  $w$  and  $q$  are positive if energy is transferred to the system as work or heat and are negative if energy is lost from the system. In other words, we view the flow of energy as work or heat from the system’s perspective.

• **A brief illustration**

If an electric motor produced 15 kJ of energy each second as mechanical work and lost 2 kJ as heat to the surroundings, then the change in the internal energy of the motor each second is

$$\Delta U = -2 \text{ kJ} - 15 \text{ kJ} = -17 \text{ kJ}$$

Suppose that, when a spring was wound, 100 J of work was done on it but 15 J escaped to the surroundings as heat. The change in internal energy of the spring is

$$\Delta U = 100 \text{ J} - 15 \text{ J} = +85 \text{ J} \quad \bullet$$

**A note on good practice** Always include the sign of  $\Delta U$  (and of  $\Delta X$  in general), even if it is positive.

## 2.3 Expansion work

**Key points** (a) Expansion work is proportional to the external pressure. (b) Free expansion (against zero pressure) does no work. (c) The work of expansion against constant pressure is proportional to that pressure and to the change in volume. (d) To achieve reversible expansion, the external pressure is matched at every stage to the pressure of the system. (e) The work of reversible, isothermal expansion of a perfect gas is a logarithmic function of the volume.

The way is opened to powerful methods of calculation by switching attention to infinitesimal changes of state (such as infinitesimal change in temperature) and infinitesimal changes in the internal energy  $dU$ . Then, if the work done on a system is  $dw$  and the energy supplied to it as heat is  $dq$ , in place of eqn 2.3 we have

$$dU = dq + dw \quad (2.4)$$

To use this expression we must be able to relate  $dq$  and  $dw$  to events taking place in the surroundings.

We begin by discussing **expansion work**, the work arising from a change in volume. This type of work includes the work done by a gas as it expands and drives back the atmosphere. Many chemical reactions result in the generation of gases (for instance, the thermal decomposition of calcium carbonate or the combustion of octane), and the thermodynamic characteristics of the reaction depend on the work that must be done to make room for the gas it has produced. The term ‘expansion work’ also includes work associated with negative changes of volume, that is, compression.

### (a) The general expression for work

The calculation of expansion work starts from the definition used in physics, which states that the work required to move an object a distance  $dz$  against an opposing force of magnitude  $F$  is

$$dw = -Fdz$$

General definition  
of work done

[2.5]

**Fig. 2.6** When a piston of area  $A$  moves out through a distance  $dz$ , it sweeps out a volume  $dV = Adz$ . The external pressure  $p_{\text{ex}}$  is equivalent to a weight pressing on the piston, and the force opposing expansion is  $F = p_{\text{ex}}A$ .

The negative sign tells us that, when the system moves an object against an opposing force of magnitude  $F$ , and there are no other changes, then the internal energy of the system doing the work will decrease. That is, if  $dz$  is positive (motion to positive  $z$ ),  $dw$  is negative, and the internal energy decreases ( $dU$  in eqn 2.4 is negative provided that  $dq = 0$ ).

Now consider the arrangement shown in Fig. 2.6, in which one wall of a system is a massless, frictionless, rigid, perfectly fitting piston of area  $A$ . If the external pressure is  $p_{\text{ex}}$ , the magnitude of the force acting on the outer face of the piston is  $F = p_{\text{ex}}A$ . When the system expands through a distance  $dz$  against an external pressure  $p_{\text{ex}}$ , it follows that the work done is  $dw = -p_{\text{ex}}Adz$ . The quantity  $Adz$  is the change in volume,  $dV$ , in the course of the expansion. Therefore, the work done when the system expands by  $dV$  against a pressure  $p_{\text{ex}}$  is

$$dw = -p_{\text{ex}}dV \quad \text{Expansion work} \quad (2.6a)$$

To obtain the total work done when the volume changes from an initial value  $V_i$  to a final value  $V_f$  we integrate this expression between the initial and final volumes:

$$w = - \int_{V_i}^{V_f} p_{\text{ex}} dV \quad (2.6b)$$

The force acting on the piston,  $p_{\text{ex}}A$ , is equivalent to the force arising from a weight that is raised as the system expands. If the system is compressed instead, then the same weight is lowered in the surroundings and eqn 2.6 can still be used, but now  $V_f < V_i$ . It is important to note that it is still the external pressure that determines the magnitude of the work. This somewhat perplexing conclusion seems to be inconsistent with the fact that the gas *inside* the container is opposing the compression. However, when a gas is compressed, the ability of the *surroundings* to do work is diminished by an amount determined by the weight that is lowered, and it is this energy that is transferred into the system.

Other types of work (for example, electrical work), which we shall call either **non-expansion work** or **additional work**, have analogous expressions, with each one the product of an intensive factor (the pressure, for instance) and an extensive factor (the change in volume). Some are collected in Table 2.1. For the present we continue with the work associated with changing the volume, the expansion work, and see what we can extract from eqn 2.6.

**Table 2.1** Varieties of work\*

| Type of work      | $dw$               | Comments                                                                 | Units†                            |
|-------------------|--------------------|--------------------------------------------------------------------------|-----------------------------------|
| Expansion         | $-p_{\text{ex}}dV$ | $p_{\text{ex}}$ is the external pressure<br>$dV$ is the change in volume | Pa<br>$\text{m}^3$                |
| Surface expansion | $\gamma d\sigma$   | $\gamma$ is the surface tension<br>$d\sigma$ is the change in area       | $\text{N m}^{-1}$<br>$\text{m}^2$ |
| Extension         | $f dl$             | $f$ is the tension<br>$dl$ is the change in length                       | N<br>m                            |
| Electrical        | $\phi dQ$          | $\phi$ is the electric potential<br>$dQ$ is the change in charge         | V<br>C                            |

\* In general, the work done on a system can be expressed in the form  $dw = -Fdz$ , where  $F$  is a ‘generalized force’ and  $dz$  is a ‘generalized displacement’.

† For work in joules (J). Note that  $1 \text{ N m} = 1 \text{ J}$  and  $1 \text{ V C} = 1 \text{ J}$ .

**(b) Free expansion**

**Free expansion** is expansion against zero opposing force. It occurs when  $p_{\text{ex}} = 0$ . According to eqn 2.6a,  $dw = 0$  for each stage of the expansion. Hence, overall:

$$w = 0 \quad \text{Work of free expansion} \quad (2.7)$$

That is, no work is done when a system expands freely. Expansion of this kind occurs when a gas expands into a vacuum.

**(c) Expansion against constant pressure**

Now suppose that the external pressure is constant throughout the expansion. For example, the piston may be pressed on by the atmosphere, which exerts the same pressure throughout the expansion. A chemical example of this condition is the expansion of a gas formed in a chemical reaction in a container that can expand. We can evaluate eqn 2.6b by taking the constant  $p_{\text{ex}}$  outside the integral:

$$w = -p_{\text{ex}} \int_{V_i}^{V_f} dV = -p_{\text{ex}}(V_f - V_i)$$

Therefore, if we write the change in volume as  $\Delta V = V_f - V_i$ ,

$$w = -p_{\text{ex}} \Delta V \quad \text{Expansion work against constant external pressure} \quad (2.8)$$

This result is illustrated graphically in Fig. 2.7, which makes use of the fact that an integral can be interpreted as an area. The magnitude of  $w$ , denoted  $|w|$ , is equal to the area beneath the horizontal line at  $p = p_{\text{ex}}$  lying between the initial and final volumes. A  $p, V$ -graph used to illustrate expansion work is called an **indicator diagram**; James Watt first used one to indicate aspects of the operation of his steam engine.

**(d) Reversible expansion**

A **reversible change** in thermodynamics is a change that can be reversed by an infinitesimal modification of a variable. The key word ‘infinitesimal’ sharpens the everyday meaning of the word ‘reversible’ as something that can change direction. One example of reversibility that we have encountered already is the thermal equilibrium of two systems with the same temperature. The transfer of energy as heat between the two is reversible because, if the temperature of either system is lowered infinitesimally, then energy flows into the system with the lower temperature. If the temperature of either system at thermal equilibrium is raised infinitesimally, then energy flows out of the hotter system. There is obviously a very close relationship between reversibility and equilibrium: systems at equilibrium are poised to undergo reversible change.

Suppose a gas is confined by a piston and that the external pressure,  $p_{\text{ex}}$ , is set equal to the pressure,  $p$ , of the confined gas. Such a system is in mechanical equilibrium with its surroundings because an infinitesimal change in the external pressure in either direction causes changes in volume in opposite directions. If the external pressure is reduced infinitesimally, the gas expands slightly. If the external pressure is increased infinitesimally, the gas contracts slightly. In either case the change is reversible in the thermodynamic sense. If, on the other hand, the external pressure differs measurably from the internal pressure, then changing  $p_{\text{ex}}$  infinitesimally will not decrease it below the pressure of the gas, so will not change the direction of the process. Such a system is not in mechanical equilibrium with its surroundings and the expansion is thermodynamically irreversible.

**Fig. 2.7** The work done by a gas when it expands against a constant external pressure,  $p_{\text{ex}}$ , is equal to the shaded area in this example of an indicator diagram.

**A brief comment**

The value of the integral  $\int_a^b f(x)dx$  is

equal to the area under the graph of  $f(x)$  between  $x = a$  and  $x = b$ . For instance, the area under the curve  $f(x) = x^2$  shown in the illustration that lies between  $x = 1$  and  $3$  is

$$\begin{aligned} \int_1^3 x^2 dx &= \left( \frac{1}{3} x^3 + \text{constant} \right) \Big|_1^3 \\ &= \frac{1}{3} (3^3 - 1^3) = \frac{26}{3} \approx 8.67 \end{aligned}$$

To achieve reversible expansion we set  $p_{\text{ex}}$  equal to  $p$  at each stage of the expansion. In practice, this equalization could be achieved by gradually removing weights from the piston so that the downward force due to the weights always matches the changing upward force due to the pressure of the gas. When we set  $p_{\text{ex}} = p$ , eqn 2.6a becomes

$$dw = -p_{\text{ex}}dV = -pdV \quad \text{Reversible expansion work} \quad (2.9a)_{\text{rev}}$$

(Equations valid only for reversible processes are labelled with a subscript rev.) Although the pressure inside the system appears in this expression for the work, it does so only because  $p_{\text{ex}}$  has been set equal to  $p$  to ensure reversibility. The total work of reversible expansion from an initial volume  $V_i$  to a final volume  $V_f$  is therefore

$$w = - \int_{V_i}^{V_f} p dV \quad (2.9b)_{\text{rev}}$$

We can evaluate the integral once we know how the pressure of the confined gas depends on its volume. Equation 2.9 is the link with the material covered in Chapter 1 for, if we know the equation of state of the gas, then we can express  $p$  in terms of  $V$  and evaluate the integral.

### (e) Isothermal reversible expansion

Consider the isothermal, reversible expansion of a perfect gas. The expansion is made isothermal by keeping the system in thermal contact with its surroundings (which may be a constant-temperature bath). Because the equation of state is  $pV = nRT$ , we know that at each stage  $p = nRT/V$ , with  $V$  the volume at that stage of the expansion. The temperature  $T$  is constant in an isothermal expansion, so (together with  $n$  and  $R$ ) it may be taken outside the integral. It follows that the work of reversible isothermal expansion of a perfect gas from  $V_i$  to  $V_f$  at a temperature  $T$  is

$$w = -nRT \int_{V_i}^{V_f} \frac{dV}{V} = -nRT \ln \frac{V_f}{V_i} \quad \text{Reversible, isothermal expansion work of a perfect gas} \quad (2.10)_{\text{rev}}^{\circ}$$

#### A brief comment

An integral that occurs throughout thermodynamics is

$$\int \frac{1}{x} dx = \ln x + \text{constant},$$

so  $\int_a^b \frac{1}{x} dx = \ln \frac{b}{a}$

When the final volume is greater than the initial volume, as in an expansion, the logarithm in eqn 2.10 is positive and hence  $w < 0$ . In this case, the system has done work on the surroundings and there is a corresponding reduction in its internal energy. (Note the cautious language: we shall see later that there is a compensating influx of energy as heat, so overall the internal energy is constant for the isothermal expansion of a perfect gas.) The equations also show that more work is done for a given change of volume when the temperature is increased: at a higher temperature the greater pressure of the confined gas needs a higher opposing pressure to ensure reversibility and the work done is correspondingly greater.

We can express the result of the calculation as an indicator diagram, for the magnitude of the work done is equal to the area under the isotherm  $p = nRT/V$  (Fig. 2.8). Superimposed on the diagram is the rectangular area obtained for irreversible expansion against constant external pressure fixed at the same final value as that reached in the reversible expansion. More work is obtained when the expansion is reversible (the area is greater) because matching the external pressure to the internal pressure at each stage of the process ensures that none of the system's pushing power is wasted. We cannot obtain more work than for the reversible process because increasing the external pressure even infinitesimally at any stage results in compression. We may infer from this discussion that, because some pushing power is wasted when  $p > p_{\text{ex}}$ , the maximum work available from a system operating between specified initial and final states and passing along a specified path is obtained when the change takes place reversibly.

We have introduced the connection between reversibility and maximum work for the special case of a perfect gas undergoing expansion. Later (in Section 3.5) we shall see that it applies to all substances and to all kinds of work.

### Example 2.1 Calculating the work of gas production

Calculate the work done when 50 g of iron reacts with hydrochloric acid to produce  $\text{FeCl}_2(\text{aq})$  and hydrogen in (a) a closed vessel of fixed volume, (b) an open beaker at  $25^\circ\text{C}$ .

**Method** We need to judge the magnitude of the volume change and then to decide how the process occurs. If there is no change in volume, there is no expansion work however the process takes place. If the system expands against a constant external pressure, the work can be calculated from eqn 2.8. A general feature of processes in which a condensed phase changes into a gas is that the volume of the former may usually be neglected relative to that of the gas it forms.

**Answer** In (a) the volume cannot change, so no expansion work is done and  $w = 0$ . In (b) the gas drives back the atmosphere and therefore  $w = -p_{\text{ex}}\Delta V$ . We can neglect the initial volume because the final volume (after the production of gas) is so much larger and  $\Delta V = V_f - V_i \approx V_f = nRT/p_{\text{ex}}$ , where  $n$  is the amount of  $\text{H}_2$  produced. Therefore,

$$w = -p_{\text{ex}}\Delta V \approx -p_{\text{ex}} \times \frac{nRT}{p_{\text{ex}}} = -nRT$$

Because the reaction is  $\text{Fe}(\text{s}) + 2 \text{HCl}(\text{aq}) \rightarrow \text{FeCl}_2(\text{aq}) + \text{H}_2(\text{g})$ , we know that 1 mol  $\text{H}_2$  is generated when 1 mol Fe is consumed, and  $n$  can be taken as the amount of Fe atoms that react. Because the molar mass of Fe is  $55.85 \text{ g mol}^{-1}$ , it follows that

$$\begin{aligned} w &\approx -\frac{50 \text{ g}}{55.85 \text{ g mol}^{-1}} \times (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K}) \\ &\approx -2.2 \text{ kJ} \end{aligned}$$

The system (the reaction mixture) does 2.2 kJ of work driving back the atmosphere. Note that (for this perfect gas system) the magnitude of the external pressure does not affect the final result: the lower the pressure, the larger the volume occupied by the gas, so the effects cancel.

**Self-test 2.1** Calculate the expansion work done when 50 g of water is electrolysed under constant pressure at  $25^\circ\text{C}$ . [−10 kJ]

**Fig. 2.8** The work done by a perfect gas when it expands reversibly and isothermally is equal to the area under the isotherm  $p = nRT/V$ . The work done during the irreversible expansion against the same final pressure is equal to the rectangular area shown slightly darker. Note that the reversible work is greater than the irreversible work.

 **InterActivity** Calculate the work of isothermal reversible expansion of 1.0 mol  $\text{CO}_2(\text{g})$  at 298 K from  $1.0 \text{ m}^3$  to  $3.0 \text{ m}^3$  on the basis that it obeys the van der Waals equation of state.

## 2.4 Heat transactions

**Key points** The energy transferred as heat at constant volume is equal to the change in internal energy of the system. (a) Calorimetry is the measurement of heat transactions. (b) The heat capacity at constant volume is the slope of the internal energy with respect to temperature.

In general, the change in internal energy of a system is

$$dU = dq + dw_{\text{exp}} + dw_e \quad (2.11)$$

where  $dw_e$  is work in addition (e for 'extra') to the expansion work,  $dw_{\text{exp}}$ . For instance,  $dw_e$  might be the electrical work of driving a current through a circuit. A

**Fig. 2.9** A constant-volume bomb calorimeter. The ‘bomb’ is the central vessel, which is strong enough to withstand high pressures. The calorimeter (for which the heat capacity must be known) is the entire assembly shown here. To ensure adiabaticity, the calorimeter is immersed in a water bath with a temperature continuously readjusted to that of the calorimeter at each stage of the combustion.

system kept at constant volume can do no expansion work, so  $dw_{\text{exp}} = 0$ . If the system is also incapable of doing any other kind of work (if it is not, for instance, an electrochemical cell connected to an electric motor), then  $dw_e = 0$  too. Under these circumstances:

$$dU = dq$$

Heat transferred at constant volume

 (2.12a)

We express this relation by writing  $dU = dq_V$ , where the subscript implies a change at constant volume. For a measurable change,

$$\Delta U = q_V \quad (2.12b)$$

It follows that, by measuring the energy supplied to a constant-volume system as heat ( $q_V > 0$ ) or released from it as heat ( $q_V < 0$ ) when it undergoes a change of state, we are in fact measuring the change in its internal energy.

### (a) Calorimetry

**Calorimetry** is the study of heat transfer during physical and chemical processes. A **calorimeter** is a device for measuring energy transferred as heat. The most common device for measuring  $\Delta U$  is an **adiabatic bomb calorimeter** (Fig. 2.9). The process we wish to study—which may be a chemical reaction—is initiated inside a constant-volume container, the ‘bomb’. The bomb is immersed in a stirred water bath, and the whole device is the calorimeter. The calorimeter is also immersed in an outer water bath. The water in the calorimeter and of the outer bath are both monitored and adjusted to the same temperature. This arrangement ensures that there is no net loss of heat from the calorimeter to the surroundings (the bath) and hence that the calorimeter is adiabatic.

The change in temperature,  $\Delta T$ , of the calorimeter is proportional to the energy that the reaction releases or absorbs as heat. Therefore, by measuring  $\Delta T$  we can determine  $q_V$  and hence find  $\Delta U$ . The conversion of  $\Delta T$  to  $q_V$  is best achieved by calibrating the calorimeter using a process of known energy output and determining the **calorimeter constant**, the constant  $C$  in the relation

$$q = C\Delta T \quad (2.13)$$

The calorimeter constant may be measured electrically by passing a constant current,  $I$ , from a source of known potential difference,  $\Delta\phi$ , through a heater for a known period of time,  $t$ , for then

$$q = It\Delta\phi \quad (2.14)$$

#### A brief comment

Electrical charge is measured in *coulombs*,  $C$ . The motion of charge gives rise to an *electric current*,  $I$ , measured in coulombs per second, or *amperes*,  $A$ , where  $1 A = 1 C s^{-1}$ . If a constant current  $I$  flows through a potential difference  $\Delta\phi$  (measured in volts,  $V$ ), the total energy supplied in an interval  $t$  is  $It\Delta\phi$ . Because  $1 A V s = 1 (C s^{-1}) V s = 1 C V = 1 J$ , the energy is obtained in joules with the current in amperes, the potential difference in volts, and the time in seconds.

#### • A brief illustration

If we pass a current of 10.0 A from a 12 V supply for 300 s, then from eqn 2.14 the energy supplied as heat is

$$q = (10.0 A) \times (12 V) \times (300 s) = 3.6 \times 10^4 A V s = 36 kJ$$

because  $1 A V s = 1 J$ . If the observed rise in temperature is 5.5 K, then the calorimeter constant is  $C = (36 kJ)/(5.5 K) = 6.5 kJ K^{-1}$ . •

Alternatively,  $C$  may be determined by burning a known mass of substance (benzoic acid is often used) that has a known heat output. With  $C$  known, it is simple to interpret an observed temperature rise as a release of heat.

**(b) Heat capacity**

The internal energy of a system increases when its temperature is raised. The increase depends on the conditions under which the heating takes place and for the present we suppose that the system has a constant volume. For example, it may be a gas in a container of fixed volume. If the internal energy is plotted against temperature, then a curve like that in Fig. 2.10 may be obtained. The slope of the tangent to the curve at any temperature is called the **heat capacity** of the system at that temperature. The **heat capacity at constant volume** is denoted  $C_V$  and is defined formally as

$$C_V = \left( \frac{\partial U}{\partial T} \right)_V \quad \text{Definition of heat capacity at constant volume} \quad [2.15]$$

In this case, the internal energy varies with the temperature and the volume of the sample, but we are interested only in its variation with the temperature, the volume being held constant (Fig. 2.11).

**• A brief illustration**

The heat capacity of a monatomic perfect gas can be calculated by inserting the expression for the internal energy derived in Section 2.2a. There we saw that

$$U_m = U_m(0) + \frac{3}{2}RT$$

so from eqn 2.15

$$C_{V,m} = \frac{\partial}{\partial T} (U_m(0) + \frac{3}{2}RT) = \frac{3}{2}R$$

The numerical value is  $12.47 \text{ J K}^{-1} \text{ mol}^{-1}$ . •

Heat capacities are extensive properties: 100 g of water, for instance, has 100 times the heat capacity of 1 g of water (and therefore requires 100 times the energy as heat to bring about the same rise in temperature). The **molar heat capacity at constant volume**,  $C_{V,m} = C_V/n$ , is the heat capacity per mole of substance, and is an intensive property (all molar quantities are intensive). Typical values of  $C_{V,m}$  for polyatomic gases are close to  $25 \text{ J K}^{-1} \text{ mol}^{-1}$ . For certain applications it is useful to know the **specific heat capacity** (more informally, the ‘specific heat’) of a substance, which is the heat capacity of the sample divided by the mass, usually in grams:  $C_{V,s} = C_V/m$ . The specific heat capacity of water at room temperature is close to  $4.2 \text{ J K}^{-1} \text{ g}^{-1}$ . In general, heat capacities depend on the temperature and decrease at low temperatures. However, over small ranges of temperature at and above room temperature, the variation is quite small and for approximate calculations heat capacities can be treated as almost independent of temperature.

The heat capacity is used to relate a change in internal energy to a change in temperature of a constant-volume system. It follows from eqn 2.15 that

$$dU = C_V dT \quad (\text{at constant volume}) \quad (2.16a)$$

That is, at constant volume, an infinitesimal change in temperature brings about an infinitesimal change in internal energy, and the constant of proportionality is  $C_V$ . If the heat capacity is independent of temperature over the range of temperatures of interest, a measurable change of temperature,  $\Delta T$ , brings about a measurable increase in internal energy,  $\Delta U$ , where

$$\Delta U = C_V \Delta T \quad (\text{at constant volume}) \quad (2.16b)$$

**Fig. 2.10** The internal energy of a system increases as the temperature is raised; this graph shows its variation as the system is heated at constant volume. The slope of the tangent to the curve at any temperature is the heat capacity at constant volume at that temperature. Note that, for the system illustrated, the heat capacity is greater at B than at A.

**A brief comment**

Partial derivatives are reviewed in [Mathematical background 2](#) following this chapter.

**Fig. 2.11** The internal energy of a system varies with volume and temperature, perhaps as shown here by the surface. The variation of the internal energy with temperature at one particular constant volume is illustrated by the curve drawn parallel to  $T$ . The slope of this curve at any point is the partial derivative  $(\partial U / \partial T)_V$ .

Because a change in internal energy can be identified with the heat supplied at constant volume (eqn 2.12b), the last equation can also be written

$$q_V = C_V \Delta T \quad (2.17)$$

This relation provides a simple way of measuring the heat capacity of a sample: a measured quantity of energy is transferred as heat to the sample (electrically, for example), and the resulting increase in temperature is monitored. The ratio of the energy transferred as heat to the temperature rise it causes ( $q_V/\Delta T$ ) is the constant-volume heat capacity of the sample.

A large heat capacity implies that, for a given quantity of energy transferred as heat, there will be only a small increase in temperature (the sample has a large capacity for heat). An infinite heat capacity implies that there will be no increase in temperature however much energy is supplied as heat. At a phase transition, such as at the boiling point of water, the temperature of a substance does not rise as energy is supplied as heat: the energy is used to drive the endothermic transition, in this case to vaporize the water, rather than to increase its temperature. Therefore, at the temperature of a phase transition, the heat capacity of a sample is infinite. The properties of heat capacities close to phase transitions are treated more fully in Section 4.6.

**Fig. 2.12** When a system is subjected to constant pressure and is free to change its volume, some of the energy supplied as heat may escape back into the surroundings as work. In such a case, the change in internal energy is smaller than the energy supplied as heat.

## 2.5 Enthalpy

**Key points** (a) Energy transferred as heat at constant pressure is equal to the change in enthalpy of a system. (b) Enthalpy changes are measured in a constant-pressure calorimeter. (c) The heat capacity at constant pressure is equal to the slope of enthalpy with temperature.

The change in internal energy is not equal to the energy transferred as heat when the system is free to change its volume. Under these circumstances some of the energy supplied as heat to the system is returned to the surroundings as expansion work (Fig. 2.12), so  $dU$  is less than  $dq$ . However, we shall now show that in this case the energy supplied as heat at constant pressure is equal to the change in another thermodynamic property of the system, the enthalpy.

### (a) The definition of enthalpy

The **enthalpy**,  $H$ , is defined as

$$H = U + pV \quad \text{Definition of enthalpy} \quad [2.18]$$

where  $p$  is the pressure of the system and  $V$  is its volume. Because  $U$ ,  $p$ , and  $V$  are all state functions, the enthalpy is a state function too. As is true of any state function, the change in enthalpy,  $\Delta H$ , between any pair of initial and final states is independent of the path between them.

Although the definition of enthalpy may appear arbitrary, it has important implications for thermochemistry. For instance, we show in the following *Justification* that eqn 2.18 implies that *the change in enthalpy is equal to the energy supplied as heat at constant pressure* (provided the system does no additional work):

$$dH = dq \quad \text{Heat transferred at constant pressure} \quad (2.19a)$$

For a measurable change

$$\Delta H = q_p \quad (2.19b)$$

**Justification 2.1** The relation  $\Delta H = q_p$

For a general infinitesimal change in the state of the system,  $U$  changes to  $U + dU$ ,  $p$  changes to  $p + dp$ , and  $V$  changes to  $V + dV$ , so from the definition in eqn 2.18,  $H$  changes from  $U + pV$  to

$$\begin{aligned} H + dH &= (U + dU) + (p + dp)(V + dV) \\ &= U + dU + pV + pdV + Vdp + dpdV \end{aligned}$$

The last term is the product of two infinitesimally small quantities and can therefore be neglected. As a result, after recognizing  $U + pV = H$  on the right, we find that  $H$  changes to

$$H + dH = H + dU + pdV + Vdp$$

and hence that

$$dH = dU + pdV + Vdp$$

If we now substitute  $dU = dq + dw$  into this expression, we get

$$dH = dq + dw + pdV + Vdp$$

If the system is in mechanical equilibrium with its surroundings at a pressure  $p$  and does only expansion work, we can write  $dw = -pdV$  and obtain

$$dH = dq + Vdp$$

Now we impose the condition that the heating occurs at constant pressure by writing  $dp = 0$ . Then

$$dH = dq \quad (\text{at constant pressure, no additional work})$$

as in eqn 2.19a.

The result expressed in eqn 2.19 states that, when a system is subjected to constant pressure and only expansion work can occur, the change in enthalpy is equal to the energy supplied as heat. For example, if we supply 36 kJ of energy through an electric heater immersed in an open beaker of water, then the enthalpy of the water increases by 36 kJ and we write  $\Delta H = +36$  kJ.

### (b) The measurement of an enthalpy change

An enthalpy change can be measured calorimetrically by monitoring the temperature change that accompanies a physical or chemical change occurring at constant pressure. A calorimeter for studying processes at constant pressure is called an **isobaric calorimeter**. A simple example is a thermally insulated vessel open to the atmosphere: the heat released in the reaction is monitored by measuring the change in temperature of the contents. For a combustion reaction an **adiabatic flame calorimeter** may be used to measure  $\Delta T$  when a given amount of substance burns in a supply of oxygen (Fig. 2.13). Another route to  $\Delta H$  is to measure the internal energy change by using a bomb calorimeter, and then to convert  $\Delta U$  to  $\Delta H$ . Because solids and liquids have small molar volumes, for them  $pV_m$  is so small that the molar enthalpy and molar internal energy are almost identical ( $H_m = U_m + pV_m \approx U_m$ ). Consequently, if a process involves only solids or liquids, the values of  $\Delta H$  and  $\Delta U$  are almost identical. Physically, such processes are accompanied by a very small change in volume; the system does negligible work on the surroundings when the process occurs, so the energy supplied as heat stays entirely within the system. The most sophisticated way to measure enthalpy changes, however, is to use a **differential scanning calorimeter**

**Fig. 2.13** A constant-pressure flame calorimeter consists of this component immersed in a stirred water bath. Combustion occurs as a known amount of reactant is passed through to fuel the flame, and the rise of temperature is monitored.

(DSC). Changes in enthalpy and internal energy may also be measured by noncalorimetric methods (see Chapter 6).

### Example 2.2 Relating $\Delta H$ and $\Delta U$

The change in molar internal energy when  $\text{CaCO}_3(\text{s})$  as calcite converts to another form, aragonite, is  $+0.21 \text{ kJ mol}^{-1}$ . Calculate the difference between the molar enthalpy and internal energy changes when the pressure is 1.0 bar given that the densities of the polymorphs are  $2.71 \text{ g cm}^{-3}$  and  $2.93 \text{ g cm}^{-3}$ , respectively.

**Method** The starting point for the calculation is the relation between the enthalpy of a substance and its internal energy (eqn 2.18). The difference between the two quantities can be expressed in terms of the pressure and the difference of their molar volumes, and the latter can be calculated from their molar masses,  $M$ , and their mass densities,  $\rho$ , by using  $\rho = M/V_{\text{m}}$ .

**Answer** The change in enthalpy when the transition occurs is

$$\begin{aligned}\Delta H_{\text{m}} &= H_{\text{m}}(\text{aragonite}) - H_{\text{m}}(\text{calcite}) \\ &= \{U_{\text{m}}(\text{a}) + pV_{\text{m}}(\text{a})\} - \{U_{\text{m}}(\text{c}) + pV_{\text{m}}(\text{c})\} \\ &= \Delta U_{\text{m}} + p\{V_{\text{m}}(\text{a}) - V_{\text{m}}(\text{c})\}\end{aligned}$$

where a denotes aragonite and c calcite. It follows by substituting  $V_{\text{m}} = M/\rho$  that

$$\Delta H_{\text{m}} - \Delta U_{\text{m}} = pM \left( \frac{1}{\rho(\text{a})} - \frac{1}{\rho(\text{c})} \right)$$

Substitution of the data, using  $M = 100 \text{ g mol}^{-1}$ , gives

$$\begin{aligned}\Delta H_{\text{m}} - \Delta U_{\text{m}} &= (1.0 \times 10^5 \text{ Pa}) \times (100 \text{ g mol}^{-1}) \times \left( \frac{1}{2.93 \text{ g cm}^{-3}} - \frac{1}{2.71 \text{ g cm}^{-3}} \right) \\ &= -2.8 \times 10^5 \text{ Pa cm}^3 \text{ mol}^{-1} = -0.28 \text{ Pa m}^3 \text{ mol}^{-1}\end{aligned}$$

Hence (because  $1 \text{ Pa m}^3 = 1 \text{ J}$ ),  $\Delta H_{\text{m}} - \Delta U_{\text{m}} = -0.28 \text{ J mol}^{-1}$ , which is only 0.1 per cent of the value of  $\Delta U_{\text{m}}$ . We see that it is usually justifiable to ignore the difference between the molar enthalpy and internal energy of condensed phases, except at very high pressures, when  $p\Delta V_{\text{m}}$  is no longer negligible.

**Self-test 2.2** Calculate the difference between  $\Delta H$  and  $\Delta U$  when 1.0 mol  $\text{Sn}(\text{s}, \text{grey})$  of density  $5.75 \text{ g cm}^{-3}$  changes to  $\text{Sn}(\text{s}, \text{white})$  of density  $7.31 \text{ g cm}^{-3}$  at 10.0 bar. At 298 K,  $\Delta H = +2.1 \text{ kJ}$ .  $[\Delta H - \Delta U = -4.4 \text{ J}]$

The enthalpy of a perfect gas is related to its internal energy by using  $pV = nRT$  in the definition of  $H$ :

$$H = U + pV = U + nRT \quad (2.20)^{\circ}$$

This relation implies that the change of enthalpy in a reaction that produces or consumes gas is

$$\Delta H = \Delta U + \Delta n_{\text{g}} RT \quad (2.21)^{\circ}$$

where  $\Delta n_{\text{g}}$  is the change in the amount of gas molecules in the reaction.

• **A brief illustration**

In the reaction  $2\text{H}_2(\text{g}) + \text{O}_2(\text{g}) \rightarrow 2\text{H}_2\text{O}(\text{l})$ , 3 mol of gas-phase molecules is replaced by 2 mol of liquid-phase molecules, so  $\Delta n_{\text{g}} = -3$  mol. Therefore, at 298 K, when  $RT = 2.48 \text{ kJ mol}^{-1}$ , the enthalpy and internal energy changes taking place in the system are related by

$$\Delta H_{\text{m}} - \Delta U_{\text{m}} = (-3 \text{ mol}) \times RT \approx -7.4 \text{ kJ mol}^{-1}$$

Note that the difference is expressed in kilojoules, not joules as in Example 2.2. The enthalpy change is smaller (in this case, less negative) than the change in internal energy because, although heat escapes from the system when the reaction occurs, the system contracts when the liquid is formed, so energy is restored to it from the surroundings. •

**Example 2.3** *Calculating a change in enthalpy*

Water is heated to boiling under a pressure of 1.0 atm. When an electric current of 0.50 A from a 12 V supply is passed for 300 s through a resistance in thermal contact with it, it is found that 0.798 g of water is vaporized. Calculate the molar internal energy and enthalpy changes at the boiling point (373.15 K).

**Method** Because the vaporization occurs at constant pressure, the enthalpy change is equal to the heat supplied by the heater. Therefore, the strategy is to calculate the energy supplied as heat (from  $q = It\Delta\phi$ ), express that as an enthalpy change, and then convert the result to a molar enthalpy change by division by the amount of  $\text{H}_2\text{O}$  molecules vaporized. To convert from enthalpy change to internal energy change, we assume that the vapour is a perfect gas and use eqn 2.21.

**Answer** The enthalpy change is

$$\Delta H = q_p = (0.50 \text{ A}) \times (12 \text{ V}) \times (300 \text{ s}) = 0.50 \times 12 \times 300 \text{ J}$$

Here we have used  $1 \text{ A V s} = 1 \text{ J}$ . Because 0.798 g of water is  $(0.798 \text{ g})/(18.02 \text{ g mol}^{-1}) = (0.798/18.02) \text{ mol H}_2\text{O}$ , the enthalpy of vaporization per mole of  $\text{H}_2\text{O}$  is

$$\Delta H_{\text{m}} = + \frac{0.50 \times 12 \times 300 \text{ J}}{(0.798/18.02) \text{ mol}} = +41 \text{ kJ mol}^{-1}$$

In the process  $\text{H}_2\text{O}(\text{l}) \rightarrow \text{H}_2\text{O}(\text{g})$  the change in the amount of gas molecules is  $\Delta n_{\text{g}} = +1 \text{ mol}$ , so

$$\Delta U_{\text{m}} = \Delta H_{\text{m}} - RT = +38 \text{ kJ mol}^{-1}$$

Notice that the internal energy change is smaller than the enthalpy change because energy has been used to drive back the surrounding atmosphere to make room for the vapour.

**Self-test 2.3** The molar enthalpy of vaporization of benzene at its boiling point (353.25 K) is  $30.8 \text{ kJ mol}^{-1}$ . What is the molar internal energy change? For how long would the same 12 V source need to supply a 0.50 A current in order to vaporize a 10 g sample?  
[+27.9 kJ mol<sup>-1</sup>,  $6.6 \times 10^2 \text{ s}$ ]

**(c) The variation of enthalpy with temperature**

The enthalpy of a substance increases as its temperature is raised. The relation between the increase in enthalpy and the increase in temperature depends on the conditions (for example, constant pressure or constant volume). The most important

**Fig. 2.14** The constant-pressure heat capacity at a particular temperature is the slope of the tangent to a curve of the enthalpy of a system plotted against temperature (at constant pressure). For gases, at a given temperature the slope of enthalpy versus temperature is steeper than that of internal energy versus temperature, and  $C_{p,m}$  is larger than  $C_{V,m}$ .

condition is constant pressure, and the slope of the tangent to a plot of enthalpy against temperature at constant pressure is called the **heat capacity at constant pressure**,  $C_p$ , at a given temperature (Fig. 2.14). More formally:

$$C_p = \left( \frac{\partial H}{\partial T} \right)_p \quad \text{Definition of heat capacity at constant pressure} \quad [2.22]$$

The heat capacity at constant pressure is the analogue of the heat capacity at constant volume and is an extensive property. The **molar heat capacity at constant pressure**,  $C_{p,m}$ , is the heat capacity per mole of material; it is an intensive property.

The heat capacity at constant pressure is used to relate the change in enthalpy to a change in temperature. For infinitesimal changes of temperature

$$dH = C_p dT \quad (\text{at constant pressure}) \quad (2.23a)$$

If the heat capacity is constant over the range of temperatures of interest, then for a measurable increase in temperature

$$\Delta H = C_p \Delta T \quad (\text{at constant pressure}) \quad (2.23b)$$

Because an increase in enthalpy can be equated with the energy supplied as heat at constant pressure, the practical form of the latter equation is

$$q_p = C_p \Delta T \quad (2.24)$$

This expression shows us how to measure the heat capacity of a sample: a measured quantity of energy is supplied as heat under conditions of constant pressure (as in a sample exposed to the atmosphere and free to expand) and the temperature rise is monitored.

The variation of heat capacity with temperature can sometimes be ignored if the temperature range is small; this approximation is highly accurate for a monatomic perfect gas (for instance, one of the noble gases at low pressure). However, when it is necessary to take the variation into account, a convenient approximate empirical expression is

$$C_{p,m} = a + bT + \frac{c}{T^2} \quad (2.25)$$

The empirical parameters  $a$ ,  $b$ , and  $c$  are independent of temperature (Table 2.2) and are found by fitting this expression to experimental data.

**Table 2.2\*** Temperature variation of molar heat capacities,  $C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1}) = a + bT + c/T^2$

|                     | $a$   | $b/(10^{-3} \text{ K})$ | $c/(10^5 \text{ K}^2)$ |
|---------------------|-------|-------------------------|------------------------|
| C(s, graphite)      | 16.86 | 4.77                    | −8.54                  |

| H <sub>2</sub> O(l) | 75.29 | 0                       | 0                      |
| N <sub>2</sub> (g)  | 28.58 | 3.77                    | −0.50                  |

\* More values are given in the *Data section*.

**Example 2.4** Evaluating an increase in enthalpy with temperature

What is the change in molar enthalpy of  $\text{N}_2$  when it is heated from  $25^\circ\text{C}$  to  $100^\circ\text{C}$ ? Use the heat capacity information in Table 2.2.

**Method** The heat capacity of  $\text{N}_2$  changes with temperature, so we cannot use eqn 2.23b (which assumes that the heat capacity of the substance is constant). Therefore, we must use eqn 2.23a, substitute eqn 2.25 for the temperature dependence of the heat capacity, and integrate the resulting expression from  $25^\circ\text{C}$  to  $100^\circ\text{C}$ .

**Answer** For convenience, we denote the two temperatures  $T_1$  (298 K) and  $T_2$  (373 K). The relation we require is

$$\int_{H(T_1)}^{H(T_2)} dH = \int_{T_1}^{T_2} \left( a + bT + \frac{c}{T^2} \right) dT$$

and the relevant integrals are

$$\int dx = x + \text{constant} \quad \int x dx = \frac{1}{2}x^2 + \text{constant} \quad \int \frac{dx}{x^2} = -\frac{1}{x} + \text{constant}$$

It follows that

$$H(T_2) - H(T_1) = a(T_2 - T_1) + \frac{1}{2}b(T_2^2 - T_1^2) - c\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

Substitution of the numerical data results in

$$H(373 \text{ K}) = H(298 \text{ K}) + 2.20 \text{ kJ mol}^{-1}$$

If we had assumed a constant heat capacity of  $29.14 \text{ J K}^{-1} \text{ mol}^{-1}$  (the value given by eqn 2.25 at  $25^\circ\text{C}$ ), we would have found that the two enthalpies differed by  $2.19 \text{ kJ mol}^{-1}$ .

**Self-test 2.4** At very low temperatures the heat capacity of a solid is proportional to  $T^3$ , and we can write  $C_p = aT^3$ . What is the change in enthalpy of such a substance when it is heated from 0 to a temperature  $T$  (with  $T$  close to 0)?  $[\Delta H = \frac{1}{4}aT^4]$

Most systems expand when heated at constant pressure. Such systems do work on the surroundings and therefore some of the energy supplied to them as heat escapes back to the surroundings. As a result, the temperature of the system rises less than when the heating occurs at constant volume. A smaller increase in temperature implies a larger heat capacity, so we conclude that in most cases the heat capacity at constant pressure of a system is larger than its heat capacity at constant volume. We show later (Section 2.11) that there is a simple relation between the two heat capacities of a perfect gas:

$$C_p - C_v = nR$$

Relation between heat capacities of a perfect gas

(2.26)<sup>o</sup>

It follows that the molar heat capacity of a perfect gas is about  $8 \text{ J K}^{-1} \text{ mol}^{-1}$  larger at constant pressure than at constant volume. Because the heat capacity at constant volume of a monatomic gas is about  $12 \text{ J K}^{-1} \text{ mol}^{-1}$ , the difference is highly significant and must be taken into account.

**Fig. 2.15** A differential scanning calorimeter. The sample and a reference material are heated in separate but identical metal heat sinks. The output is the difference in power needed to maintain the heat sinks at equal temperatures as the temperature rises.

**Fig. 2.16** A thermogram for the protein ubiquitin at pH = 2.45. The protein retains its native structure up to about 45°C and then undergoes an endothermic conformational change. (Adapted from B. Chowdhry and S. LeHarne, *J. Chem. Educ.* 74, 236 (1997).)

## IMPACT ON BIOCHEMISTRY AND MATERIALS SCIENCE

### 12.1 Differential scanning calorimetry

A *differential scanning calorimeter* (DSC) measures the energy transferred as heat to or from a sample at constant pressure during a physical or chemical change. The term ‘differential’ refers to the fact that the behaviour of the sample is compared to that of a reference material that does not undergo a physical or chemical change during the analysis. The term ‘scanning’ refers to the fact that the temperatures of the sample and reference material are increased, or scanned, during the analysis.

A DSC consists of two small compartments that are heated electrically at a constant rate. The temperature,  $T$ , at time  $t$  during a linear scan is  $T = T_0 + \alpha t$ , where  $T_0$  is the initial temperature and  $\alpha$  is the temperature scan rate. A computer controls the electrical power supply that maintains the same temperature in the sample and reference compartments throughout the analysis (Fig. 2.15).

If no physical or chemical change occurs in the sample at temperature  $T$ , we write the heat transferred to the sample as  $q_p = C_p \Delta T$ , where  $\Delta T = T - T_0$  and we have assumed that  $C_p$  is independent of temperature. Because  $T = T_0 + \alpha t$ ,  $\Delta T = \alpha t$ . The chemical or physical process requires the transfer of  $q_p + q_{p,\text{ex}}$  where  $q_{p,\text{ex}}$  is the excess energy transferred as heat needed to attain the same change in temperature of the sample as the control. The quantity  $q_{p,\text{ex}}$  is interpreted in terms of an apparent change in the heat capacity at constant pressure of the sample,  $C_{p,\text{ex}}$ , during the temperature scan:

$$C_{p,\text{ex}} = \frac{q_{p,\text{ex}}}{\Delta T} = \frac{q_{p,\text{ex}}}{\alpha t} = \frac{P_{\text{ex}}}{\alpha}$$

where  $P_{\text{ex}} = q_{p,\text{ex}}/t$  is the excess electrical power necessary to equalize the temperature of the sample and reference compartments. A DSC trace, also called a *thermogram*, consists of a plot of  $C_{p,\text{ex}}$  against  $T$  (Fig. 2.16). From eqn 2.23a, the enthalpy change associated with the process is

$$\Delta H = \int_{T_1}^{T_2} C_{p,\text{ex}} dT$$

where  $T_1$  and  $T_2$  are, respectively, the temperatures at which the process begins and ends. This relation shows that the enthalpy change is equal to the area under the plot of  $C_{p,\text{ex}}$  against  $T$ .

With a DSC, enthalpy changes may be determined in samples of masses as low as 0.5 mg, which is a significant advantage over conventional calorimeters, which require several grams of material. The technique is used in the chemical industry to characterize polymers in terms of their structural integrity, stability, and nanoscale organization. For example, it is possible to detect the ability of certain polymers such as ethylene oxide (EO) and propylene oxide (PO) to self-aggregate as their temperature is raised. These copolymers are widely used as surfactants and detergents with the amphiphilic (both water- and hydrocarbon-attracting) character provided by the hydrophobic central PO block and the more hydrophilic EO blocks attached on either side. They aggregate to form micelles (clusters) as the temperature is raised because the more hydrophobic central PO block becomes less soluble at higher temperature but the terminal EO blocks retain their strong interaction with water. This enhanced amphiphilic character of the molecules at higher temperature drives the copolymers to form micelles that are spherical in shape. The micellization process is strongly endothermic, reflecting the initial destruction of the hydrogen bonds of the PO block with water, and is readily detected by DSC. Further increases in temperature affect the shape of the micelle, changing from spherical to rod-like. A new but weaker DSC

signal at higher temperature reflects a small change in enthalpy as micelles aggregate to form the rod-like structure. The marked decrease in the heat capacity accompanying the sphere-to-rod transition presumably reflects an extensive decrease in the degree of hydration of the polymer.

The technique is also used to assess the stability of proteins, nucleic acids, and membranes. For example, the thermogram shown in Fig. 2.16 indicates that the protein ubiquitin undergoes an endothermic conformational change in which a large number of non-covalent interactions (such as hydrogen bonds) are broken simultaneously and result in denaturation, the loss of the protein's three-dimensional structure. The area under the curve represents the heat absorbed in this process and can be identified with the enthalpy change. The thermogram also reveals the formation of new intermolecular interactions in the denatured form. The increase in heat capacity accompanying the native  $\rightarrow$  denatured transition reflects the change from a more compact native conformation to one in which the more exposed amino acid side chains in the denatured form have more extensive interactions with the surrounding water molecules.

## 2.6 Adiabatic changes

**Key point** For the reversible adiabatic expansion of a perfect gas, pressure and volume are related by an expression that depends on the ratio of heat capacities.

We are now equipped to deal with the changes that occur when a perfect gas expands adiabatically. A decrease in temperature should be expected: because work is done but no heat enters the system, the internal energy falls, and therefore the temperature of the working gas also falls. In molecular terms, the kinetic energy of the molecules falls as work is done, so their average speed decreases, and hence the temperature falls.

The change in internal energy of a perfect gas when the temperature is changed from  $T_i$  to  $T_f$  and the volume is changed from  $V_i$  to  $V_f$  can be expressed as the sum of two steps (Fig. 2.17). In the first step, only the volume changes and the temperature is held constant at its initial value. However, because the internal energy of a perfect gas is independent of the volume the molecules occupy, the overall change in internal energy arises solely from the second step, the change in temperature at constant volume. Provided the heat capacity is independent of temperature, this change is

$$\Delta U = C_V(T_f - T_i) = C_V\Delta T$$

Because the expansion is adiabatic, we know that  $q = 0$ ; because  $\Delta U = q + w$ , it then follows that  $\Delta U = w_{\text{ad}}$ . The subscript 'ad' denotes an adiabatic process. Therefore, by equating the two expressions we have obtained for  $\Delta U$ , we obtain

$$w_{\text{ad}} = C_V\Delta T \quad (2.27)$$

That is, the work done during an adiabatic expansion of a perfect gas is proportional to the temperature difference between the initial and final states. That is exactly what we expect on molecular grounds, because the mean kinetic energy is proportional to  $T$ , so a change in internal energy arising from temperature alone is also expected to be proportional to  $\Delta T$ . In *Further information 2.1* we show that the initial and final temperatures of a perfect gas that undergoes reversible adiabatic expansion (reversible expansion in a thermally insulated container) can be calculated from

$$T_f = T_i \left( \frac{V_i}{V_f} \right)^{1/c} \quad (2.28a)_{\text{rev}}^{\circ}$$

**Fig. 2.17** To achieve a change of state from one temperature and volume to another temperature and volume, we may consider the overall change as composed of two steps. In the first step, the system expands at constant temperature; there is no change in internal energy if the system consists of a perfect gas. In the second step, the temperature of the system is reduced at constant volume. The overall change in internal energy is the sum of the changes for the two steps.

where  $c = C_{V,m}/R$ . By raising each side of this expression to the power  $c$ , an equivalent expression is

$$V_i T_i^c = V_f T_f^c \quad (2.28b)_{\text{rev}}^{\circ}$$

This result is often summarized in the form  $VT^c = \text{constant}$ .

### • A brief illustration

Consider the adiabatic, reversible expansion of 0.020 mol Ar, initially at 25°C, from 0.50 dm<sup>3</sup> to 1.00 dm<sup>3</sup>. The molar heat capacity of argon at constant volume is 12.48 J K<sup>-1</sup> mol<sup>-1</sup>, so  $c = 1.501$ . Therefore, from eqn 2.28a,

$$T_f = (298 \text{ K}) \times \left( \frac{0.50 \text{ dm}^3}{1.00 \text{ dm}^3} \right)^{1/1.501} = 188 \text{ K}$$

It follows that  $\Delta T = -110 \text{ K}$  and, therefore, from eqn 2.27, that

$$w = \{(0.020 \text{ mol}) \times (12.48 \text{ J K}^{-1} \text{ mol}^{-1})\} \times (-110 \text{ K}) = -27 \text{ J}$$

Note that temperature change is independent of the amount of gas but the work is not. •

**Self-test 2.5** Calculate the final temperature, the work done, and the change of internal energy when ammonia is used in a reversible adiabatic expansion from 0.50 dm<sup>3</sup> to 2.00 dm<sup>3</sup>, the other initial conditions being the same.

[195 K, -56 J, -56 J]

**Fig. 2.18** An adiabat depicts the variation of pressure with volume when a gas expands adiabatically. Note that the pressure declines more steeply for an adiabat than it does for an isotherm because the temperature decreases in the former.

**interActivity** Explore how the parameter  $\gamma$  affects the dependence of the pressure on the volume. Does the pressure–volume dependence become stronger or weaker with increasing volume?

We also show in *Further information 2.1* that the pressure of a perfect gas that undergoes reversible adiabatic expansion from a volume  $V_i$  to a volume  $V_f$  is related to its initial pressure by

$$p_f V_f^\gamma = p_i V_i^\gamma \quad \text{Reversible adiabatic expansion of a perfect gas} \quad (2.29)_{\text{rev}}^{\circ}$$

where  $\gamma = C_{p,m}/C_{V,m}$ . This result is commonly summarized in the form  $pV^\gamma = \text{constant}$ . For a monatomic perfect gas (Section 2.2a), and from eqn 2.26  $C_{p,m} = \frac{5}{2}R$ , so  $\gamma = \frac{5}{3}$ . For a gas of nonlinear polyatomic molecules (which can rotate as well as translate),  $C_{V,m} = 3R$ , so  $\gamma = \frac{4}{3}$ . The curves of pressure versus volume for adiabatic change are known as **adiabats**, and one for a reversible path is illustrated in Fig. 2.18. Because  $\gamma > 1$ , an adiabat falls more steeply ( $p \propto 1/V^\gamma$ ) than the corresponding isotherm ( $p \propto 1/V$ ). The physical reason for the difference is that, in an isothermal expansion, energy flows into the system as heat and maintains the temperature; as a result, the pressure does not fall as much as in an adiabatic expansion.

### • A brief illustration

When a sample of argon (for which  $\gamma = \frac{5}{3}$ ) at 100 kPa expands reversibly and adiabatically to twice its initial volume the final pressure will be

$$p_f = \left( \frac{V_i}{V_f} \right)^\gamma p_i = \left( \frac{1}{2} \right)^{5/3} \times (100 \text{ kPa}) = 31.5 \text{ kPa}$$

For an isothermal doubling of volume, the final pressure would be 50 kPa. •

## Thermochemistry

The study of the energy transferred as heat during the course of chemical reactions is called **thermochemistry**. Thermochemistry is a branch of thermodynamics because a reaction vessel and its contents form a system, and chemical reactions result in the exchange of energy between the system and the surroundings. Thus we can use calorimetry to measure the energy supplied or discarded as heat by a reaction, and can identify  $q$  with a change in internal energy if the reaction occurs at constant volume or with a change in enthalpy if the reaction occurs at constant pressure. Conversely, if we know  $\Delta U$  or  $\Delta H$  for a reaction, we can predict the heat the reaction can produce.

We have already remarked that a process that releases energy as heat into the surroundings is classified as exothermic and one that absorbs energy as heat from the surroundings is classified as endothermic. Because the release of heat signifies a decrease in the enthalpy of a system, we can now see that an exothermic process is one for which  $\Delta H < 0$ . Conversely, because the absorption of heat results in an increase in enthalpy, an endothermic process has  $\Delta H > 0$ :

exothermic process:  $\Delta H < 0$       endothermic process:  $\Delta H > 0$

### 2.7 Standard enthalpy changes

**Key points** (a) The standard enthalpy of transition is equal to the energy transferred as heat at constant pressure in the transition. (b) A thermochemical equation is a chemical equation and its associated change in enthalpy. (c) Hess's law states that the standard enthalpy of an overall reaction is the sum of the standard enthalpies of the individual reactions into which a reaction may be divided.

Changes in enthalpy are normally reported for processes taking place under a set of standard conditions. In most of our discussions we shall consider the **standard enthalpy change**,  $\Delta H^\circ$ , the change in enthalpy for a process in which the initial and final substances are in their standard states:

The **standard state** of a substance at a specified temperature is its pure form at 1 bar.

Specification of standard state

For example, the standard state of liquid ethanol at 298 K is pure liquid ethanol at 298 K and 1 bar; the standard state of solid iron at 500 K is pure iron at 500 K and 1 bar. The standard enthalpy change for a reaction or a physical process is the difference between the products in their standard states and the reactants in their standard states, all at the same specified temperature.

As an example of a standard enthalpy change, the *standard enthalpy of vaporization*,  $\Delta_{\text{vap}}H^\circ$ , is the enthalpy change per mole when a pure liquid at 1 bar vaporizes to a gas at 1 bar, as in

As implied by the examples, standard enthalpies may be reported for any temperature. However, the conventional temperature for reporting thermodynamic data is 298.15 K (corresponding to 25.00°C). Unless otherwise mentioned, all thermodynamic data in this text will refer to this conventional temperature.

#### (a) Enthalpies of physical change

The standard enthalpy change that accompanies a change of physical state is called the **standard enthalpy of transition** and is denoted  $\Delta_{\text{trs}}H^\circ$  (Table 2.3). The **standard**

#### A brief comment

The definition of standard state is more sophisticated for a real gas (*Further information 3.2*) and for solutions (Sections 5.10 and 5.11).

#### A note on good practice

The attachment of the name of the transition to the symbol  $\Delta$ , as in  $\Delta_{\text{vap}}H$ , is the modern convention. However, the older convention,  $\Delta H_{\text{vap}}$ , is still widely used. The new convention is more logical because the subscript identifies the type of change, not the physical observable related to the change.

**Table 2.3\*** Standard enthalpies of fusion and vaporization at the transition temperature,  $\Delta_{\text{trs}}H^\ominus/(\text{kJ mol}^{-1})$ 

|                               | $T_f/\text{K}$ | Fusion | $T_b/\text{K}$ | Vaporization             |
|-------------------------------|----------------|--------|----------------|--------------------------|

| Combustion    | Compound(s, l, g) + O <sub>2</sub> (g) $\rightarrow$ CO <sub>2</sub> (g), H <sub>2</sub> O(l, g) | $\Delta_cH$            |
| Formation     | Elements $\rightarrow$ compound                                                                  | $\Delta_fH$            |
| Activation    | Reactants $\rightarrow$ activated complex                                                        | $\Delta^\ddagger H$    |

\* IUPAC recommendations. In common usage, the transition subscript is often attached to  $\Delta H$ , as in  $\Delta H_{\text{trs}}$ .

**enthalpy of vaporization**,  $\Delta_{\text{vap}}H^\ominus$ , is one example. Another is the **standard enthalpy of fusion**,  $\Delta_{\text{fus}}H^\ominus$ , the standard enthalpy change accompanying the conversion of a solid to a liquid, as in

As in this case, it is sometimes convenient to know the standard enthalpy change at the transition temperature as well as at the conventional temperature of 298 K. The different types of enthalpies encountered in thermochemistry are summarized in Table 2.4. We shall meet them again in various locations throughout the text.

Because enthalpy is a state function, a change in enthalpy is independent of the path between the two states. This feature is of great importance in thermochemistry, for it implies that the same value of  $\Delta H^\ominus$  will be obtained however the change is brought about between the same initial and final states. For example, we can picture the conversion of a solid to a vapour either as occurring by sublimation (the direct conversion from solid to vapour)

or as occurring in two steps, first fusion (melting) and then vaporization of the resulting liquid:

Because the overall result of the indirect path is the same as that of the direct path, the overall enthalpy change is the same in each case (1), and we can conclude that (for processes occurring at the same temperature)

$$\Delta_{\text{sub}} H^\circ = \Delta_{\text{fus}} H^\circ + \Delta_{\text{vap}} H^\circ \quad (2.30)$$

An immediate conclusion is that, because all enthalpies of fusion are positive, the enthalpy of sublimation of a substance is greater than its enthalpy of vaporization (at a given temperature).

Another consequence of  $H$  being a state function is that the standard enthalpy changes of a forward process and its reverse differ in sign (2):

$$\Delta H^\circ(\text{A} \rightarrow \text{B}) = -\Delta H^\circ(\text{B} \rightarrow \text{A}) \quad (2.31)$$

For instance, because the enthalpy of vaporization of water is  $+44 \text{ kJ mol}^{-1}$  at 298 K, its enthalpy of condensation at that temperature is  $-44 \text{ kJ mol}^{-1}$ .

The vaporization of a solid often involves a large increase in energy, especially when the solid is ionic and the strong Coulombic interaction of the ions must be overcome in a process such as

The **lattice enthalpy**,  $\Delta H_L$ , is the change in standard molar enthalpy for this process. The lattice enthalpy is equal to the lattice internal energy at  $T=0$ ; at normal temperatures they differ by only a few kilojoules per mole, and the difference is normally neglected.

Experimental values of the lattice enthalpy are obtained by using a **Born–Haber cycle**, a closed path of transformations starting and ending at the same point, one step of which is the formation of the solid compound from a gas of widely separated ions.

### • A brief illustration

A typical Born–Haber cycle, for potassium chloride, is shown in Fig. 2.19. It consists of the following steps (for convenience, starting at the elements):

|                                                        | $\Delta H^\circ/(\text{kJ mol}^{-1})$ |                                                                               |
|--------------------------------------------------------|---------------------------------------|-------------------------------------------------------------------------------|
| 1. Sublimation of K(s)                                 | +89                                   | [dissociation enthalpy of K(s)]                                               |
| 2. Dissociation of $\frac{1}{2} \text{Cl}_2(\text{g})$ | +122                                  | $[\frac{1}{2} \times \text{dissociation enthalpy of } \text{Cl}_2(\text{g})]$ |
| 3. Ionization of K(g)                                  | +418                                  | [ionization enthalpy of K(g)]                                                 |
| 4. Electron attachment to Cl(g)                        | −349                                  | [electron gain enthalpy of Cl(g)]                                             |
| 5. Formation of solid from gas                         | $-\Delta H_L/(\text{kJ mol}^{-1})$    |                                                                               |
| 6. Decomposition of compound                           | +437                                  | [negative of enthalpy of formation of KCl(s)]                                 |

Because the sum of these enthalpy changes is equal to zero, we can infer from

$$89 + 122 + 418 - 349 - \Delta H_L/(\text{kJ mol}^{-1}) + 437 = 0$$

that  $\Delta H_L = +717 \text{ kJ mol}^{-1}$ . •

Some lattice enthalpies obtained in the same way as in the *brief illustration* are listed in Table 2.5. They are large when the ions are highly charged and small, for then they are close together and attract each other strongly. We examine the quantitative relation between lattice enthalpy and structure in Section 19.6.

**Fig. 2.19** The Born–Haber cycle for KCl at 298 K. Enthalpies changes are in kilojoules per mole.

**Table 2.5\*** Lattice enthalpies at 298 K

|      | $\Delta H_L/(\text{kJ mol}^{-1})$ |
|------|-----------------------------------|
| NaF  | 787                               |
| NaBr | 751                               |
| MgO  | 3850                              |
| MgS  | 3406                              |

\* More values are given in the *Data section*.**(b) Enthalpies of chemical change**

Now we consider enthalpy changes that accompany chemical reactions. There are two ways of reporting the change in enthalpy that accompanies a chemical reaction. One is to write the **thermochemical equation**, a combination of a chemical equation and the corresponding change in standard enthalpy:

$\Delta H^\circ$  is the change in enthalpy when reactants in their standard states change to products in their standard states:

Pure, separate reactants in their standard states

→ pure, separate products in their standard states

Except in the case of ionic reactions in solution, the enthalpy changes accompanying mixing and separation are insignificant in comparison with the contribution from the reaction itself. For the combustion of methane, the standard value refers to the reaction in which 1 mol  $\text{CH}_4$  in the form of pure methane gas at 1 bar reacts completely with 2 mol  $\text{O}_2$  in the form of pure oxygen gas at 1 bar to produce 1 mol  $\text{CO}_2$  as pure carbon dioxide gas at 1 bar and 2 mol  $\text{H}_2\text{O}$  as pure liquid water at 1 bar; the numerical value is for the reaction at 298.15 K.

Alternatively, we write the chemical equation and then report the **standard reaction enthalpy**,  $\Delta_r H^\circ$  (or ‘standard enthalpy of reaction’). Thus, for the combustion of methane, we write

For a reaction of the form  $2 \text{A} + \text{B} \rightarrow 3 \text{C} + \text{D}$  the standard reaction enthalpy would be

$$\Delta_r H^\circ = \{3H_m^\circ(\text{C}) + H_m^\circ(\text{D})\} - \{2H_m^\circ(\text{A}) + H_m^\circ(\text{B})\}$$

where  $H_m^\circ(\text{J})$  is the standard molar enthalpy of species J at the temperature of interest. Note how the ‘per mole’ of  $\Delta_r H^\circ$  comes directly from the fact that molar enthalpies appear in this expression. We interpret the ‘per mole’ by noting the stoichiometric coefficients in the chemical equation. In this case ‘per mole’ in  $\Delta_r H^\circ$  means ‘per 2 mol A’, ‘per mole B’, ‘per 3 mol C’, or ‘per mol D’. In general,

$$\Delta_r H^\circ = \sum_{\text{Products}} \nu H_m^\circ - \sum_{\text{Reactants}} \nu H_m^\circ \quad \text{Definition of standard reaction enthalpy} \quad [2.32]$$

where in each case the molar enthalpies of the species are multiplied by their (dimensionless and positive) stoichiometric coefficients,  $\nu$ .

Some standard reaction enthalpies have special names and a particular significance. For instance, the **standard enthalpy of combustion**,  $\Delta_c H^\circ$ , is the standard reaction enthalpy for the complete oxidation of an organic compound to  $\text{CO}_2$  gas and liquid  $\text{H}_2\text{O}$  if the compound contains C, H, and O, and to  $\text{N}_2$  gas if N is also present. An example is the combustion of glucose:

The value quoted shows that 2808 kJ of heat is released when 1 mol  $\text{C}_6\text{H}_{12}\text{O}_6$  burns under standard conditions (at 298 K). More values are given in Table 2.6.

**(c) Hess’s law**

Standard enthalpies of individual reactions can be combined to obtain the enthalpy of another reaction. This application of the First Law is called **Hess’s law**:

**Table 2.6\*** Standard enthalpies of formation and combustion of organic compounds at 298 K

|                                                        | $\Delta_f H^\ominus / (\text{kJ mol}^{-1})$ | $\Delta_c H^\ominus / (\text{kJ mol}^{-1})$ |
|--------------------------------------------------------|---------------------------------------------|---------------------------------------------|
| Benzene, $\text{C}_6\text{H}_6(\text{l})$              | +49.0                                       | −3268                                       |
| Ethane, $\text{C}_2\text{H}_6(\text{g})$               | −84.7                                       | −1560                                       |
| Glucose, $\text{C}_6\text{H}_{12}\text{O}_6(\text{s})$ | −1274                                       | −2808                                       |
| Methane, $\text{CH}_4(\text{g})$                       | −74.8                                       | −890                                        |
| Methanol, $\text{CH}_3\text{OH}(\text{l})$             | −238.7                                      | −726                                        |

\* More values are given in the *Data section*.

The standard enthalpy of an overall reaction is the sum of the standard enthalpies of the individual reactions into which a reaction may be divided.

Hess's  
law

The individual steps need not be realizable in practice: they may be hypothetical reactions, the only requirement being that their chemical equations should balance. The thermodynamic basis of the law is the path-independence of the value of  $\Delta_r H^\ominus$  and the implication that we may take the specified reactants, pass through any (possibly hypothetical) set of reactions to the specified products, and overall obtain the same change of enthalpy. The importance of Hess's law is that information about a reaction of interest, which may be difficult to determine directly, can be assembled from information on other reactions.

### Example 2.5 Using Hess's law

The standard reaction enthalpy for the hydrogenation of propene

is  $-124 \text{ kJ mol}^{-1}$ . The standard reaction enthalpy for the combustion of propane

is  $-2220 \text{ kJ mol}^{-1}$ . Calculate the standard enthalpy of combustion of propene.

**Method** The skill to develop is the ability to assemble a given thermochemical equation from others. Add or subtract the reactions given, together with any others needed, so as to reproduce the reaction required. Then add or subtract the reaction enthalpies in the same way. Additional data are in Table 2.6.

**Answer** The combustion reaction we require is

This reaction can be recreated from the following sum:

|                                                                                                                                          | $\Delta_r H^\ominus / (\text{kJ mol}^{-1})$ |
|------------------------------------------------------------------------------------------------------------------------------------------|---------------------------------------------|
| $\text{C}_3\text{H}_6(\text{g}) + \text{H}_2(\text{g}) \rightarrow \text{C}_3\text{H}_8(\text{g})$                                       | −124                                        |
| $\text{C}_3\text{H}_8(\text{g}) + 5 \text{O}_2(\text{g}) \rightarrow 3 \text{CO}_2(\text{g}) + 4 \text{H}_2\text{O}(\text{l})$           | −2220                                       |
| $\text{H}_2\text{O}(\text{l}) \rightarrow \text{H}_2(\text{g}) + \frac{1}{2} \text{O}_2(\text{g})$                                       | +286                                        |
| $\text{C}_3\text{H}_6(\text{g}) + \frac{9}{2} \text{O}_2(\text{g}) \rightarrow 3 \text{CO}_2(\text{g}) + 3 \text{H}_2\text{O}(\text{l})$ | −2058                                       |

**IMPACT ON BIOLOGY****12.2 Food and energy reserves**

The thermochemical properties of fuels and foods are commonly discussed in terms of their *specific enthalpy*, the enthalpy of combustion per gram of material. Thus, if the standard enthalpy of combustion is  $\Delta_c H^\ominus$  and the molar mass of the compound is  $M$ , then the specific enthalpy is  $\Delta_c H^\ominus/M$ . Table 2.7 lists the specific enthalpies of several fuels.

A typical 18–20 year old man requires a daily input of about 12 MJ; a woman of the same age needs about 9 MJ. If the entire consumption were in the form of glucose (3; which has a specific enthalpy of 16 kJ g<sup>-1</sup>), that would require the consumption of 750 g of glucose for a man and 560 g for a woman. In fact, digestible carbohydrates have a slightly higher specific enthalpy (17 kJ g<sup>-1</sup>) than glucose itself, so a carbohydrate diet is slightly less daunting than a pure glucose diet, as well as being more appropriate in the form of fibre, the indigestible cellulose that helps move digestion products through the intestine.

**3** α-D-Glucose  
(α-D-Glucopyranose)

Fats are long-chain esters like tristearin (beef fat). The enthalpy of combustion of a fat at around 38 kJ g<sup>-1</sup> is much greater than that of carbohydrates and only slightly less than that of the hydrocarbon oils used as fuel (48 kJ g<sup>-1</sup>). Fats are commonly used as an energy store, to be used only when the more readily accessible carbohydrates have fallen into short supply. In Arctic species, the stored fat also acts as a layer of insulation; in desert species (such as the camel), the fat is also a source of water, one of its oxidation products.

Proteins are also used as a source of energy, but their components, the amino acids, are often too valuable to squander in this way, and are used to construct other proteins instead. When proteins are oxidized (to urea, CO(NH<sub>2</sub>)<sub>2</sub>), the equivalent enthalpy density is comparable to that of carbohydrates.

The heat released by the oxidation of foods needs to be discarded in order to maintain body temperature within its typical range of 35.6–37.8°C. A variety of mechanisms contribute to this aspect of homeostasis, the ability of an organism to counteract environmental changes with physiological responses. The general uniformity of temperature throughout the body is maintained largely by the flow of blood. When heat needs to be dissipated rapidly, warm blood is allowed to flow through the capillaries of the skin, so producing flushing. Radiation is one means of discarding heat; another is evaporation and the energy demands of the enthalpy of vaporization of water. Evaporation removes about 2.4 kJ per gram of water perspired. When vigorous exercise promotes sweating (through the influence of heat selectors on the hypothalamus), 1–2 dm<sup>3</sup> of perspired water can be produced per hour, corresponding to a heat loss of 2.4–5.0 MJ h<sup>-1</sup>.

## 2.8 Standard enthalpies of formation

**Key points** Standard enthalpies of formation are defined in terms of the reference states of elements. (a) The standard reaction enthalpy is expressed as the difference of the standard enthalpies of formation of products and reactants. (b) Computer modelling is used to estimate standard enthalpies of formation.

The **standard enthalpy of formation**,  $\Delta_f H^\circ$ , of a substance is the standard reaction enthalpy for the formation of the compound from its elements in their reference states:

The **reference state** of an element is its most stable state at the specified temperature and 1 bar.

Specification of reference state

For example, at 298 K the reference state of nitrogen is a gas of  $N_2$  molecules, that of mercury is liquid mercury, that of carbon is graphite, and that of tin is the white (metallic) form. There is one exception to this general prescription of reference states: the reference state of phosphorus is taken to be white phosphorus despite this allotrope not being the most stable form but simply the more reproducible form of the element. Standard enthalpies of formation are expressed as enthalpies per mole of molecules or (for ionic substances) formula units of the compound. The standard enthalpy of formation of liquid benzene at 298 K, for example, refers to the reaction

and is  $+49.0 \text{ kJ mol}^{-1}$ . The standard enthalpies of formation of elements in their reference states are zero at all temperatures because they are the enthalpies of such 'null' reactions as  $N_2(\text{g}) \rightarrow N_2(\text{g})$ . Some enthalpies of formation are listed in Tables 2.6 and 2.8.

The standard enthalpy of formation of ions in solution poses a special problem because it is impossible to prepare a solution of cations alone or of anions alone. This problem is solved by defining one ion, conventionally the hydrogen ion, to have zero standard enthalpy of formation at all temperatures:

$$\Delta_f H^\circ(\text{H}^+, \text{aq}) = 0$$

Convention for ions in solution

[2.33]

Thus, if the enthalpy of formation of  $\text{HBr}(\text{aq})$  is found to be  $-122 \text{ kJ mol}^{-1}$ , then the whole of that value is ascribed to the formation of  $\text{Br}^-(\text{aq})$ , and we write  $\Delta_f H^\circ(\text{Br}^-, \text{aq}) = -122 \text{ kJ mol}^{-1}$ . That value may then be combined with, for instance, the enthalpy formation of  $\text{AgBr}(\text{aq})$  to determine the value of  $\Delta_f H^\circ(\text{Ag}^+, \text{aq})$ , and so on. In essence, this definition adjusts the actual values of the enthalpies of formation of ions by a fixed amount, which is chosen so that the standard value for one of them,  $\text{H}^+(\text{aq})$ , has the value zero.

### (a) The reaction enthalpy in terms of enthalpies of formation

Conceptually, we can regard a reaction as proceeding by decomposing the reactants into their elements and then forming those elements into the products. The value of  $\Delta_r H^\circ$  for the overall reaction is the sum of these 'unforming' and forming enthalpies. Because 'unforming' is the reverse of forming, the enthalpy of an unforming step is the negative of the enthalpy of formation (4). Hence, in the enthalpies of formation of substances, we have enough information to calculate the enthalpy of any reaction by using

$$\Delta_r H^\circ = \sum_{\text{Products}} \nu \Delta_f H^\circ - \sum_{\text{Reactants}} \nu \Delta_f H^\circ$$

Procedure for calculating standard reaction enthalpy

(2.34a)

**Table 2.8\*** Standard enthalpies of formation of inorganic compounds at 298 K

\* More values are given in the Data section.

**A brief comment**

Stoichiometric numbers, which have a sign, are denoted  $\nu_j$  or  $\nu(J)$ . Stoichiometric coefficients, which are all positive, are denoted simply  $\nu$  (with no subscript).

where in each case the enthalpies of formation of the species that occur are multiplied by their stoichiometric coefficients. A more sophisticated way of expressing the same result is to introduce the **stoichiometric numbers**  $\nu_j$  (as distinct from the stoichiometric coefficients) which are positive for products and negative for reactants. Then we can write

$$\Delta_r H^\circ = \sum_j \nu_j \Delta_f H^\circ(J) \quad (2.34b)$$

• **A brief illustration**

According to eqn 2.34a, the standard enthalpy of the reaction  $2 \text{HN}_3(\text{l}) + 2 \text{NO}(\text{g}) \rightarrow \text{H}_2\text{O}_2(\text{l}) + 4 \text{N}_2(\text{g})$  is calculated as follows:

$$\begin{aligned} \Delta_r H^\circ &= \{\Delta_f H^\circ(\text{H}_2\text{O}_2, \text{l}) + 4\Delta_f H^\circ(\text{N}_2, \text{g})\} - \{2\Delta_f H^\circ(\text{HN}_3, \text{l}) + 2\Delta_f H^\circ(\text{NO}, \text{g})\} \\ &= \{-187.78 + 4(0)\} \text{ kJ mol}^{-1} - \{2(264.0) + 2(90.25)\} \text{ kJ mol}^{-1} \\ &= -896.3 \text{ kJ mol}^{-1} \end{aligned}$$

To use eqn 2.34b we identify  $\nu(\text{HN}_3) = -2$ ,  $\nu(\text{NO}) = -2$ ,  $\nu(\text{H}_2\text{O}_2) = +1$ , and  $\nu(\text{N}_2) = +4$ , and then write

$$\Delta_r H^\circ = -2\Delta_f H^\circ(\text{HN}_3, \text{l}) - 2\Delta_f H^\circ(\text{NO}, \text{g}) + \Delta_f H^\circ(\text{H}_2\text{O}_2, \text{l}) + 4\Delta_f H^\circ(\text{N}_2, \text{g})$$

which gives the same result. •

**(b) Enthalpies of formation and molecular modelling**

We have seen how to construct standard reaction enthalpies by combining standard enthalpies of formation. The question that now arises is whether we can construct standard enthalpies of formation from a knowledge of the chemical constitution of the species. The short answer is that there is no thermodynamically exact way of expressing enthalpies of formation in terms of contributions from individual atoms and bonds. In the past, approximate procedures based on **mean bond enthalpies**,  $\Delta H(\text{A-B})$ , the average enthalpy change associated with the breaking of a specific A-B bond,

have been used. However, this procedure is notoriously unreliable, in part because the  $\Delta H(\text{A-B})$  are average values for a series of related compounds. Nor does the approach distinguish between geometrical isomers, where the same atoms and bonds may be present but experimentally the enthalpies of formation might be significantly different.

Computer-aided molecular modelling has largely displaced this more primitive approach. Commercial software packages use the principles developed in Chapter 10 to calculate the standard enthalpy of formation of a molecule drawn on the computer screen. These techniques can be applied to different conformations of the same molecule. In the case of methylcyclohexane, for instance, the calculated conformational energy difference ranges from 5.9 to 7.9 kJ mol<sup>-1</sup>, with the equatorial conformer having the lower standard enthalpy of formation. These estimates compare favourably with the experimental value of 7.5 kJ mol<sup>-1</sup>. However, good agreement between calculated and experimental values is relatively rare. Computational methods almost always predict correctly which conformer is more stable but do not always predict the correct magnitude of the conformational energy difference. The most reliable technique for the determination of enthalpies of formation remains calorimetry, typically by using enthalpies of combustion.

## 2.9 The temperature dependence of reaction enthalpies

**Key point** The temperature dependence of a reaction enthalpy is expressed by Kirchhoff's law.

The standard enthalpies of many important reactions have been measured at different temperatures. However, in the absence of this information, standard reaction enthalpies at different temperatures may be calculated from heat capacities and the reaction enthalpy at some other temperature (Fig. 2.20). In many cases heat capacity data are more accurate than reaction enthalpies. Therefore, providing the information is available, the procedure we are about to describe is more accurate than the direct measurement of a reaction enthalpy at an elevated temperature.

It follows from eqn 2.23a that, when a substance is heated from  $T_1$  to  $T_2$ , its enthalpy changes from  $H(T_1)$  to

$$H(T_2) = H(T_1) + \int_{T_1}^{T_2} C_p dT \quad (2.35)$$

(We have assumed that no phase transition takes place in the temperature range of interest.) Because this equation applies to each substance in the reaction, the standard reaction enthalpy changes from  $\Delta_r H^\circ(T_1)$  to

$$\Delta_r H^\circ(T_2) = \Delta_r H^\circ(T_1) + \int_{T_1}^{T_2} \Delta_r C_p^\circ dT \quad \text{Kirchhoff's law} \quad (2.36a)$$

where  $\Delta_r C_p^\circ$  is the difference of the molar heat capacities of products and reactants under standard conditions weighted by the stoichiometric coefficients that appear in the chemical equation:

$$\Delta_r C_p^\circ = \sum_{\text{Products}} \nu C_{p,m}^\circ - \sum_{\text{Reactants}} \nu C_{p,m}^\circ \quad (2.36b)$$

Equation 2.36a is known as **Kirchhoff's law**. It is normally a good approximation to assume that  $\Delta_r C_p^\circ$  is independent of the temperature, at least over reasonably limited ranges. Although the individual heat capacities may vary, their difference varies less significantly. In some cases the temperature dependence of heat capacities is taken into account by using eqn 2.25.

**Fig. 2.20** An illustration of the content of Kirchhoff's law. When the temperature is increased, the enthalpy of the products and the reactants both increase, but may do so to different extents. In each case, the change in enthalpy depends on the heat capacities of the substances. The change in reaction enthalpy reflects the difference in the changes of the enthalpies.

### Example 2.6 Using Kirchhoff's law

The standard enthalpy of formation of  $\text{H}_2\text{O}(\text{g})$  at 298 K is  $-241.82 \text{ kJ mol}^{-1}$ . Estimate its value at  $100^\circ\text{C}$  given the following values of the molar heat capacities at constant pressure:  $\text{H}_2\text{O}(\text{g})$ :  $33.58 \text{ J K}^{-1} \text{ mol}^{-1}$ ;  $\text{H}_2(\text{g})$ :  $28.82 \text{ J K}^{-1} \text{ mol}^{-1}$ ;  $\text{O}_2(\text{g})$ :  $29.36 \text{ J K}^{-1} \text{ mol}^{-1}$ . Assume that the heat capacities are independent of temperature.

**Method** When  $\Delta_r C_p^\circ$  is independent of temperature in the range  $T_1$  to  $T_2$ , the integral in eqn 2.36a evaluates to  $(T_2 - T_1)\Delta_r C_p^\circ$ . Therefore,

$$\Delta_r H^\circ(T_2) = \Delta_r H^\circ(T_1) + (T_2 - T_1)\Delta_r C_p^\circ$$

To proceed, write the chemical equation, identify the stoichiometric coefficients, and calculate  $\Delta_r C_p^\circ$  from the data.

**Answer** The reaction is  $\text{H}_2(\text{g}) + \frac{1}{2} \text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{g})$ , so

$$\Delta_r C_p^\circ = C_{p,m}^\circ(\text{H}_2\text{O}, \text{g}) - \{C_{p,m}^\circ(\text{H}_2, \text{g}) + \frac{1}{2}C_{p,m}^\circ(\text{O}_2, \text{g})\} = -9.92 \text{ J K}^{-1} \text{ mol}^{-1}$$

It then follows that

$$\Delta_r H^\circ(373 \text{ K}) = -241.82 \text{ kJ mol}^{-1} + (75 \text{ K}) \times (-9.92 \text{ J K}^{-1} \text{ mol}^{-1}) = -242.6 \text{ kJ mol}^{-1}$$

**Self-test 2.7** Estimate the standard enthalpy of formation of cyclohexane,  $\text{C}_6\text{H}_{12}(\text{l})$ , at 400 K from the data in Table 2.6. [−163 kJ mol<sup>−1</sup>]

## State functions and exact differentials

We saw in Section 2.2 that a state function is a property that depends only on the current state of a system and is independent of its history. The internal energy and enthalpy are two examples of state functions. Physical quantities that do depend on the path between two states are called **path functions**. Examples of path functions are the work and the heating that are done when preparing a state. We do not speak of a system in a particular state as possessing work or heat. In each case, the energy transferred as work or heat relates to the path being taken between states, not the current state itself.

A part of the richness of thermodynamics is that it uses the mathematical properties of state functions to draw far-reaching conclusions about the relations between physical properties and thereby establish connections that may be completely unexpected. The practical importance of this ability is that we can combine measurements of different properties to obtain the value of a property we require.

### 2.10 Exact and inexact differentials

**Key points** The quantity  $dU$  is an exact differential;  $dw$  and  $dq$  are not.

**Fig. 2.21** As the volume and temperature of a system are changed, the internal energy changes. An adiabatic and a non-adiabatic path are shown as Path 1 and Path 2, respectively: they correspond to different values of  $q$  and  $w$  but to the same value of  $\Delta U$ .

Consider a system undergoing the changes depicted in Fig. 2.21. The initial state of the system is  $i$  and in this state the internal energy is  $U_i$ . Work is done by the system as it expands adiabatically to a state  $f$ . In this state the system has an internal energy  $U_f$  and the work done on the system as it changes along Path 1 from  $i$  to  $f$  is  $w$ . Notice our use of language:  $U$  is a property of the state;  $w$  is a property of the path. Now consider another process, Path 2, in which the initial and final states are the same as those in Path 1 but in which the expansion is not adiabatic. The internal energy of both the initial and the final states are the same as before (because  $U$  is a state function). However, in the second path an energy  $q'$  enters the system as heat and the work  $w'$  is not the same as  $w$ . The work and the heat are path functions.

If a system is taken along a path (for example, by heating it),  $U$  changes from  $U_i$  to  $U_f$ , and the overall change is the sum (integral) of all the infinitesimal changes along the path:

$$\Delta U = \int_i^f dU \quad (2.37)$$

The value of  $\Delta U$  depends on the initial and final states of the system but is independent of the path between them. This path independence of the integral is expressed by saying that  $dU$  is an 'exact differential'. In general, an **exact differential** is an infinitesimal quantity that, when integrated, gives a result that is independent of the path between the initial and final states.

When a system is heated, the total energy transferred as heat is the sum of all individual contributions at each point of the path:

$$q = \int_{i, \text{path}}^f dq \quad (2.38)$$

Notice the differences between this equation and eqn 2.37. First, we do not write  $\Delta q$ , because  $q$  is not a state function and the energy supplied as heat cannot be expressed as  $q_f - q_i$ . Secondly, we must specify the path of integration because  $q$  depends on the path selected (for example, an adiabatic path has  $q = 0$ , whereas a non-adiabatic path between the same two states would have  $q \neq 0$ ). This path-dependence is expressed by saying that  $dq$  is an ‘inexact differential’. In general, an **inexact differential** is an infinitesimal quantity that, when integrated, gives a result that depends on the path between the initial and final states. Often  $dq$  is written  $\bar{d}q$  to emphasize that it is inexact and requires the specification of a path.

The work done on a system to change it from one state to another depends on the path taken between the two specified states; for example, in general the work is different if the change takes place adiabatically and non-adiabatically. It follows that  $dw$  is an inexact differential. It is often written  $\bar{d}w$ .

### Example 2.7 Calculating work, heat, and change in internal energy

Consider a perfect gas inside a cylinder fitted with a piston. Let the initial state be  $T, V_i$  and the final state be  $T, V_f$ . The change of state can be brought about in many ways, of which the two simplest are the following: Path 1, in which there is free expansion against zero external pressure; Path 2, in which there is reversible, isothermal expansion. Calculate  $w$ ,  $q$ , and  $\Delta U$  for each process.

**Method** To find a starting point for a calculation in thermodynamics, it is often a good idea to go back to first principles and to look for a way of expressing the quantity we are asked to calculate in terms of other quantities that are easier to calculate. We saw in Section 2.2a that the internal energy of a perfect gas depends only on the temperature and is independent of the volume those molecules occupy, so for any isothermal change,  $\Delta U = 0$ . We also know that in general  $\Delta U = q + w$ . The question depends on being able to combine the two expressions. We have already derived a number of expressions for the work done in a variety of processes, and here we need to select the appropriate ones.

**Answer** Because  $\Delta U = 0$  for both paths and  $\Delta U = q + w$ , in each case  $q = -w$ . The work of free expansion is zero (Section 2.3b), so in Path 1,  $w = 0$  and therefore  $q = 0$  too. For Path 2, the work is given by eqn 2.10, so  $w = -nRT \ln(V_f/V_i)$  and consequently  $q = nRT \ln(V_f/V_i)$ .

**Self-test 2.8** Calculate the values of  $q$ ,  $w$ , and  $\Delta U$  for an irreversible isothermal expansion of a perfect gas against a constant non-zero external pressure.

$$[q = p_{\text{ex}} \Delta V, w = -p_{\text{ex}} \Delta V, \Delta U = 0]$$

## 2.11 Changes in internal energy

**Key points** (a) The change in internal energy may be expressed in terms of changes in temperature and volume. The internal pressure is the variation of internal energy with volume at constant temperature. (b) Joule’s experiment showed that the internal pressure of a perfect gas is zero. (c) The change in internal energy with volume and temperature is expressed in terms of the internal pressure and the heat capacity and leads to a general expression for the relation between heat capacities.

**Fig. 2.22** An overall change in  $U$ , which is denoted  $dU$ , arises when both  $V$  and  $T$  are allowed to change. If second-order infinitesimals are ignored, the overall change is the sum of changes for each variable separately.

**Fig. 2.23** The internal pressure,  $\pi_T$ , is the slope of  $U$  with respect to  $V$  with the temperature  $T$  held constant.

We begin to unfold the consequences of  $dU$  being an exact differential by exploring a closed system of constant composition (the only type of system considered in the rest of this chapter). The internal energy  $U$  can be regarded as a function of  $V$ ,  $T$ , and  $p$ , but, because there is an equation of state, stating the values of two of the variables fixes the value of the third. Therefore, it is possible to write  $U$  in terms of just two independent variables:  $V$  and  $T$ ,  $p$  and  $T$ , or  $p$  and  $V$ . Expressing  $U$  as a function of volume and temperature fits the purpose of our discussion.

### (a) General considerations

Because the internal energy is a function of the volume and the temperature, when these two quantities change, the internal energy changes by

$$dU = \left( \frac{\partial U}{\partial V} \right)_T dV + \left( \frac{\partial U}{\partial T} \right)_V dT \quad (2.39)$$

General expression  
for a change in  $U$   
with  $T$  and  $V$

The interpretation of this equation is that, in a closed system of constant composition, any infinitesimal change in the internal energy is proportional to the infinitesimal changes of volume and temperature, the coefficients of proportionality being the two partial derivatives (Fig. 2.22).

In many cases partial derivatives have a straightforward physical interpretation, and thermodynamics gets shapeless and difficult only when that interpretation is not kept in sight. In the present case, we have already met  $(\partial U/\partial T)_V$  in eqn 2.15, where we saw that it is the constant-volume heat capacity,  $C_V$ . The other coefficient,  $(\partial U/\partial V)_T$ , plays a major role in thermodynamics because it is a measure of the variation of the internal energy of a substance as its volume is changed at constant temperature (Fig. 2.23). We shall denote it  $\pi_T$  and, because it has the same dimensions as pressure but arises from the interactions between the molecules within the sample, call it the **internal pressure**:

$$\pi_T = \left( \frac{\partial U}{\partial V} \right)_T \quad (2.40)$$

Definition of  
internal pressure

In terms of the notation  $C_V$  and  $\pi_T$ , eqn 2.39 can now be written

$$dU = \pi_T dV + C_V dT \quad (2.41)$$

### (b) The Joule experiment

When there are no interactions between the molecules, the internal energy is independent of their separation and hence independent of the volume of the sample (Section 2.2a). Therefore, for a perfect gas we can write  $\pi_T = 0$ . The statement  $\pi_T = 0$  (that is, the internal energy is independent of the volume occupied by the sample) can be taken to be the definition of a perfect gas, for later we shall see that it implies the equation of state  $pV \propto T$ . If the attractive forces between the particles dominate the repulsive forces, then the internal energy increases ( $dU > 0$ ) as the volume of the sample increases ( $dV > 0$ ) and the molecules attract each other less strongly; in this case a plot of internal energy against volume slopes upwards and  $\pi_T > 0$  (Fig. 2.24).

James Joule thought that he could measure  $\pi_T$  by observing the change in temperature of a gas when it is allowed to expand into a vacuum. He used two metal vessels immersed in a water bath (Fig. 2.25). One was filled with air at about 22 atm and the

other was evacuated. He then tried to measure the change in temperature of the water of the bath when a stopcock was opened and the air expanded into a vacuum. He observed no change in temperature.

The thermodynamic implications of the experiment are as follows. No work was done in the expansion into a vacuum, so  $w = 0$ . No energy entered or left the system (the gas) as heat because the temperature of the bath did not change, so  $q = 0$ . Consequently, within the accuracy of the experiment,  $\Delta U = 0$ . Joule concluded that  $U$  does not change when a gas expands isothermally and therefore that  $\pi_T = 0$ . His experiment, however, was crude. In particular, the heat capacity of the apparatus was so large that the temperature change that gases do in fact cause was too small to measure. Nevertheless, from his experiment Joule had extracted an essential limiting property of a gas, a property of a perfect gas, without detecting the small deviations characteristic of real gases.

### (c) Changes in internal energy at constant pressure

Partial derivatives have many useful properties and some that we shall draw on frequently are reviewed in *Mathematical background 2*. Skilful use of them can often turn some unfamiliar quantity into a quantity that can be recognized, interpreted, or measured.

As an example, suppose we want to find out how the internal energy varies with temperature when the pressure rather than the volume of the system is kept constant. If we divide both sides of eqn 2.41 ( $dU = \pi_T dV + C_V dT$ ) by  $dT$  and impose the condition of constant pressure on the resulting differentials, so that  $dU/dT$  on the left becomes  $(\partial U/\partial T)_p$ , we obtain

$$\left(\frac{\partial U}{\partial T}\right)_p = \pi_T \left(\frac{\partial V}{\partial T}\right)_p + C_V$$

It is usually sensible in thermodynamics to inspect the output of a manipulation like this to see if it contains any recognizable physical quantity. The partial derivative on the right in this expression is the slope of the plot of volume against temperature (at constant pressure). This property is normally tabulated as the **expansion coefficient**,  $\alpha$ , of a substance, which is defined as

$$\alpha = \frac{1}{V} \left(\frac{\partial V}{\partial T}\right)_p \quad \text{Definition of the expansion coefficient} \quad [2.42]$$

and physically is the fractional change in volume that accompanies a rise in temperature. A large value of  $\alpha$  means that the volume of the sample responds strongly to changes in temperature. Table 2.9 lists some experimental values of  $\alpha$ . For future reference, it also lists the **isothermal compressibility**,  $\kappa_T$  (kappa), which is defined as

$$\kappa_T = -\frac{1}{V} \left(\frac{\partial V}{\partial p}\right)_T \quad \text{Definition of the isothermal compressibility} \quad [2.43]$$

The isothermal compressibility is a measure of the fractional change in volume when the pressure is increased by a small amount; the negative sign in the definition ensures that the compressibility is a positive quantity, because an increase of pressure, implying a positive  $dp$ , brings about a reduction of volume, a negative  $dV$ .

**Fig. 2.24** For a perfect gas, the internal energy is independent of the volume (at constant temperature). If attractions are dominant in a real gas, the internal energy increases with volume because the molecules become farther apart on average. If repulsions are dominant, the internal energy decreases as the gas expands.

**Fig. 2.25** A schematic diagram of the apparatus used by Joule in an attempt to measure the change in internal energy when a gas expands isothermally. The heat absorbed by the gas is proportional to the change in temperature of the bath.

**Table 2.9\*** Expansion coefficients ( $\alpha$ ) and isothermal compressibilities ( $\kappa_T$ ) at 298 K

|         | $\alpha/(10^{-4} \text{ K}^{-1})$ | $\kappa_T/(10^{-6} \text{ bar}^{-1})$ |
|---------|-----------------------------------|---------------------------------------|
| Benzene | 12.4                              | 90.9                                  |
| Diamond | 0.030                             | 0.185                                 |

\* More values are given in the Data section.

**Example 2.8** Calculating the expansion coefficient of a gas

Derive an expression for the expansion coefficient of a perfect gas.

**Method** The expansion coefficient is defined in eqn 2.42. To use this expression, substitute the expression for  $V$  in terms of  $T$  obtained from the equation of state for the gas. As implied by the subscript in eqn 2.42, the pressure,  $p$ , is treated as a constant.

**Answer** Because  $pV = nRT$ , we can write

$$\alpha = \frac{1}{V} \left( \frac{\partial(nRT/p)}{\partial T} \right)_p = \frac{1}{V} \times \frac{nR}{p} \frac{dT}{dT} = \frac{nR}{pV} = \frac{1}{T}$$

The higher the temperature, the less responsive is the volume of a perfect gas to a change in temperature.

**Self-test 2.9** Derive an expression for the isothermal compressibility of a perfect gas. [ $\kappa_T = 1/p$ ]

When we introduce the definition of  $\alpha$  into the equation for  $(\partial U/\partial T)_p$ , we obtain

$$\left( \frac{\partial U}{\partial T} \right)_p = \alpha \pi_T V + C_V \quad (2.44)$$

This equation is entirely general (provided the system is closed and its composition is constant). It expresses the dependence of the internal energy on the temperature at constant pressure in terms of  $C_V$ , which can be measured in one experiment, in terms of  $\alpha$ , which can be measured in another, and in terms of the quantity  $\pi_T$ . For a perfect gas,  $\pi_T = 0$ , so then

$$\left( \frac{\partial U}{\partial T} \right)_p = C_V \quad (2.45)^\circ$$

That is, although the constant-volume heat capacity of a perfect gas is defined as the slope of a plot of internal energy against temperature at constant volume, for a perfect gas  $C_V$  is also the slope at constant pressure.

Equation 2.45 provides an easy way to derive the relation between  $C_p$  and  $C_V$  for a perfect gas. Thus, we can use it to express both heat capacities in terms of derivatives at constant pressure:

$$C_p - C_V = \left( \frac{\partial H}{\partial T} \right)_p - \left( \frac{\partial U}{\partial T} \right)_p = \left( \frac{\partial H}{\partial T} \right)_p - \left( \frac{\partial U}{\partial T} \right)_p \quad (2.46)^\circ$$

Then we introduce  $H = U + pV = U + nRT$  into the first term, which results in

$$C_p - C_V = \left( \frac{\partial U}{\partial T} \right)_p + nR - \left( \frac{\partial U}{\partial T} \right)_p = nR \quad (2.47)^\circ$$

which is eqn 2.26. We show in *Further information 2.2* that in general

$$C_p - C_V = \frac{\alpha^2 TV}{\kappa_T} \quad (2.48)$$

Equation 2.48 applies to any substance (that is, it is ‘universally true’). It reduces to eqn 2.47 for a perfect gas when we set  $\alpha = 1/T$  and  $\kappa_T = 1/p$ . Because expansion coefficients  $\alpha$  of liquids and solids are small, it is tempting to deduce from eqn 2.48 that for them  $C_p \approx C_V$ . But this is not always so, because the compressibility  $\kappa_T$  might also be small, so  $\alpha^2/\kappa_T$  might be large. That is, although only a little work need be done to push back the atmosphere, a great deal of work may have to be done to pull atoms apart from one another as the solid expands. As an illustration, for water at 25°C, eqn 2.48 gives  $C_{p,m} = 75.3 \text{ J K}^{-1} \text{ mol}^{-1}$  compared with  $C_{V,m} = 74.8 \text{ J K}^{-1} \text{ mol}^{-1}$ . In some cases, the two heat capacities differ by as much as 30 per cent.

## 2.12 The Joule–Thomson effect

**Key point** The Joule–Thomson effect is the change in temperature of a gas when it undergoes isenthalpic expansion.

We can carry out a similar set of operations on the enthalpy,  $H = U + pV$ . The quantities  $U$ ,  $p$ , and  $V$  are all state functions; therefore  $H$  is also a state function and  $dH$  is an exact differential. It turns out that  $H$  is a useful thermodynamic function when the pressure is under our control: we saw a sign of that in the relation  $\Delta H = q_p$  (eqn 2.19b). We shall therefore regard  $H$  as a function of  $p$  and  $T$ , and adapt the argument in Section 2.11 to find an expression for the variation of  $H$  with temperature at constant volume. As explained in the following *Justification*, we find that for a closed system of constant composition

$$dH = -\mu C_p dp + C_p dT \quad (2.49)$$

where the **Joule–Thomson coefficient**,  $\mu$  ( $\mu$ ), is defined as

$$\mu = \left( \frac{\partial T}{\partial p} \right)_H \quad \text{Definition of the Joule–Thomson coefficient} \quad [2.50]$$

This relation will prove useful for relating the heat capacities at constant pressure and volume and for a discussion of the liquefaction of gases.

### Justification 2.2 The variation of enthalpy with pressure and temperature

Because  $H$  is a function of  $p$  and  $T$  we can write, when these two quantities change by an infinitesimal amount, that the enthalpy changes by

$$dH = \left( \frac{\partial H}{\partial p} \right)_T dp + \left( \frac{\partial H}{\partial T} \right)_p dT \quad (2.51)$$

The second partial derivative is  $C_p$ ; our task here is to express  $(\partial H/\partial p)_T$  in terms of recognizable quantities. If the enthalpy is constant,  $dH = 0$  and this expression then requires that

$$\left( \frac{\partial H}{\partial p} \right)_T dp = -C_p dT \quad \text{at constant } H$$

Division of both sides by  $dp$  then gives

$$\left( \frac{\partial H}{\partial p} \right)_T = -C_p \left( \frac{\partial T}{\partial p} \right)_H = -C_p \mu$$

Equation 2.49 now follows directly.

**Fig. 2.26** The apparatus used for measuring the Joule–Thomson effect. The gas expands through the porous barrier, which acts as a throttle, and the whole apparatus is thermally insulated. As explained in the text, this arrangement corresponds to an isenthalpic expansion (expansion at constant enthalpy). Whether the expansion results in a heating or a cooling of the gas depends on the conditions.

**Fig. 2.27** The thermodynamic basis of Joule–Thomson expansion. The pistons represent the upstream and downstream gases, which maintain constant pressures either side of the throttle. The transition from the top diagram to the bottom diagram, which represents the passage of a given amount of gas through the throttle, occurs without change of enthalpy.

### (a) Observation of the Joule–Thomson effect

The analysis of the Joule–Thomson coefficient is central to the technological problems associated with the liquefaction of gases. We need to be able to interpret it physically and to measure it. As shown in the following *Justification*, the cunning required to impose the constraint of constant enthalpy, so that the process is **isenthalpic**, was supplied by Joule and William Thomson (later Lord Kelvin). They let a gas expand through a porous barrier from one constant pressure to another and monitored the difference of temperature that arose from the expansion (Fig. 2.26). The whole apparatus was insulated so that the process was adiabatic. They observed a lower temperature on the low pressure side, the difference in temperature being proportional to the pressure difference they maintained. This cooling by isenthalpic expansion is now called the **Joule–Thomson effect**.

#### **Justification 2.3** *The Joule–Thomson effect*

Here we show that the experimental arrangement results in expansion at constant enthalpy. Because all changes to the gas occur adiabatically,  $q=0$  implies that  $\Delta U=w$ . Next, consider the work done as the gas passes through the barrier. We focus on the passage of a fixed amount of gas from the high pressure side, where the pressure is  $p_i$ , the temperature  $T_i$ , and the gas occupies a volume  $V_i$  (Fig. 2.27). The gas emerges on the low pressure side, where the same amount of gas has a pressure  $p_f$ , a temperature  $T_f$ , and occupies a volume  $V_f$ . The gas on the left is compressed

isothermally by the upstream gas acting as a piston. The relevant pressure is  $p_i$  and the volume changes from  $V_i$  to 0; therefore, the work done on the gas is

$$w_1 = -p_i(0 - V_i) = p_i V_i$$

The gas expands isothermally on the right of the barrier (but possibly at a different constant temperature) against the pressure  $p_f$  provided by the downstream gas acting as a piston to be driven out. The volume changes from 0 to  $V_f$ , so the work done on the gas in this stage is

$$w_2 = -p_f(V_f - 0) = -p_f V_f$$

The total work done on the gas is the sum of these two quantities, or

$$w = w_1 + w_2 = p_i V_i - p_f V_f$$

It follows that the change of internal energy of the gas as it moves adiabatically from one side of the barrier to the other is

$$U_f - U_i = w = p_i V_i - p_f V_f$$

Reorganization of this expression gives

$$U_f + p_f V_f = U_i + p_i V_i \quad \text{or} \quad H_f = H_i$$

Therefore, the expansion occurs without change of enthalpy.

The property measured in the experiment is the ratio of the temperature change to the change of pressure,  $\Delta T/\Delta p$ . Adding the constraint of constant enthalpy and taking the limit of small  $\Delta p$  implies that the thermodynamic quantity measured is  $(\partial T/\partial p)_H$ , which is the Joule–Thomson coefficient,  $\mu$ . In other words, the physical interpretation of  $\mu$  is that it is the ratio of the change in temperature to the change in pressure when a gas expands under conditions that ensure there is no change in enthalpy.

The modern method of measuring  $\mu$  is indirect, and involves measuring the isothermal Joule–Thomson coefficient, the quantity

$$\mu_T = \left( \frac{\partial H}{\partial p} \right)_T \quad \text{Definition of the isothermal Joule–Thomson coefficient} \quad [2.52]$$

which is the slope of a plot of enthalpy against pressure at constant temperature (Fig. 2.28). Comparing eqns 2.51 and 2.52, we see that the two coefficients are related by

$$\mu_T = -C_p \mu \quad [2.53]$$

To measure  $\mu_T$ , the gas is pumped continuously at a steady pressure through a heat exchanger, which brings it to the required temperature, and then through a porous plug inside a thermally insulated container. The steep pressure drop is measured and the cooling effect is exactly offset by an electric heater placed immediately after the plug (Fig. 2.29). The energy provided by the heater is monitored. Because  $\Delta H = q_p$ , the energy transferred as heat can be identified with the value of  $\Delta H$ . The pressure change  $\Delta p$  is known, so we can find  $\mu_T$  from the limiting value of  $\Delta H/\Delta p$  as  $\Delta p \rightarrow 0$  and then convert it to  $\mu$ . Table 2.10 lists some values obtained in this way.

Real gases have nonzero Joule–Thomson coefficients. Depending on the identity of the gas, the pressure, the relative magnitudes of the attractive and repulsive intermolecular forces, and the temperature, the sign of the coefficient may be either positive or negative (Fig. 2.30). A positive sign implies that  $dT$  is negative when  $dp$  is negative, in which case the gas cools on expansion. Gases that show a heating effect ( $\mu < 0$ ) at one temperature show a cooling effect ( $\mu > 0$ ) when the temperature is below their upper inversion temperature,  $T_i$  (Table 2.10, Fig. 2.31). As indicated in

**Fig. 2.28** The isothermal Joule–Thomson coefficient is the slope of the enthalpy with respect to changing pressure, the temperature being held constant.

**Fig. 2.29** A schematic diagram of the apparatus used for measuring the isothermal Joule–Thomson coefficient. The electrical heating required to offset the cooling arising from expansion is interpreted as  $\Delta H$  and used to calculate  $(\partial H/\partial p)_T$ , which is then converted to  $\mu$  as explained in the text.

**Table 2.10\*** Inversion temperatures ( $T_i$ ), normal freezing ( $T_f$ ) and boiling ( $T_b$ ) points, and Joule–Thomson coefficient ( $\mu$ ) at 1 atm and 298 K

\* More values are given in the Data section.

**Fig. 2.30** The sign of the Joule–Thomson coefficient,  $\mu$ , depends on the conditions. Inside the boundary, the blue area, it is positive and outside it is negative. The temperature corresponding to the boundary at a given pressure is the ‘inversion temperature’ of the gas at that pressure. For a given pressure, the temperature must be below a certain value if cooling is required but, if it becomes too low, the boundary is crossed again and heating occurs. Reduction of pressure under adiabatic conditions moves the system along one of the isenthalps, or curves of constant enthalpy. The inversion temperature curve runs through the points of the isenthalps where their slope changes from negative to positive.

**Fig. 2.31** The inversion temperatures for three real gases, nitrogen, hydrogen, and helium.

**Fig. 2.32** The principle of the Linde refrigerator is shown in this diagram. The gas is recirculated, and, so long as it is beneath its inversion temperature, it cools on expansion through the throttle. The cooled gas cools the high-pressure gas, which cools still further as it expands. Eventually liquefied gas drips from the throttle.

Fig. 2.31, a gas typically has two inversion temperatures, one at high temperature and the other at low.

The ‘Linde refrigerator’ makes use of Joule–Thomson expansion to liquefy gases (Fig. 2.32). The gas at high pressure is allowed to expand through a throttle; it cools and is circulated past the incoming gas. That gas is cooled, and its subsequent expansion cools it still further. There comes a stage when the circulating gas becomes so cold that it condenses to a liquid.

For a perfect gas,  $\mu = 0$ ; hence, the temperature of a perfect gas is unchanged by Joule–Thomson expansion. (Simple adiabatic expansion does cool a perfect gas, because the gas does work, Section 2.6.) This characteristic points clearly to the involvement of intermolecular forces in determining the size of the effect. However, the Joule–Thomson coefficient of a real gas does not necessarily approach zero as the pressure is reduced even though the equation of state of the gas approaches that of a perfect gas. The coefficient behaves like the properties discussed in Section 1.3b in the sense that it depends on derivatives and not on  $p$ ,  $V$ , and  $T$  themselves.

**(b) The molecular interpretation of the Joule–Thomson effect**

The kinetic model of gases (Section 1.2b) and the equipartition theorem (Section F.5) jointly imply that the mean kinetic energy of molecules in a gas is proportional to the temperature. It follows that reducing the average speed of the molecules is equivalent to cooling the gas. If the speed of the molecules can be reduced to the point that neighbours can capture each other by their intermolecular attractions, then the cooled gas will condense to a liquid.

To slow the gas molecules, we make use of an effect similar to that seen when a ball is thrown into the air: as it rises it slows in response to the gravitational attraction of the Earth and its kinetic energy is converted into potential energy. We saw in Section 1.3 that molecules in a real gas attract each other (the attraction is not gravitational, but the effect is the same). It follows that, if we can cause the molecules to move apart from each other, like a ball rising from a planet, then they should slow. It is very easy to move molecules apart from each other: we simply allow the gas to expand, which increases the average separation of the molecules. To cool a gas, therefore, we allow it to expand without allowing any energy to enter from outside as heat. As the gas expands, the molecules move apart to fill the available volume, struggling as they do so against the attraction of their neighbours. Because some kinetic energy must be converted into potential energy to reach greater separations, the molecules travel more slowly as their separation increases. This sequence of molecular events explains the Joule–Thomson effect: the cooling of a real gas by adiabatic expansion. The cooling effect, which corresponds to  $\mu > 0$ , is observed under conditions when attractive interactions are dominant ( $Z < 1$ , eqn 1.17), because the molecules have to climb apart against the attractive force in order for them to travel more slowly. For molecules under conditions when repulsions are dominant ( $Z > 1$ ), the Joule–Thomson effect results in the gas becoming warmer, or  $\mu < 0$ .

## Checklist of key equations

| Property                                                 | Equation                                                                                          | Comment                                           |

## Further information

### Further information 2.1 *Adiabatic processes*

Consider a stage in a reversible adiabatic expansion when the pressure inside and out is  $p$ . The work done when the gas expands by  $dV$  is  $dw = -pdV$ ; however, for a perfect gas,  $dU = C_V dT$ . Therefore, because for an adiabatic change ( $dq = 0$ )  $dU = dw + dq = dw$ , we can equate these two expressions for  $dU$  and write

$$C_V dT = -pdV$$

We are dealing with a perfect gas, so we can replace  $p$  by  $nRT/V$  and obtain

$$\frac{C_V dT}{T} = -\frac{nR dV}{V}$$

To integrate this expression we note that  $T$  is equal to  $T_i$  when  $V$  is equal to  $V_i$ , and is equal to  $T_f$  when  $V$  is equal to  $V_f$  at the end of the expansion. Therefore,

$$C_V \int_{T_i}^{T_f} \frac{dT}{T} = -nR \int_{V_i}^{V_f} \frac{dV}{V}$$

(We are taking  $C_V$  to be independent of temperature.) Then, because  $\int dx/x = \ln x + \text{constant}$ , we obtain

$$C_V \ln \frac{T_f}{T_i} = -nR \ln \frac{V_f}{V_i}$$

Because  $\ln(x/y) = -\ln(y/x)$ , this expression rearranges to

$$\frac{C_V}{nR} \ln \frac{T_f}{T_i} = \ln \frac{V_i}{V_f}$$

With  $c = C_V/nR$  we obtain (because  $\ln x^a = a \ln x$ )

$$\ln \left( \frac{T_f}{T_i} \right)^c = \ln \left( \frac{V_i}{V_f} \right)$$

which implies that  $(T_f/T_i)^c = (V_i/V_f)$  and, upon rearrangement, eqn 2.28.

The initial and final states of a perfect gas satisfy the perfect gas law regardless of how the change of state takes place, so we can use  $pV = nRT$  to write

$$\frac{p_i V_i}{p_f V_f} = \frac{T_i}{T_f}$$

However, we have just shown that

$$\frac{T_i}{T_f} = \left( \frac{V_f}{V_i} \right)^{1/c} = \left( \frac{V_i}{V_f} \right)^{\gamma-1}$$

where we use the definition of the heat capacity ratio where  $\gamma = C_{p,m}/C_{V,m}$  and the fact that, for a perfect gas,  $C_{p,m} - C_{V,m} = R$

(the molar version of eqn 2.26). Then we combine the two expressions, to obtain

$$\frac{p_i}{p_f} = \frac{V_f}{V_i} \times \left( \frac{V_f}{V_i} \right)^{\gamma-1} = \left( \frac{V_f}{V_i} \right)^{\gamma}$$

which rearranges to  $p_i V_i^{\gamma} = p_f V_f^{\gamma}$ , which is eqn 2.29.

### Further information 2.2 *The relation between heat capacities*

A useful rule when doing a problem in thermodynamics is to go back to first principles. In the present problem we do this twice, first by expressing  $C_p$  and  $C_V$  in terms of their definitions and then by inserting the definition  $H = U + pV$ :

$$\begin{aligned} C_p - C_V &= \left( \frac{\partial H}{\partial T} \right)_p - \left( \frac{\partial U}{\partial T} \right)_V \\ &= \left( \frac{\partial U}{\partial T} \right)_p + \left( \frac{\partial(pV)}{\partial T} \right)_p - \left( \frac{\partial U}{\partial T} \right)_V \end{aligned}$$

We have already calculated the difference of the first and third terms on the right, and eqn 2.44 lets us write this difference as  $\alpha \pi_T V$ . The factor  $\alpha V$  gives the change in volume when the temperature is raised, and  $\pi_T = (\partial U / \partial V)_T$  converts this change in volume into a change in internal energy. We can simplify the remaining term by noting that, because  $p$  is constant,

$$\left( \frac{\partial(pV)}{\partial T} \right)_p = p \left( \frac{\partial V}{\partial T} \right)_p = \alpha p V$$

The middle term of this expression identifies it as the contribution to the work of pushing back the atmosphere:  $(\partial V / \partial T)_p$  is the change of volume caused by a change of temperature, and multiplication by  $p$  converts this expansion into work.

Collecting the two contributions gives

$$C_p - C_V = \alpha(p + \pi_T)V \quad (2.54)$$

As just remarked, the first term on the right,  $\alpha p V$ , is a measure of the work needed to push back the atmosphere; the second term on the right,  $\alpha \pi_T V$ , is the work required to separate the molecules composing the system.

At this point we can go further by using the result we prove in Section 3.8 that

$$\pi_T = T \left( \frac{\partial p}{\partial T} \right)_V - p$$

When this expression is inserted in the last equation we obtain

$$C_p - C_V = \alpha T V \left( \frac{\partial p}{\partial T} \right)_V \quad (2.55)$$

We now transform the remaining partial derivative. With  $V$  regarded as a function of  $p$  and  $T$ , when these two quantities change the resulting change in  $V$  is

$$dV = \left( \frac{\partial V}{\partial T} \right)_p dT + \left( \frac{\partial V}{\partial p} \right)_T dp \quad (2.56)$$

If (as in eqn 2.56) we require the volume to be constant,  $dV = 0$  implies that

$$\left( \frac{\partial V}{\partial T} \right)_p dT = - \left( \frac{\partial V}{\partial p} \right)_T dp \quad \text{at constant volume} \quad (2.57)$$

On division by  $dT$ , this relation becomes

$$\left( \frac{\partial V}{\partial T} \right)_p = - \left( \frac{\partial V}{\partial p} \right)_T \left( \frac{\partial p}{\partial T} \right)_V \quad (2.58)$$

and therefore

$$\left( \frac{\partial p}{\partial T} \right)_V = - \frac{(\partial V / \partial T)_p}{(\partial V / \partial p)_T} = \frac{\alpha}{\kappa_T} \quad (2.59)$$

Insertion of this relation into eqn 2.55 produces eqn 2.48.

## Discussion questions

**2.1** Provide mechanical and molecular definitions of work and heat.

**2.2** Consider the reversible expansion of a perfect gas. Provide a physical interpretation for the fact that  $pV^\gamma = \text{constant}$  for an adiabatic change, whereas  $pV = \text{constant}$  for an isothermal change.

**2.3** Explain the difference between the change in internal energy and the change in enthalpy accompanying a chemical or physical process.

**2.4** Explain the significance of a physical observable being a state function and compile a list of as many state functions as you can identify.

**2.5** Explain the significance of the Joule and Joule–Thomson experiments. What would Joule observe in a more sensitive apparatus?

**2.6** Suggest (with explanation) how the internal energy of a van der Waals gas should vary with volume at constant temperature.

## Exercises

Assume all gases are perfect unless stated otherwise. Unless otherwise stated, thermodynamic data are for 298.15 K.

**2.1(a)** Calculate the work needed for a 65 kg person to climb through 4.0 m on the surface of (a) the Earth and (b) the Moon ( $g = 1.60 \text{ m s}^{-2}$ ).

**2.1(b)** Calculate the work needed for a bird of mass 120 g to fly to a height of 50 m from the surface of the Earth.

**2.2(a)** A chemical reaction takes place in a container of cross-sectional area  $100 \text{ cm}^2$ . As a result of the reaction, a piston is pushed out through 10 cm against an external pressure of 1.0 atm. Calculate the work done by the system.

**2.2(b)** A chemical reaction takes place in a container of cross-sectional area  $50.0 \text{ cm}^2$ . As a result of the reaction, a piston is pushed out through 15 cm against an external pressure of 121 kPa. Calculate the work done by the system.

**2.3(a)** A sample consisting of 1.00 mol Ar is expanded isothermally at  $0^\circ\text{C}$  from  $22.4 \text{ dm}^3$  to  $44.8 \text{ dm}^3$  (a) reversibly, (b) against a constant external pressure equal to the final pressure of the gas, and (c) freely (against zero external pressure). For the three processes calculate  $q$ ,  $w$ ,  $\Delta U$ , and  $\Delta H$ .

**2.3(b)** A sample consisting of 2.00 mol He is expanded isothermally at  $22^\circ\text{C}$  from  $22.8 \text{ dm}^3$  to  $31.7 \text{ dm}^3$  (a) reversibly, (b) against a constant external pressure equal to the final pressure of the gas, and (c) freely (against zero external pressure). For the three processes calculate  $q$ ,  $w$ ,  $\Delta U$ , and  $\Delta H$ .

**2.4(a)** A sample consisting of 1.00 mol of perfect gas atoms, for which  $C_{V,m} = \frac{3}{2}R$ , initially at  $p_1 = 1.00 \text{ atm}$  and  $T_1 = 300 \text{ K}$ , is heated reversibly to 400 K at constant volume. Calculate the final pressure,  $\Delta U$ ,  $q$ , and  $w$ .

**2.4(b)** A sample consisting of 2.00 mol of perfect gas molecules, for which  $C_{V,m} = \frac{5}{2}R$ , initially at  $p_1 = 111 \text{ kPa}$  and  $T_1 = 277 \text{ K}$ , is heated reversibly to 356 K at constant volume. Calculate the final pressure,  $\Delta U$ ,  $q$ , and  $w$ .

**2.5(a)** A sample of 4.50 g of methane occupies  $12.7 \text{ dm}^3$  at 310 K. (a) Calculate the work done when the gas expands isothermally against a constant external pressure of 200 Torr until its volume has increased by  $3.3 \text{ dm}^3$ . (b) Calculate the work that would be done if the same expansion occurred reversibly.

**2.5(b)** A sample of argon of mass 6.56 g occupies  $18.5 \text{ dm}^3$  at 305 K. (a) Calculate the work done when the gas expands isothermally against a constant external pressure of 7.7 kPa until its volume has increased by  $2.5 \text{ dm}^3$ . (b) Calculate the work that would be done if the same expansion occurred reversibly.

**2.6(a)** A sample of 1.00 mol  $\text{H}_2\text{O}(\text{g})$  is condensed isothermally and reversibly to liquid water at  $100^\circ\text{C}$ . The standard enthalpy of vaporization of water at  $100^\circ\text{C}$  is  $40.656 \text{ kJ mol}^{-1}$ . Find  $w$ ,  $q$ ,  $\Delta U$ , and  $\Delta H$  for this process.

**2.6(b)** A sample of 2.00 mol  $\text{CH}_3\text{OH}(\text{g})$  is condensed isothermally and reversibly to liquid at  $64^\circ\text{C}$ . The standard enthalpy of vaporization of methanol at  $64^\circ\text{C}$  is  $35.3 \text{ kJ mol}^{-1}$ . Find  $w$ ,  $q$ ,  $\Delta U$ , and  $\Delta H$  for this process.

**2.7(a)** A strip of magnesium of mass 15 g is placed in a beaker of dilute hydrochloric acid. Calculate the work done by the system as a result of the reaction. The atmospheric pressure is 1.0 atm and the temperature  $25^\circ\text{C}$ .

**2.7(b)** A piece of zinc of mass 5.0 g is placed in a beaker of dilute hydrochloric acid. Calculate the work done by the system as a result of the reaction. The atmospheric pressure is 1.1 atm and the temperature  $23^\circ\text{C}$ .

**2.8(a)** The constant-pressure heat capacity of a sample of a perfect gas was found to vary with temperature according to the expression  $C_p/(J\ K^{-1}) = 20.17 + 0.3665(T/K)$ . Calculate  $q$ ,  $w$ ,  $\Delta U$ , and  $\Delta H$  when the temperature is raised from 25°C to 200°C (a) at constant pressure, (b) at constant volume.

**2.8(b)** The constant-pressure heat capacity of a sample of a perfect gas was found to vary with temperature according to the expression  $C_p/(J\ K^{-1}) = 20.17 + 0.4001(T/K)$ . Calculate  $q$ ,  $w$ ,  $\Delta U$ , and  $\Delta H$  when the temperature is raised from 0°C to 100°C (a) at constant pressure, (b) at constant volume.

**2.9(a)** Calculate the final temperature of a sample of argon of mass 12.0 g that is expanded reversibly and adiabatically from 1.0 dm<sup>3</sup> at 273.15 K to 3.0 dm<sup>3</sup>.

**2.9(b)** Calculate the final temperature of a sample of carbon dioxide of mass 16.0 g that is expanded reversibly and adiabatically from 500 cm<sup>3</sup> at 298.15 K to 2.00 dm<sup>3</sup>.

**2.10(a)** A sample of carbon dioxide of mass 2.45 g at 27.0°C is allowed to expand reversibly and adiabatically from 500 cm<sup>3</sup> to 3.00 dm<sup>3</sup>. What is the work done by the gas?

**2.10(b)** A sample of nitrogen of mass 3.12 g at 23.0°C is allowed to expand reversibly and adiabatically from 400 cm<sup>3</sup> to 2.00 dm<sup>3</sup>. What is the work done by the gas?

**2.11(a)** Calculate the final pressure of a sample of carbon dioxide that expands reversibly and adiabatically from 57.4 kPa and 1.0 dm<sup>3</sup> to a final volume of 2.0 dm<sup>3</sup>. Take  $\gamma = 1.4$ .

**2.11(b)** Calculate the final pressure of a sample of water vapour that expands reversibly and adiabatically from 87.3 Torr and 500 cm<sup>3</sup> to a final volume of 3.0 dm<sup>3</sup>. Take  $\gamma = 1.3$ .

**2.12(a)** When 229 J of energy is supplied as heat to 3.0 mol Ar(g) at constant pressure, the temperature of the sample increases by 2.55 K. Calculate the molar heat capacities at constant volume and constant pressure of the gas.

**2.12(b)** When 178 J of energy is supplied as heat to 1.9 mol of gas molecules at constant pressure, the temperature of the sample increases by 1.78 K. Calculate the molar heat capacities at constant volume and constant pressure of the gas.

**2.13(a)** When 3.0 mol O<sub>2</sub> is heated at a constant pressure of 3.25 atm, its temperature increases from 260 K to 285 K. Given that the molar heat capacity of O<sub>2</sub>(g) at constant pressure is 29.4 J K<sup>-1</sup> mol<sup>-1</sup>, calculate  $q$ ,  $\Delta H$ , and  $\Delta U$ .

**2.13(b)** When 2.0 mol CO<sub>2</sub> is heated at a constant pressure of 1.25 atm, its temperature increases from 250 K to 277 K. Given that the molar heat capacity of CO<sub>2</sub>(g) at constant pressure is 37.11 J K<sup>-1</sup> mol<sup>-1</sup>, calculate  $q$ ,  $\Delta H$ , and  $\Delta U$ .

**2.14(a)** A sample of 4.0 mol O<sub>2</sub>(g) is originally confined in 20 dm<sup>3</sup> at 270 K and then undergoes adiabatic expansion against a constant pressure of 600 Torr until the volume has increased by a factor of 3.0. Calculate  $q$ ,  $w$ ,  $\Delta T$ ,  $\Delta U$ , and  $\Delta H$ . (The final pressure of the gas is not necessarily 600 Torr.)

**2.14(b)** A sample of 5.0 mol CO<sub>2</sub>(g) is originally confined in 15 dm<sup>3</sup> at 280 K and then undergoes adiabatic expansion against a constant pressure of 78.5 kPa until the volume has increased by a factor of 4.0. Calculate  $q$ ,  $w$ ,  $\Delta T$ ,  $\Delta U$ , and  $\Delta H$ . (The final pressure of the gas is not necessarily 78.5 kPa.)

**2.15(a)** A sample consisting of 1.0 mol of perfect gas molecules with  $C_V = 20.8\ J\ K^{-1}$  is initially at 3.25 atm and 310 K. It undergoes reversible adiabatic expansion until its pressure reaches 2.50 atm. Calculate the final volume and temperature and the work done.

**2.15(b)** A sample consisting of 1.5 mol of perfect gas molecules with  $C_{p,m} = 20.8\ J\ K^{-1}\ mol^{-1}$  is initially at 230 kPa and 315 K. It undergoes reversible adiabatic expansion until its pressure reaches 170 kPa. Calculate the final volume and temperature and the work done.

**2.16(a)** A certain liquid has  $\Delta_{\text{vap}}H^\circ = 26.0\ kJ\ mol^{-1}$ . Calculate  $q$ ,  $w$ ,  $\Delta H$ , and  $\Delta U$  when 0.50 mol is vaporized at 250 K and 750 Torr.

**2.16(b)** A certain liquid has  $\Delta_{\text{vap}}H^\circ = 32.0\ kJ\ mol^{-1}$ . Calculate  $q$ ,  $w$ ,  $\Delta H$ , and  $\Delta U$  when 0.75 mol is vaporized at 260 K and 765 Torr.

**2.17(a)** Calculate the lattice enthalpy of SrI<sub>2</sub> from the following data:

|                                                                     | $\Delta H/(kJ\ mol^{-1})$ |
|---------------------------------------------------------------------|---------------------------|
| Sublimation of Sr(s)                                                | +164                      |
| Ionization of Sr(g) to Sr <sup>2+</sup> (g)                         | +1626                     |
| Sublimation of I <sub>2</sub> (s)                                   | +62                       |
| Dissociation of I <sub>2</sub> (g)                                  | +151                      |
| Electron attachment to I(g)                                         | -304                      |
| Formation of SrI <sub>2</sub> (s) from Sr(s) and I <sub>2</sub> (s) | -558                      |

**2.17(b)** Calculate the lattice enthalpy of MgBr<sub>2</sub> from the following data:

|                                                                       | $\Delta H/(kJ\ mol^{-1})$ |
|-----------------------------------------------------------------------|---------------------------|
| Sublimation of Mg(s)                                                  | +148                      |
| Ionization of Mg(g) to Mg <sup>2+</sup> (g)                           | +2187                     |
| Vaporization of Br <sub>2</sub> (l)                                   | +31                       |
| Dissociation of Br <sub>2</sub> (g)                                   | +193                      |
| Electron attachment to Br(g)                                          | -331                      |
| Formation of MgBr <sub>2</sub> (s) from Mg(s) and Br <sub>2</sub> (l) | -524                      |

**2.18(a)** The standard enthalpy of formation of ethylbenzene is -12.5 kJ mol<sup>-1</sup>. Calculate its standard enthalpy of combustion.

**2.18(b)** The standard enthalpy of formation of phenol is -165.0 kJ mol<sup>-1</sup>. Calculate its standard enthalpy of combustion.

**2.19(a)** The standard enthalpy of combustion of cyclopropane is -2091 kJ mol<sup>-1</sup> at 25°C. From this information and enthalpy of formation data for CO<sub>2</sub>(g) and H<sub>2</sub>O(g), calculate the enthalpy of formation of cyclopropane. The enthalpy of formation of propene is +20.42 kJ mol<sup>-1</sup>. Calculate the enthalpy of isomerization of cyclopropane to propene.

**2.19(b)** From the following data, determine  $\Delta_f H^\circ$  for diborane, B<sub>2</sub>H<sub>6</sub>(g), at 298 K:

**2.20(a)** When 120 mg of naphthalene, C<sub>10</sub>H<sub>8</sub>(s), was burned in a bomb calorimeter the temperature rose by 3.05 K. Calculate the calorimeter constant. By how much will the temperature rise when 10 mg of phenol, C<sub>6</sub>H<sub>5</sub>OH(s), is burned in the calorimeter under the same conditions?

**2.20(b)** When 2.25 mg of anthracene, C<sub>14</sub>H<sub>10</sub>(s), was burned in a bomb calorimeter the temperature rose by 1.35 K. Calculate the calorimeter constant. By how much will the temperature rise when 135 mg of phenol, C<sub>6</sub>H<sub>5</sub>OH(s), is burned in the calorimeter under the same conditions? ( $\Delta_c H^\circ(C_{14}H_{10}, s) = -7061\ kJ\ mol^{-1}$ .)

**2.21(a)** Calculate the standard enthalpy of solution of AgCl(s) in water from the enthalpies of formation of the solid and the aqueous ions.

**2.21(b)** Calculate the standard enthalpy of solution of AgBr(s) in water from the enthalpies of formation of the solid and the aqueous ions.

**2.22(a)** The standard enthalpy of decomposition of the yellow complex H<sub>3</sub>NSO<sub>2</sub> into NH<sub>3</sub> and SO<sub>2</sub> is +40 kJ mol<sup>-1</sup>. Calculate the standard enthalpy of formation of H<sub>3</sub>NSO<sub>2</sub>.

**2.22(b)** Given that the standard enthalpy of combustion of graphite is  $-393.51 \text{ kJ mol}^{-1}$  and that of diamond is  $-395.41 \text{ kJ mol}^{-1}$ , calculate the enthalpy of the graphite-to-diamond transition.

**2.23(a)** Given the reactions (1) and (2) below, determine (a)  $\Delta_r H^\circ$  and  $\Delta_r U^\circ$  for reaction (3), (b)  $\Delta_r H^\circ$  for both  $\text{HCl(g)}$  and  $\text{H}_2\text{O(g)}$  all at 298 K.

**2.23(b)** Given the reactions (1) and (2) below, determine (a)  $\Delta_r H^\circ$  and  $\Delta_r U^\circ$  for reaction (3), (b)  $\Delta_r H^\circ$  for both  $\text{HI(g)}$  and  $\text{H}_2\text{O(g)}$  all at 298 K.

**2.24(a)** For the reaction  $\text{C}_2\text{H}_5\text{OH(l)} + 3 \text{O}_2(\text{g}) \rightarrow 2 \text{CO}_2(\text{g}) + 3 \text{H}_2\text{O(g)}$ ,  $\Delta_r U^\circ = -1373 \text{ kJ mol}^{-1}$  at 298 K, calculate  $\Delta_r H^\circ$ .

**2.24(b)** For the reaction  $2 \text{C}_6\text{H}_5\text{COOH(s)} + 13 \text{O}_2(\text{g}) \rightarrow 12 \text{CO}_2(\text{g}) + 6 \text{H}_2\text{O(g)}$ ,  $\Delta_r U^\circ = -772.7 \text{ kJ mol}^{-1}$  at 298 K, calculate  $\Delta_r H^\circ$ .

**2.25(a)** Calculate the standard enthalpies of formation of (a)  $\text{KClO}_3(\text{s})$  from the enthalpy of formation of  $\text{KCl}$ , (b)  $\text{NaHCO}_3(\text{s})$  from the enthalpies of formation of  $\text{CO}_2$  and  $\text{NaOH}$  together with the following information:

**2.25(b)** Calculate the standard enthalpy of formation of  $\text{NOCl(g)}$  from the enthalpy of formation of  $\text{NO}$  given in Table 2.8, together with the following information:

**2.26(a)** Use the information in Table 2.8 to predict the standard reaction enthalpy of  $2 \text{NO}_2(\text{g}) \rightarrow \text{N}_2\text{O}_4(\text{g})$  at  $100^\circ\text{C}$  from its value at  $25^\circ\text{C}$ .

**2.26(b)** Use the information in Table 2.8 to predict the standard reaction enthalpy of  $2 \text{H}_2(\text{g}) + \text{O}_2(\text{g}) \rightarrow 2 \text{H}_2\text{O(l)}$  at  $100^\circ\text{C}$  from its value at  $25^\circ\text{C}$ .

**2.27(a)** From the data in Table 2.8, calculate  $\Delta_r H^\circ$  and  $\Delta_r U^\circ$  at (a) 298 K, (b) 378 K for the reaction  $\text{C(graphite)} + \text{H}_2\text{O(g)} \rightarrow \text{CO(g)} + \text{H}_2(\text{g})$ . Assume all heat capacities to be constant over the temperature range of interest.

**2.27(b)** Calculate  $\Delta_r H^\circ$  and  $\Delta_r U^\circ$  at 298 K and  $\Delta_r H^\circ$  at 348 K for the hydrogenation of ethyne (acetylene) to ethene (ethylene) from the enthalpy of combustion and heat capacity data in Tables 2.6 and 2.8. Assume the heat capacities to be constant over the temperature range involved.

**2.28(a)** Calculate  $\Delta_r H^\circ$  for the reaction  $\text{Zn(s)} + \text{CuSO}_4(\text{aq}) \rightarrow \text{ZnSO}_4(\text{aq}) + \text{Cu(s)}$  from the information in Table 2.8 in the *Data section*.

**2.28(b)** Calculate  $\Delta_r H^\circ$  for the reaction  $\text{NaCl(aq)} + \text{AgNO}_3(\text{aq}) \rightarrow \text{AgCl(s)} + \text{NaNO}_3(\text{aq})$  from the information in Table 2.8 in the *Data section*.

**2.29(a)** Set up a thermodynamic cycle for determining the enthalpy of hydration of  $\text{Mg}^{2+}$  ions using the following data: enthalpy of sublimation of  $\text{Mg(s)}$ ,  $+167.2 \text{ kJ mol}^{-1}$ ; first and second ionization enthalpies of  $\text{Mg(g)}$ ,

$7.646 \text{ eV}$  and  $15.035 \text{ eV}$ ; dissociation enthalpy of  $\text{Cl}_2(\text{g})$ ,  $+241.6 \text{ kJ mol}^{-1}$ ; electron gain enthalpy of  $\text{Cl(g)}$ ,  $-3.78 \text{ eV}$ ; enthalpy of solution of  $\text{MgCl}_2(\text{s})$ ,  $-150.5 \text{ kJ mol}^{-1}$ ; enthalpy of hydration of  $\text{Cl}^-(\text{g})$ ,  $-383.7 \text{ kJ mol}^{-1}$ .

**2.29(b)** Set up a thermodynamic cycle for determining the enthalpy of hydration of  $\text{Ca}^{2+}$  ions using the following data: enthalpy of sublimation of  $\text{Ca(s)}$ ,  $+178.2 \text{ kJ mol}^{-1}$ ; first and second ionization enthalpies of  $\text{Ca(g)}$ ,  $589.7 \text{ kJ mol}^{-1}$  and  $1145 \text{ kJ mol}^{-1}$ ; enthalpy of vaporization of bromine,  $30.91 \text{ kJ mol}^{-1}$ ; dissociation enthalpy of  $\text{Br}_2(\text{g})$ ,  $+192.9 \text{ kJ mol}^{-1}$ ; electron gain enthalpy of  $\text{Br(g)}$ ,  $-331.0 \text{ kJ mol}^{-1}$ ; enthalpy of solution of  $\text{CaBr}_2(\text{s})$ ,  $-103.1 \text{ kJ mol}^{-1}$ ; enthalpy of hydration of  $\text{Br}^-(\text{g})$ ,  $-97.5 \text{ kJ mol}^{-1}$ .

**2.30(a)** When a certain freon used in refrigeration was expanded adiabatically from an initial pressure of 32 atm and  $0^\circ\text{C}$  to a final pressure of 1.00 atm, the temperature fell by 22 K. Calculate the Joule–Thomson coefficient,  $\mu$ , at  $0^\circ\text{C}$ , assuming it remains constant over this temperature range.

**2.30(b)** A vapour at 22 atm and  $5^\circ\text{C}$  was allowed to expand adiabatically to a final pressure of 1.00 atm; the temperature fell by 10 K. Calculate the Joule–Thomson coefficient,  $\mu$ , at  $5^\circ\text{C}$ , assuming it remains constant over this temperature range.

**2.31(a)** For a van der Waals gas,  $\pi_T = a/V_m^2$ . Calculate  $\Delta U_m$  for the isothermal expansion of nitrogen gas from an initial volume of  $1.00 \text{ dm}^3$  to  $24.8 \text{ dm}^3$  at 298 K. What are the values of  $q$  and  $w$ ?

**2.31(b)** Repeat Exercise 2.31(a) for argon, from an initial volume of  $1.00 \text{ dm}^3$  to  $22.1 \text{ dm}^3$  at 298 K.

**2.32(a)** The volume of a certain liquid varies with temperature as

$$V = V' \{0.75 + 3.9 \times 10^{-4}(T/\text{K}) + 1.48 \times 10^{-6}(T/\text{K})^2\}$$

where  $V'$  is its volume at 300 K. Calculate its expansion coefficient,  $\alpha$ , at 320 K.

**2.32(b)** The volume of a certain liquid varies with temperature as

$$V = V' \{0.77 + 3.7 \times 10^{-4}(T/\text{K}) + 1.52 \times 10^{-6}(T/\text{K})^2\}$$

where  $V'$  is its volume at 298 K. Calculate its expansion coefficient,  $\alpha$ , at 310 K.

**2.33(a)** The isothermal compressibility of copper at 293 K is  $7.35 \times 10^{-7} \text{ atm}^{-1}$ . Calculate the pressure that must be applied in order to increase its density by 0.08 per cent.

**2.33(b)** The isothermal compressibility of lead at 293 K is  $2.21 \times 10^{-6} \text{ atm}^{-1}$ . Calculate the pressure that must be applied in order to increase its density by 0.08 per cent.

**2.34(a)** Given that  $\mu = 0.25 \text{ K atm}^{-1}$  for nitrogen, calculate the value of its isothermal Joule–Thomson coefficient. Calculate the energy that must be supplied as heat to maintain constant temperature when 15.0 mol  $\text{N}_2$  flows through a throttle in an isothermal Joule–Thomson experiment and the pressure drop is 75 atm.

**2.34(b)** Given that  $\mu = 1.11 \text{ K atm}^{-1}$  for carbon dioxide, calculate the value of its isothermal Joule–Thomson coefficient. Calculate the energy that must be supplied as heat to maintain constant temperature when 12.0 mol  $\text{CO}_2$  flows through a throttle in an isothermal Joule–Thomson experiment and the pressure drop is 55 atm.

## Problems\*

Assume all gases are perfect unless stated otherwise. Note that 1 atm = 1.013 25 bar. Unless otherwise stated, thermochemical data are for 298.15 K.

## Numerical problems

**2.1** A sample consisting of 1 mol of perfect gas atoms (for which  $C_{V,m} = \frac{3}{2}R$ ) is taken through the cycle shown in Fig. 2.33. (a) Determine the temperature at the points 1, 2, and 3. (b) Calculate  $q$ ,  $w$ ,  $\Delta U$ , and  $\Delta H$  for each step and for the overall cycle. If a numerical answer cannot be obtained from the information given, then write +, −, 0, or ? as appropriate.

Fig. 2.33

**2.2** A sample consisting of 1.0 mol  $\text{CaCO}_3(\text{s})$  was heated to  $800^\circ\text{C}$ , when it decomposed. The heating was carried out in a container fitted with a piston that was initially resting on the solid. Calculate the work done during complete decomposition at 1.0 atm. What work would be done if instead of having a piston the container was open to the atmosphere?

**2.3** A sample consisting of 2.0 mol  $\text{CO}_2$  occupies a fixed volume of  $15.0 \text{ dm}^3$  at 300 K. When it is supplied with 2.35 kJ of energy as heat its temperature increases to 341 K. Assume that  $\text{CO}_2$  is described by the van der Waals equation of state, and calculate  $w$ ,  $\Delta U$ , and  $\Delta H$ .

**2.4** A sample of 70 mmol  $\text{Kr}(\text{g})$  expands reversibly and isothermally at 373 K from  $5.25 \text{ cm}^3$  to  $6.29 \text{ cm}^3$ , and the internal energy of the sample is known to increase by 83.5 J. Use the virial equation of state up to the second coefficient  $B = -28.7 \text{ cm}^3 \text{ mol}^{-1}$  to calculate  $w$ ,  $q$ , and  $\Delta H$  for this change of state.

**2.5** A sample of 1.00 mol perfect gas molecules with  $C_{p,m} = \frac{7}{2}R$  is put through the following cycle: (a) constant-volume heating to twice its initial pressure, (b) reversible, adiabatic expansion back to its initial temperature, (c) reversible isothermal compression back to 1.00 atm. Calculate  $q$ ,  $w$ ,  $\Delta U$ , and  $\Delta H$  for each step and overall.

**2.6** Calculate the work done during the isothermal reversible expansion of a van der Waals gas. Account physically for the way in which the coefficients  $a$  and  $b$  appear in the final expression. Plot on the same graph the indicator diagrams for the isothermal reversible expansion of (a) a perfect gas, (b) a van der Waals gas in which  $a = 0$  and  $b = 5.11 \times 10^{-2} \text{ dm}^3 \text{ mol}^{-1}$ , and (c)  $a = 4.2 \text{ dm}^6 \text{ atm mol}^{-2}$  and  $b = 0$ . The values selected exaggerate the imperfections but give rise to significant effects on the indicator diagrams. Take  $V_i = 1.0 \text{ dm}^3$ ,  $n = 1.0 \text{ mol}$ , and  $T = 298 \text{ K}$ .

**2.7** The molar heat capacity of ethane is represented in the temperature range 298 K to 400 K by the empirical expression  $C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1}) = 14.73 + 0.1272(T/\text{K})$ . The corresponding expressions for  $\text{C}(\text{s})$  and  $\text{H}_2(\text{g})$  are given in

Table 2.2. Calculate the standard enthalpy of formation of ethane at 350 K from its value at 298 K.

**2.8** A sample of the sugar D-ribose ( $\text{C}_5\text{H}_{10}\text{O}_5$ ) of mass 0.727 g was placed in a constant-volume calorimeter and then ignited in the presence of excess oxygen. The temperature rose by 0.910 K. In a separate experiment in the same calorimeter, the combustion of 0.825 g of benzoic acid, for which the internal energy of combustion is  $-3251 \text{ kJ mol}^{-1}$ , gave a temperature rise of 1.940 K. Calculate the internal energy of combustion of D-ribose and its enthalpy of formation.

**2.9** The standard enthalpy of formation of the metallocene bis(benzene)chromium was measured in a calorimeter. It was found for the reaction  $\text{Cr}(\text{C}_6\text{H}_6)_2(\text{s}) \rightarrow \text{Cr}(\text{s}) + 2 \text{C}_6\text{H}_6(\text{g})$  that  $\Delta_r U^\circ(583 \text{ K}) = +8.0 \text{ kJ mol}^{-1}$ . Find the corresponding reaction enthalpy and estimate the standard enthalpy of formation of the compound at 583 K. The constant-pressure molar heat capacity of benzene is  $136.1 \text{ J K}^{-1} \text{ mol}^{-1}$  in its liquid range and  $81.67 \text{ J K}^{-1} \text{ mol}^{-1}$  as a gas.

**2.10†** From the enthalpy of combustion data in Table 2.6 for the alkanes methane through octane, test the extent to which the relation  $\Delta_c H^\circ = k\{M/(\text{g mol}^{-1})\}^n$  holds and find the numerical values for  $k$  and  $n$ . Predict  $\Delta_c H^\circ$  for decane and compare to the known value.

**2.11** An average human produces about 10 MJ of heat each day through metabolic activity. If a human body were an isolated system of mass 65 kg with the heat capacity of water, what temperature rise would the body experience? Human bodies are actually open systems, and the main mechanism of heat loss is through the evaporation of water. What mass of water should be evaporated each day to maintain constant temperature?

**2.12** Glucose and fructose are simple sugars with the molecular formula  $\text{C}_6\text{H}_{12}\text{O}_6$ . Sucrose, or table sugar, is a complex sugar with molecular formula  $\text{C}_{12}\text{H}_{22}\text{O}_{11}$  that consists of a glucose unit covalently bound to a fructose unit (a water molecule is given off as a result of the reaction between glucose and fructose to form sucrose). (a) Calculate the energy released as heat when a typical table sugar cube of mass 1.5 g is burned in air. (b) To what height could you climb on the energy a table sugar cube provides assuming 25 per cent of the energy is available for work? (c) The mass of a typical glucose tablet is 2.5 g. Calculate the energy released as heat when a glucose tablet is burned in air. (d) To what height could you climb on the energy a cube provides assuming 25 per cent of the energy is available for work?

**2.13** It is possible to investigate the thermochemical properties of hydrocarbons with molecular modelling methods. (a) Use electronic structure software to predict  $\Delta_c H^\circ$  values for the alkanes methane through pentane. To calculate  $\Delta_c H^\circ$  values, estimate the standard enthalpy of formation of  $\text{C}_n\text{H}_{2(n+1)}(\text{g})$  by performing semi-empirical calculations (for example, AM1 or PM3 methods) and use experimental standard enthalpy of formation values for  $\text{CO}_2(\text{g})$  and  $\text{H}_2\text{O}(\text{l})$ . (b) Compare your estimated values with the experimental values of  $\Delta_c H^\circ$  (Table 2.6) and comment on the reliability of the molecular modelling method. (c) Test the extent to which the relation  $\Delta_c H^\circ = k\{M/(\text{g mol}^{-1})\}^n$  holds and find the numerical values for  $k$  and  $n$ .

**2.14†** When 1.3584 g of sodium acetate trihydrate was mixed into  $100.0 \text{ cm}^3$  of 0.2000 M  $\text{HCl}(\text{aq})$  at  $25^\circ\text{C}$  in a solution calorimeter, its temperature fell by  $0.397^\circ\text{C}$  on account of the reaction:

The heat capacity of the calorimeter is  $91.0 \text{ J K}^{-1}$  and the heat capacity density of the acid solution is  $4.144 \text{ J K}^{-1} \text{ cm}^{-3}$ . Determine the standard enthalpy of

\* Problems denoted with the symbol † were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

formation of the aqueous sodium cation. The standard enthalpy of formation of sodium acetate trihydrate is  $-1604 \text{ kJ mol}^{-1}$ .

**2.15†** Since their discovery in 1985, fullerenes have received the attention of many chemical researchers. Kolesov *et al.* (*J. Chem. Thermodynamics* 28, 1121 (1996)) reported the standard enthalpy of combustion and of formation of crystalline  $C_{60}$  based on calorimetric measurements. In one of their runs, they found the standard specific internal energy of combustion to be  $-36.0334 \text{ kJ g}^{-1}$  at 298.15 K. Compute  $\Delta_f H^\circ$  and  $\Delta_f H^\circ$  of  $C_{60}$ .

**2.16†** A thermodynamic study of  $DyCl_3$  by Cordfunke *et al.* (*J. Chem. Thermodynamics* 28, 1387 (1996)) determined its standard enthalpy of formation from the following information

- (1)  $DyCl_3(s) \rightarrow DyCl_3(aq, \text{ in } 4.9 \text{ M HCl}) \quad \Delta_f H^\circ = -180.06 \text{ kJ mol}^{-1}$
- (2)  $Dy(s) + 3 \text{ HCl}(aq, 4.0 \text{ M}) \rightarrow DyCl_3(aq, \text{ in } 4.0 \text{ M HCl}(aq)) + \frac{3}{2} H_2(g) \quad \Delta_f H^\circ = -699.43 \text{ kJ mol}^{-1}$
- (3)  $\frac{1}{2} H_2(g) + \frac{1}{2} Cl_2(g) \rightarrow HCl(aq, 4.0 \text{ M}) \quad \Delta_f H^\circ = -158.31 \text{ kJ mol}^{-1}$

Determine  $\Delta_f H^\circ(DyCl_3(s))$  from these data.

**2.17†** Silylene ( $SiH_2$ ) is a key intermediate in the thermal decomposition of silicon hydrides such as silane ( $SiH_4$ ) and disilane ( $Si_2H_6$ ). Moffat *et al.* (*J. Phys. Chem.* 95, 145 (1991)) report  $\Delta_f H^\circ(SiH_2) = +274 \text{ kJ mol}^{-1}$ . If  $\Delta_f H^\circ(SiH_4) = +34.3 \text{ kJ mol}^{-1}$  and  $\Delta_f H^\circ(Si_2H_6) = +80.3 \text{ kJ mol}^{-1}$  (*CRC Handbook* (2008)), compute the standard enthalpies of the following reactions:

- (a)  $SiH_4(g) \rightarrow SiH_2(g) + H_2(g)$
- (b)  $Si_2H_6(g) \rightarrow SiH_2(g) + SiH_4(g)$

**2.18†** Silanone ( $SiH_2O$ ) and silanol ( $SiH_3OH$ ) are species believed to be important in the oxidation of silane ( $SiH_4$ ). These species are much more elusive than their carbon counterparts. C.L. Darling and H.B. Schlegel (*J. Phys. Chem.* 97, 8207 (1993)) report the following values (converted from calories) from a computational study:  $\Delta_f H^\circ(SiH_2O) = -98.3 \text{ kJ mol}^{-1}$  and  $\Delta_f H^\circ(SiH_3OH) = -282 \text{ kJ mol}^{-1}$ . Compute the standard enthalpies of the following reactions:

- (a)  $SiH_4(g) + \frac{1}{2} O_2(g) \rightarrow SiH_3OH(g)$
- (b)  $SiH_4(g) + O_2(g) \rightarrow SiH_2O(g) + H_2O(l)$
- (c)  $SiH_3OH(g) \rightarrow SiH_2O(g) + H_2(g)$

Note that  $\Delta_f H^\circ(SiH_4(g)) = +34.3 \text{ kJ mol}^{-1}$  (*CRC Handbook* (2008)).

**2.19** The constant-volume heat capacity of a gas can be measured by observing the decrease in temperature when it expands adiabatically and reversibly. If the decrease in pressure is also measured, we can use it to infer the value of  $\gamma = C_p/C_V$  and hence, by combining the two values, deduce the constant-pressure heat capacity. A fluorocarbon gas was allowed to expand reversibly and adiabatically to twice its volume; as a result, the temperature fell from 298.15 K to 248.44 K and its pressure fell from 202.94 kPa to 81.840 kPa. Evaluate  $C_p$ .

**2.20** A sample consisting of 1.00 mol of a van der Waals gas is compressed from  $20.0 \text{ dm}^3$  to  $10.0 \text{ dm}^3$  at 300 K. In the process, 20.2 kJ of work is done on the gas. Given that  $\mu = \{(2a/RT) - b\}/C_{p,m}$ , with  $C_{p,m} = 38.4 \text{ J K}^{-1} \text{ mol}^{-1}$ ,  $a = 3.60 \text{ dm}^6 \text{ atm mol}^{-2}$ , and  $b = 0.044 \text{ dm}^3 \text{ mol}^{-1}$ , calculate  $\Delta H$  for the process.

**2.21** Take nitrogen to be a van der Waals gas with  $a = 1.352 \text{ dm}^6 \text{ atm mol}^{-2}$  and  $b = 0.0387 \text{ dm}^3 \text{ mol}^{-1}$ , and calculate  $\Delta H_m$  when the pressure on the gas is decreased from 500 atm to 1.00 atm at 300 K. For a van der Waals gas,  $\mu = \{(2a/RT) - b\}/C_{p,m}$ . Assume  $C_{p,m} = \frac{7}{2} R$ .

## Theoretical problems

**2.22** Show that the following functions have exact differentials: (a)  $x^2y + 3y^2$ , (b)  $x \cos xy$ , (c)  $x^3y^2$ , (d)  $t(t + e^t) + s$ .

**2.23** (a) What is the total differential of  $z = x^2 + 2y^2 - 2xy + 2x - 4y - 8$ ? (b) Show that  $\partial^2 z / \partial y \partial x = \partial^2 z / \partial x \partial y$  for this function. (c) Let  $z = xy - y \ln x + 2$ . Find  $dz$  and show that it is exact.

**2.24** (a) Express  $(\partial C_V / \partial V)_T$  as a second derivative of  $U$  and find its relation to  $(\partial U / \partial V)_T$  and  $(\partial C_p / \partial p)_T$  as a second derivative of  $H$  and find its relation to  $(\partial H / \partial p)_T$ . (b) From these relations show that  $(\partial C_V / \partial V)_T = 0$  and  $(\partial C_p / \partial p)_T = 0$  for a perfect gas.

**2.25** (a) Derive the relation  $C_V = -(\partial U / \partial V)_T (\partial V / \partial T)_U$  from the expression for the total differential of  $U(T, V)$  and (b) starting from the expression for the total differential of  $H(T, p)$ , express  $(\partial H / \partial p)_T$  in terms of  $C_p$  and the Joule–Thomson coefficient,  $\mu$ .

**2.26** Starting from the expression  $C_p - C_V = T(\partial p / \partial T)_V (\partial V / \partial T)_p$ , use the appropriate relations between partial derivatives to show that

$$C_p - C_V = -\frac{T(\partial V / \partial T)_p^2}{(\partial V / \partial p)_T}$$

Evaluate  $C_p - C_V$  for a perfect gas.

**2.27** (a) By direct differentiation of  $H = U + pV$ , obtain a relation between  $(\partial H / \partial U)_p$  and  $(\partial U / \partial V)_p$ . (b) Confirm that  $(\partial H / \partial U)_p = 1 + p(\partial V / \partial U)_p$  by expressing  $(\partial H / \partial U)_p$  as the ratio of two derivatives with respect to volume and then using the definition of enthalpy.

**2.28** Use the chain relation and the reciprocal identity of partial derivatives (*Mathematical background 2*) to derive the relation  $(\partial H / \partial p)_T = -\mu C_p$ .

**2.29** Use the chain relation and the reciprocal identity of partial derivatives (*Mathematical background 2*) to derive the relation  $(\partial p / \partial T)_V = \alpha / \kappa_T$ . Confirm this relation by evaluating all three terms for (a) a perfect gas, (b) a van der Waals gas.

**2.30** (a) Write expressions for  $dV$  and  $dp$  given that  $V$  is a function of  $p$  and  $T$  and  $p$  is a function of  $V$  and  $T$ . (b) Deduce expressions for  $d \ln V$  and  $d \ln p$  in terms of the expansion coefficient and the isothermal compressibility.

**2.31** Calculate the work done during the isothermal reversible expansion of a gas that satisfies the virial equation of state, eqn 1.19. Evaluate (a) the work for 1.0 mol Ar at 273 K (for data, see Table 1.4) and (b) the same amount of a perfect gas. Let the expansion be from  $500 \text{ cm}^3$  to  $1000 \text{ cm}^3$  in each case.

**2.32** Express the work of isothermal reversible expansion of a van der Waals gas in reduced variables and find a definition of reduced work that makes the overall expression independent of the identity of the gas. Calculate the work of isothermal reversible expansion along the critical isotherm from  $V_c$  to  $xV_c$ .

**2.33†** A gas obeying the equation of state  $p(V - nb) = nRT$  is subjected to a Joule–Thomson expansion. Will the temperature increase, decrease, or remain the same?

**2.34** Use the fact that  $(\partial U / \partial V)_T = a/V_m^2$  for a van der Waals gas to show that  $\mu C_{p,m} \approx (2a/RT) - b$  by using the definition of  $\mu$  and appropriate relations between partial derivatives. (*Hint.* Use the approximation  $pV_m \approx RT$  when it is justifiable to do so.)

**2.35** Rearrange the van der Waals equation of state to give an expression for  $T$  as a function of  $p$  and  $V$  (with  $n$  constant). Calculate  $(\partial T / \partial p)_V$  and confirm that  $(\partial T / \partial p)_V = 1 / (\partial p / \partial T)_V$ . Go on to confirm Euler's chain relation.

**2.36** Calculate the isothermal compressibility and the expansion coefficient of a van der Waals gas. Show, using Euler's chain relation, that  $\kappa_T R = \alpha(V_m - b)$ .

**2.37** Given that  $\mu C_p = T(\partial V / \partial T)_p - V$ , derive an expression for  $\mu$  in terms of the van der Waals parameters  $a$  and  $b$ , and express it in terms of reduced variables. Evaluate  $\mu$  at  $25^\circ\text{C}$  and 1.0 atm, when the molar volume of the gas is  $24.6 \text{ dm}^3 \text{ mol}^{-1}$ . Use the expression obtained to derive a formula for the inversion temperature of a van der Waals gas in terms of reduced variables, and evaluate it for the xenon sample.

**2.38** The thermodynamic equation of state  $(\partial U/\partial V)_T = T(\partial p/\partial T)_V - p$  was quoted in the chapter. Derive its partner

$$\left(\frac{\partial H}{\partial p}\right)_T = -T\left(\frac{\partial V}{\partial T}\right)_p + V$$

from it and the general relations between partial differentials.

**2.39** Show that for a van der Waals gas,

$$C_{p,m} - C_{V,m} = \lambda R \quad \frac{1}{\lambda} = 1 - \frac{(3V_r - 1)^2}{4V_r^3 T_r}$$

and evaluate the difference for xenon at 25°C and 10.0 atm.

**2.40** The speed of sound,  $c_s$ , in a gas of molar mass  $M$  is related to the ratio of heat capacities  $\gamma$  by  $c_s = (\gamma RT/M)^{1/2}$ . Show that  $c_s = (\gamma p/\rho)^{1/2}$ , where  $\rho$  is the mass density of the gas. Calculate the speed of sound in argon at 25°C.

**2.41†** A gas obeys the equation of state  $V_m = RT/p + aT^2$  and its constant-pressure heat capacity is given by  $C_{p,m} = A + BT + Cp$ , where  $a$ ,  $A$ ,  $B$ , and  $C$  are constants independent of  $T$  and  $p$ . Obtain expressions for (a) the Joule–Thomson coefficient and (b) its constant-volume heat capacity.

### Applications: to biology and the environment

**2.42** In biological cells that have a plentiful supply of  $O_2$ , glucose is oxidized completely to  $CO_2$  and  $H_2O$  by a process called *aerobic oxidation*. Muscle cells may be deprived of  $O_2$  during vigorous exercise and, in that case, one molecule of glucose is converted to two molecules of lactic acid ( $CH_3CH(OH)COOH$ ) by a process called *anaerobic glycolysis* (see *Impact 16.1*). (a) When 0.3212 g of glucose was burned in a bomb calorimeter of calorimeter constant 641 J K<sup>−1</sup> the temperature rose by 7.793 K. Calculate (i) the standard molar enthalpy of combustion, (ii) the standard internal energy of combustion, and (iii) the standard enthalpy of formation of glucose. (b) What is the biological advantage (in kilojoules per mole of energy released as heat) of complete aerobic oxidation compared with anaerobic glycolysis to lactic acid?

**2.43†** Alkyl radicals are important intermediates in the combustion and atmospheric chemistry of hydrocarbons. Seakins *et al.* (*J. Phys. Chem.* **96**, 9847 (1992)) report  $\Delta_f H^\circ$  for a variety of alkyl radicals in the gas phase, information that is applicable to studies of pyrolysis and oxidation reactions of hydrocarbons. This information can be combined with thermodynamic data on alkenes to determine the reaction enthalpy for possible fragmentation of a large alkyl radical into smaller radicals and alkenes. Use the following data to compute the standard reaction enthalpies for three possible fates of the *tert*-butyl radical, namely, (a) *tert*-C<sub>4</sub>H<sub>9</sub> → *sec*-C<sub>4</sub>H<sub>9</sub>, (b) *tert*-C<sub>4</sub>H<sub>9</sub> → C<sub>3</sub>H<sub>6</sub> + CH<sub>3</sub>, (c) *tert*-C<sub>4</sub>H<sub>9</sub> → C<sub>2</sub>H<sub>4</sub> + C<sub>2</sub>H<sub>5</sub>.

|                                             |                               |                                           |                                            |
|---------------------------------------------|-------------------------------|-------------------------------------------|--------------------------------------------|
| Species:                                    | C <sub>2</sub> H <sub>5</sub> | <i>sec</i> -C <sub>4</sub> H <sub>9</sub> | <i>tert</i> -C <sub>4</sub> H <sub>9</sub> |
| $\Delta_f H^\circ$ /(kJ mol <sup>−1</sup> ) | +121.0                        | +67.5                                     | +51.3                                      |

**2.44†** In 2007, the Intergovernmental Panel on Climate Change (IPCC) considered a global average temperature rise of 1.0–3.5°C likely by the year 2100 with 2.0°C its best estimate. Predict the average rise in sea level due to

thermal expansion of sea water based on temperature rises of 1.0°C, 2.0°C, and 3.5°C given that the volume of the Earth's oceans is  $1.37 \times 10^9$  km<sup>3</sup> and their surface area is  $361 \times 10^6$  km<sup>2</sup>, and state the approximations that go into the estimates.

**2.45†** Concerns over the harmful effects of chlorofluorocarbons on stratospheric ozone have motivated a search for new refrigerants. One such alternative is 2,2-dichloro-1,1,1-trifluoroethane (refrigerant 123). Younglove and McLinden published a compendium of thermophysical properties of this substance (*J. Phys. Chem. Ref. Data* **23**, 7 (1994)), from which properties such as the Joule–Thomson coefficient  $\mu$  can be computed. (a) Compute  $\mu$  at 1.00 bar and 50°C given that  $(\partial H/\partial p)_T = -3.29 \times 10^3$  J MPa<sup>−1</sup> mol<sup>−1</sup> and  $C_{p,m} = 110.0$  J K<sup>−1</sup> mol<sup>−1</sup>. (b) Compute the temperature change that would accompany adiabatic expansion of 2.0 mol of this refrigerant from 1.5 bar to 0.5 bar at 50°C.

**2.46†** Another alternative refrigerant (see preceding problem) is 1,1,1,2-tetrafluoroethane (refrigerant HFC-134a). Tillner-Roth and Baehr published a compendium of thermophysical properties of this substance (*J. Phys. Chem. Ref. Data* **23**, 657 (1994)), from which properties such as the Joule–Thomson coefficient  $\mu$  can be computed. (a) Compute  $\mu$  at 0.100 MPa and 300 K from the following data (all referring to 300 K):

|                                          |        |        |        |
|------------------------------------------|--------|--------|--------|
| $p$ /MPa                                 | 0.080  | 0.100  | 0.12   |
| Specific enthalpy/(kJ kg <sup>−1</sup> ) | 426.48 | 426.12 | 425.76 |

(The specific constant-pressure heat capacity is 0.7649 kJ K<sup>−1</sup> kg<sup>−1</sup>.)

(b) Compute  $\mu$  at 1.00 MPa and 350 K from the following data (all referring to 350 K):

|                                          |        |        |        |
|------------------------------------------|--------|--------|--------|
| $p$ /MPa                                 | 0.80   | 1.00   | 1.2    |
| Specific enthalpy/(kJ kg <sup>−1</sup> ) | 461.93 | 459.12 | 456.15 |

(The specific constant-pressure heat capacity is 1.0392 kJ K<sup>−1</sup> kg<sup>−1</sup>.)

**2.47** Differential scanning calorimetry is used to examine the role of solvent–protein interactions in the denaturation process. Figure 2.34 shows the thermogram for ubiquitin in water with the signal observed for ubiquitin in methanol/water mixtures. Suggest an interpretation of the thermograms.

Fig. 2.34

## MATHEMATICAL BACKGROUND 2

## Multivariate calculus

A thermodynamic property of a system typically depends on a number of variables, such as the internal energy depending on the amount, volume, and temperature. To understand how these properties vary with the conditions we need to understand how to manipulate their derivatives. This is the field of **multivariate calculus**, the calculus of several variables.

## MB2.1 Partial derivatives

A **partial derivative** of a function of more than one variable, such as  $f(x, y)$ , is the slope of the function with respect to one of the variables, all the other variables being held constant (Fig. MB2.1). Although a partial derivative shows how a function changes when one variable changes, it may be used to determine how the function changes when more than one variable changes by an infinitesimal amount. Thus, if  $f$  is a function of  $x$  and  $y$ , then when  $x$  and  $y$  change by  $dx$  and  $dy$ , respectively,  $f$  changes by

$$df = \left( \frac{\partial f}{\partial x} \right)_y dx + \left( \frac{\partial f}{\partial y} \right)_x dy \quad (\text{MB2.1})$$

where the symbol  $\partial$  is used (instead of  $d$ ) to denote a partial derivative and the subscript on the parentheses indicates which variable is being held constant. The quantity  $df$  is also called the

**Fig. MB2.1** A function of two variables,  $f(x, y)$ , as depicted by the coloured surface, and the two partial derivatives,  $(\partial f / \partial x)_y$  and  $(\partial f / \partial y)_x$ , the slope of the function parallel to the  $x$ - and  $y$ -axes, respectively. The function plotted here is  $f(x, y) = ax^3y + by^2$  with  $a = 1$  and  $b = -2$ .

**differential** of  $f$ . Successive partial derivatives may be taken in any order:

$$\left( \frac{\partial}{\partial y} \left( \frac{\partial f}{\partial x} \right) \right)_x = \left( \frac{\partial}{\partial x} \left( \frac{\partial f}{\partial y} \right) \right)_y \quad (\text{MB2.2})$$

## • A brief illustration

Suppose that  $f(x, y) = ax^3y + by^2$  (the function plotted in Fig. MB2.1) then

$$\left( \frac{\partial f}{\partial x} \right)_y = 3ax^2y \quad \left( \frac{\partial f}{\partial y} \right)_x = ax^3 + 2by$$

Then, when  $x$  and  $y$  undergo infinitesimal changes,  $f$  changes by

$$df = 3ax^2y dx + (ax^3 + 2by) dy$$

To verify that the order of taking the second partial derivative is irrelevant, we form

$$\begin{aligned} \left( \frac{\partial}{\partial y} \left( \frac{\partial f}{\partial x} \right) \right)_x &= \left( \frac{\partial (3ax^2y)}{\partial y} \right)_x = 3ax^2 \\ \left( \frac{\partial}{\partial x} \left( \frac{\partial f}{\partial y} \right) \right)_y &= \left( \frac{\partial (ax^3 + 2by)}{\partial x} \right)_y = 3ax^2 \quad \bullet \end{aligned}$$

**Self test MB2.1** Evaluate  $df$  for  $f(x, y) = 2x^2 \sin 3y$  and verify that the order of taking the second derivative is irrelevant.  
 $[df = 4x \sin 3y dx + 6x^2 \cos 3y dy]$

In the following,  $z$  is a variable on which  $x$  and  $y$  depend (for example,  $x$ ,  $y$ , and  $z$  might correspond to  $p$ ,  $V$ , and  $T$ ).

**Relation 1** When  $x$  is changed at constant  $z$ :

$$\left( \frac{\partial f}{\partial x} \right)_z = \left( \frac{\partial f}{\partial x} \right)_y + \left( \frac{\partial f}{\partial y} \right)_x \left( \frac{\partial y}{\partial x} \right)_z \quad (\text{MB2.3a})$$

**Relation 2**

$$\left( \frac{\partial y}{\partial x} \right)_z = \frac{1}{(\partial x / \partial y)_z} \quad (\text{MB2.3b})$$

**Relation 3**

$$\left( \frac{\partial x}{\partial y} \right)_z = - \left( \frac{\partial x}{\partial z} \right)_y \left( \frac{\partial z}{\partial y} \right)_x \quad (\text{MB2.3c})$$

By combining this relation and Relation 2 we obtain the **Euler chain relation**:

$$\left( \frac{\partial y}{\partial x} \right)_z \left( \frac{\partial x}{\partial z} \right)_y \left( \frac{\partial z}{\partial y} \right)_x = -1 \quad \boxed{\text{Euler chain relation}} \quad (\text{MB2.4})$$

**MB2.2 Exact differentials**

The relation in eqn MB2.2 is the basis of a test for an **exact differential**, that is, the test of whether

$$df = g(x,y)dx + h(x,y)dy \quad (\text{MB2.5})$$

has the form in eqn MB2.1. If it has that form, then  $g$  can be identified with  $(\partial f / \partial x)_y$  and  $h$  can be identified with  $(\partial f / \partial y)_x$ . Then eqn MB2.2 becomes

$$\left( \frac{\partial g}{\partial y} \right)_x = \left( \frac{\partial h}{\partial x} \right)_y \quad \boxed{\text{Test for exact differential}} \quad (\text{MB2.6})$$

• **A brief illustration**

Suppose, instead of the form  $df = 3ax^2y dx + (ax^3 + 2by)dy$  in the previous *brief illustration* we were presented with the expression

$$df = \overbrace{3ax^2y dx}^{g(x,y)} + \overbrace{(ax^2 + 2by) dy}^{h(x,y)}$$

with  $ax^2$  in place of  $ax^3$  inside the second parentheses. To test whether this is an exact differential, we form

$$\left( \frac{\partial g}{\partial y} \right)_x = \left( \frac{\partial (3ax^2y)}{\partial y} \right)_x = 3ax^2$$

$$\left( \frac{\partial h}{\partial x} \right)_y = \left( \frac{\partial (ax^2 + 2by)}{\partial x} \right)_y = 2ax$$

These two expressions are not equal, so this form of  $df$  is not an exact differential and there is not a corresponding integrated function of the form  $f(x,y)$ . •

**Self-test MB2.2** Determine whether the expression  $df = (2y - x^3)dx + xdy$  is an exact differential. [No]

If  $df$  is exact, then we can do two things: (1) from a knowledge of the functions  $g$  and  $h$  we can reconstruct the function  $f$ ; (2) we can be confident that the integral of  $df$  between specified limits is independent of the path between those limits. The first conclusion is best demonstrated with a specific example.

• **A brief illustration**

We consider the differential  $df = 3ax^2y dx + (ax^3 + 2by)dy$ , which we know to be exact. Because  $(\partial f / \partial x)_y = 3ax^2y$ , we can integrate with respect to  $x$  with  $y$  held constant, to obtain

$$f = \int df = \int 3ax^2y dx = 3ay \int x^2 dx = ax^3y + k$$

where the ‘constant’ of integration  $k$  may depend on  $y$  (which has been treated as a constant in the integration), but not on  $x$ . To find  $k(y)$ , we note that  $(\partial f / \partial y)_x = ax^3 + 2by$ , and therefore

$$\left( \frac{\partial f}{\partial y} \right)_x = \left( \frac{\partial (ax^3y + k)}{\partial y} \right)_x = ax^3 + \frac{dk}{dy} = ax^3 + 2by$$

Therefore

$$\frac{dk}{dy} = 2by$$

from which it follows that  $k = by^2 + \text{constant}$ . We have found, therefore, that

$$f(x,y) = ax^3y + by^2 + \text{constant}$$

which, apart from the constant, is the original function in the first *brief illustration*. The value of the constant is pinned down by stating the boundary conditions; thus, if it is known that  $f(0,0) = 0$ , then the constant is zero. •

**Self-test MB2.3** Confirm that  $df = 3x^2 \cos y dx - x^3 \sin y dy$  is exact and find the function  $f(x,y)$ . [ $f = x^3 \cos y$ ]

To demonstrate that the integral of  $df$  is independent of the path is now straightforward. Because  $df$  is a differential, its integral between the limits  $a$  and  $b$  is

$$\int_a^b df = f(b) - f(a)$$

The value of the integral depends only on the values at the end points and is independent of the path between them. If  $df$  is not an exact differential, the function  $f$  does not exist, and this argument no longer holds. In such cases, the integral of  $df$  does depend on the path.

• **A brief illustration**

Consider the inexact differential (the expression with  $ax^2$  in place of  $ax^3$  inside the second parentheses):

$$df = 3ax^2y dx + (ax^2 + 2by)dy$$

Suppose we integrate  $df$  from  $(0,0)$  to  $(2,2)$  along the two paths shown in Fig. MB2.2. Along Path 1,

$$\begin{aligned} \int_{\text{Path 1}} df &= \int_{0,0}^{2,0} 3ax^2y dx + \int_{2,0}^{2,2} (ax^2 + 2by) dy \\ &= 0 + 4a \int_0^2 dy + 2b \int_0^2 y dy = 8a + 4b \end{aligned}$$

whereas along Path 2,

$$\begin{aligned} \int_{\text{Path 2}} df &= \int_{0,2}^{2,2} 3ax^2y dx + \int_{0,0}^{0,2} (ax^2 + 2by) dy \\ &= 6a \int_0^2 x^2 dx + 0 + 2b \int_0^2 y dy = 16a + 4b \end{aligned}$$

The two integrals are not the same. •

**Self-test MB2.4** Confirm that the two paths do give the same value for the exact differential in the first *brief illustration*.  
[Both paths:  $16a + 4b$ ]

An inexact differential may sometimes be converted into an exact differential by multiplication by a factor known as an *integrating factor*. A physical example is the integrating factor  $1/T$  that converts the inexact differential  $dq_{\text{rev}}$  into the exact differential  $dS$  in thermodynamics (see Chapter 3).

#### • A brief illustration

We have seen that the differential  $df = 3ax^2ydx + (ax^2 + 2by)dy$  is inexact; the same is true when we set  $b = 0$  and consider

$df = 3ax^2ydx + ax^2dy$  instead. Suppose we multiply this  $df$  by  $x^m y^n$  and write  $x^m y^n df = df'$ , then we obtain

$$df' = \overbrace{3ax^{m+2}y^{n+1}}^{g(x,y)}dx + \overbrace{ax^{m+2}y^n}_{h(x,y)}dy$$

We evaluate the following two partial derivatives:

$$\left(\frac{\partial g}{\partial y}\right)_x = \left(\frac{\partial(3ax^{m+2}y^{n+1})}{\partial y}\right)_x = 3a(n+1)x^{m+2}y^n$$

$$\left(\frac{\partial h}{\partial x}\right)_y = \left(\frac{\partial(ax^{m+2}y^n)}{\partial x}\right)_y = a(m+2)x^{m+1}y^n$$

For the new differential to be exact, these two partial derivatives must be equal, so we write

$$3a(n+1)x^{m+2}y^n = a(m+2)x^{m+1}y^n$$

which simplifies to

$$3(n+1)x = m+2$$

The only solution that is independent of  $x$  is  $n = -1$  and  $m = -2$ . It follows that

$$df' = 3adx + (a/y)dy$$

is an exact differential. By the procedure already illustrated, its integrated form is  $f'(x,y) = 3ax + a \ln y + \text{constant}$ . •

**Self-test MB2.5** Find an integrating factor of the form  $x^m y^n$  for the inexact differential  $df = (2y - x^3)dx + xdy$  and the integrated form of  $f'$ .

$$[df' = xdf, f' = yx^2 - \frac{1}{5}x^5 + \text{constant}]$$

Problems

The purpose of this chapter is to explain the origin of the spontaneity of physical and chemical change. We examine two simple processes and show how to define, measure, and use a property, the entropy, to discuss spontaneous changes quantitatively. The chapter also introduces a major subsidiary thermodynamic property, the Gibbs energy, which lets us express the spontaneity of a process in terms of the properties of a system. The Gibbs energy also enables us to predict the maximum non-expansion work that a process can do. As we began to see in Chapter 2, one application of thermodynamics is to find relations between properties that might not be thought to be related. Several relations of this kind can be established by making use of the fact that the Gibbs energy is a state function. We also see how to derive expressions for the variation of the Gibbs energy with temperature and pressure and how to formulate expressions that are valid for real gases. These expressions will prove useful later when we discuss the effect of temperature and pressure on equilibrium constants.

Some things happen naturally; some things don't. A gas expands to fill the available volume, a hot body cools to the temperature of its surroundings, and a chemical reaction runs in one direction rather than another. Some aspect of the world determines the **spontaneous** direction of change, the direction of change that does not require work to bring it about. A gas can be confined to a smaller volume, an object can be cooled by using a refrigerator, and some reactions can be driven in reverse (as in the electrolysis of water). However, none of these processes is spontaneous; each one must be brought about by doing work. An important point, though, is that throughout this text 'spontaneous' must be interpreted as a natural *tendency* that may or may not be realized in practice. Thermodynamics is silent on the rate at which a spontaneous change in fact occurs, and some spontaneous processes (such as the conversion of diamond to graphite) may be so slow that the tendency is never realized in practice whereas others (such as the expansion of a gas into a vacuum) are almost instantaneous.

The recognition of two classes of process, spontaneous and non-spontaneous, is summarized by the **Second Law of thermodynamics**. This law may be expressed in a variety of equivalent ways. One statement was formulated by Kelvin:

No process is possible in which the sole result is the absorption of heat from a reservoir and its complete conversion into work.

For example, it has proved impossible to construct an engine like that shown in Fig. 3.1, in which heat is drawn from a hot reservoir and completely converted into work. All real heat engines have both a hot source and a cold sink; some energy is always discarded into the cold sink as heat and not converted into work. The Kelvin

statement is a generalization of another everyday observation, that a ball at rest on a surface has never been observed to leap spontaneously upwards. An upward leap of the ball would be equivalent to the conversion of heat from the surface into work.

## The direction of spontaneous change

What determines the direction of spontaneous change? It is not the total energy of the isolated system. The First Law of thermodynamics states that energy is conserved in any process, and we cannot disregard that law now and say that everything tends towards a state of lower energy: the total energy of an isolated system is constant.

Is it perhaps the energy of the *system* that tends towards a minimum? Two arguments show that this cannot be so. First, a perfect gas expands spontaneously into a vacuum, yet its internal energy remains constant as it does so. Secondly, if the energy of a system does happen to decrease during a spontaneous change, the energy of its surroundings must increase by the same amount (by the First Law). The increase in energy of the surroundings is just as spontaneous a process as the decrease in energy of the system.

When a change occurs, the total energy of an isolated system remains constant but it is parcelled out in different ways. Can it be, therefore, that the direction of change is related to the *distribution* of energy? We shall see that this idea is the key, and that spontaneous changes are always accompanied by a dispersal of energy.

### 3.1 The dispersal of energy

**Key point** During a spontaneous change in an isolated system the total energy is dispersed into random thermal motion of the particles in the system.

We can begin to understand the role of the distribution of energy by thinking about a ball (the system) bouncing on a floor (the surroundings). The ball does not rise as high after each bounce because there are inelastic losses in the materials of the ball and floor. The kinetic energy of the ball's overall motion is spread out into the energy of thermal motion of its particles and those of the floor that it hits. The direction of spontaneous change is towards a state in which the ball is at rest with all its energy dispersed into disorderly thermal motion of molecules in the air and of the atoms of the virtually infinite floor (Fig. 3.2).

A ball resting on a warm floor has never been observed to start bouncing. For bouncing to begin, something rather special would need to happen. In the first place, some of the thermal motion of the atoms in the floor would have to accumulate in a single, small object, the ball. This accumulation requires a spontaneous localization of energy from the myriad vibrations of the atoms of the floor into the much smaller number of atoms that constitute the ball (Fig. 3.3). Furthermore, whereas the thermal motion is random, for the ball to move upwards its atoms must all move in the same direction. The localization of random, disorderly motion as concerted, ordered motion is so unlikely that we can dismiss it as virtually impossible.<sup>1</sup>

We appear to have found the signpost of spontaneous change: *we look for the direction of change that leads to dispersal of the total energy of the isolated system*. This principle accounts for the direction of change of the bouncing ball, because its energy

**Fig. 3.1** The Kelvin statement of the Second Law denies the possibility of the process illustrated here, in which heat is changed completely into work, there being no other change. The process is not in conflict with the First Law because energy is conserved.

**Fig. 3.2** The direction of spontaneous change for a ball bouncing on a floor. On each bounce some of its energy is degraded into the thermal motion of the atoms of the floor, and that energy disperses. The reverse has never been observed to take place on a macroscopic scale.

<sup>1</sup> Concerted motion, but on a much smaller scale, is observed as *Brownian motion*, the jittering motion of small particles suspended in a liquid or gas.

**Fig. 3.3** The molecular interpretation of the irreversibility expressed by the Second Law. (a) A ball resting on a warm surface; the atoms are undergoing thermal motion (vibration, in this instance), as indicated by the arrows. (b) For the ball to fly upwards, some of the random vibrational motion would have to change into coordinated, directed motion. Such a conversion is highly improbable.

is spread out as thermal motion of the atoms of the floor. The reverse process is not spontaneous because it is highly improbable that energy will become localized, leading to uniform motion of the ball's atoms. A gas does not contract spontaneously because to do so the random motion of its molecules, which spreads out the distribution of kinetic energy throughout the container, would have to take them all into the same region of the container, thereby localizing the energy. The opposite change, spontaneous expansion, is a natural consequence of energy becoming more dispersed as the gas molecules occupy a larger volume. An object does not spontaneously become warmer than its surroundings because it is highly improbable that the jostling of randomly vibrating atoms in the surroundings will lead to the localization of thermal motion in the object. The opposite change, the spreading of the object's energy into the surroundings as thermal motion, is natural.

It may seem very puzzling that the spreading out of energy and matter can lead to the formation of such ordered structures as crystals or proteins. Nevertheless, in due course, we shall see that dispersal of energy and matter accounts for change in all its forms.

### 3.2 Entropy

**Key points** The entropy acts as a signpost of spontaneous change. (a) Entropy change is defined in terms of heat transactions (the Clausius definition). (b) Absolute entropies are defined in terms of the number of ways of achieving a configuration (the Boltzmann formula). (c) The Carnot cycle is used to prove that entropy is a state function. (d) The efficiency of a heat engine is the basis of the definition of the thermodynamic temperature scale and one realization, the Kelvin scale. (e) The Clausius inequality is used to show that the entropy increases in a spontaneous change and therefore that the Clausius definition is consistent with the Second Law.

The First Law of thermodynamics led to the introduction of the internal energy,  $U$ . The internal energy is a state function that lets us assess whether a change is permissible: only those changes may occur for which the internal energy of an isolated system remains constant. The law that is used to identify the signpost of spontaneous change, the Second Law of thermodynamics, may also be expressed in terms of another state function, the **entropy**,  $S$ . We shall see that the entropy (which we shall define shortly, but is a measure of the energy dispersed in a process) lets us assess whether one state is accessible from another by a spontaneous change. The First Law uses the internal energy to identify *permissible* changes; the Second Law uses the entropy to identify the *spontaneous changes* among those permissible changes.

The Second Law of thermodynamics can be expressed in terms of the entropy:

The entropy of an isolated system increases in the course of a spontaneous change:  

$$\Delta S_{\text{tot}} > 0$$

where  $S_{\text{tot}}$  is the total entropy of the system and its surroundings. Thermodynamically irreversible processes (like cooling to the temperature of the surroundings and the free expansion of gases) are spontaneous processes, and hence must be accompanied by an increase in total entropy.

#### (a) The thermodynamic definition of entropy

The thermodynamic definition of entropy concentrates on the change in entropy,  $dS$ , that occurs as a result of a physical or chemical change (in general, as a result of a 'process'). The definition is motivated by the idea that a change in the extent to which energy is dispersed depends on how much energy is transferred as heat. As we have remarked, heat stimulates random motion in the surroundings. On the other hand,

work stimulates uniform motion of atoms in the surroundings and so does not change their entropy.

The thermodynamic definition of entropy is based on the expression

$$dS = \frac{dq_{\text{rev}}}{T} \quad \text{Definition of entropy change} \quad [3.1]$$

where  $q_{\text{rev}}$  is the heat supplied reversibly. For a measurable change between two states i and f this expression integrates to

$$\Delta S = \int_i^f \frac{dq_{\text{rev}}}{T} \quad (3.2)$$

That is, to calculate the difference in entropy between any two states of a system, we find a *reversible* path between them, and integrate the energy supplied as heat at each stage of the path divided by the temperature at which heating occurs.

**Example 3.1** Calculating the entropy change for the isothermal expansion of a perfect gas

Calculate the entropy change of a sample of perfect gas when it expands isothermally from a volume  $V_i$  to a volume  $V_f$ .

**Method** The definition of entropy instructs us to find the energy supplied as heat for a reversible path between the stated initial and final states regardless of the actual manner in which the process takes place. A simplification is that the expansion is isothermal, so the temperature is a constant and may be taken outside the integral in eqn 3.2. The energy absorbed as heat during a reversible isothermal expansion of a perfect gas can be calculated from  $\Delta U = q + w$  and  $\Delta U = 0$ , which implies that  $q = -w$  in general and therefore that  $q_{\text{rev}} = -w_{\text{rev}}$  for a reversible change. The work of reversible isothermal expansion was calculated in Section 2.3.

**Answer** Because the temperature is constant, eqn 3.2 becomes

$$\Delta S = \frac{1}{T} \int_i^f dq_{\text{rev}} = \frac{q_{\text{rev}}}{T}$$

From eqn 2.10, we know that

$$q_{\text{rev}} = -w_{\text{rev}} = nRT \ln \frac{V_f}{V_i}$$

It follows that

$$\Delta S = nR \ln \frac{V_f}{V_i}$$

• **A brief illustration**

When the volume occupied by 1.00 mol of any perfect gas molecules is doubled at any constant temperature,  $V_f/V_i = 2$  and

$$\Delta S = (1.00 \text{ mol}) \times (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times \ln 2 = +5.76 \text{ J K}^{-1} \quad \bullet$$

**A note on good practice** According to eqn 3.2, when the energy transferred as heat is expressed in joules and the temperature is in kelvins, the units of entropy are joules per kelvin ( $\text{J K}^{-1}$ ). Entropy is an extensive property. Molar entropy, the entropy divided by the amount of substance, is expressed in joules per kelvin per mole ( $\text{J K}^{-1} \text{ mol}^{-1}$ ). The units of entropy are the same as those of the gas constant,  $R$ , and molar heat capacities. Molar entropy is an intensive property.

**Self-test 3.1** Calculate the change in entropy when the pressure of a fixed amount of perfect gas is changed isothermally from  $p_i$  to  $p_f$ . What is this change due to?

[ $\Delta S = nR \ln(p_i/p_f)$ ; the change in volume when the gas is compressed]

We can use the definition in eqn 3.1 to formulate an expression for the change in entropy of the surroundings,  $\Delta S_{\text{sur}}$ . Consider an infinitesimal transfer of heat  $dq_{\text{sur}}$  to the surroundings. The surroundings consist of a reservoir of constant volume, so the energy supplied to them by heating can be identified with the change in the internal energy of the surroundings,  $dU_{\text{sur}}$ .<sup>2</sup> The internal energy is a state function, and  $dU_{\text{sur}}$  is an exact differential. As we have seen, these properties imply that  $dU_{\text{sur}}$  is independent of how the change is brought about and in particular is independent of whether the process is reversible or irreversible. The same remarks therefore apply to  $dq_{\text{sur}}$ , to which  $dU_{\text{sur}}$  is equal. Therefore, we can adapt the definition in eqn 3.1, delete the constraint ‘reversible’, and write

$$dS_{\text{sur}} = \frac{dq_{\text{sur,rev}}}{T_{\text{sur}}} = \frac{dq_{\text{sur}}}{T_{\text{sur}}} \quad \text{Entropy change of the surroundings} \quad (3.3a)$$

Furthermore, because the temperature of the surroundings is constant whatever the change, for a measurable change

$$\Delta S_{\text{sur}} = \frac{q_{\text{sur}}}{T_{\text{sur}}} \quad (3.3b)$$

That is, regardless of how the change is brought about in the system, reversibly or irreversibly, we can calculate the change of entropy of the surroundings by dividing the heat transferred by the temperature at which the transfer takes place.

Equation 3.3 makes it very simple to calculate the changes in entropy of the surroundings that accompany any process. For instance, for any adiabatic change,  $q_{\text{sur}} = 0$ , so

$$\text{For an adiabatic change:} \quad \Delta S_{\text{sur}} = 0 \quad (3.4)$$

This expression is true however the change takes place, reversibly or irreversibly, provided no local hot spots are formed in the surroundings. That is, it is true so long as the surroundings remain in internal equilibrium. If hot spots do form, then the localized energy may subsequently disperse spontaneously and hence generate more entropy.

#### • A brief illustration

To calculate the entropy change in the surroundings when 1.00 mol  $\text{H}_2\text{O}(\text{l})$  is formed from its elements under standard conditions at 298 K, we use  $\Delta H^\circ = -286 \text{ kJ}$  from Table 2.8. The energy released as heat is supplied to the surroundings, now regarded as being at constant pressure, so  $q_{\text{sur}} = +286 \text{ kJ}$ . Therefore,

$$\Delta S_{\text{sur}} = \frac{2.86 \times 10^5 \text{ J}}{298 \text{ K}} = +960 \text{ J K}^{-1}$$

This strongly exothermic reaction results in an increase in the entropy of the surroundings as energy is released as heat into them. •

**Self-test 3.2** Calculate the entropy change in the surroundings when 1.00 mol  $\text{N}_2\text{O}_4(\text{g})$  is formed from 2.00 mol  $\text{NO}_2(\text{g})$  under standard conditions at 298 K.  
[−192 J K<sup>−1</sup>]

<sup>2</sup> Alternatively, the surroundings can be regarded as being at constant pressure, in which case we could equate  $dq_{\text{sur}}$  to  $dH_{\text{sur}}$ .

**(b) The statistical view of entropy**

The entry point into the molecular interpretation of the Second Law of thermodynamics is Boltzmann's insight, first explored in Section F.5a, that an atom or molecule can possess only certain values of the energy, called its 'energy levels'. The continuous thermal agitation that molecules experience in a sample at  $T > 0$  ensures that they are distributed over the available energy levels. Boltzmann also made the link between the distribution of molecules over energy levels and the entropy. He proposed that the entropy of a system is given by

$$S = k \ln W \quad \text{Boltzmann formula for the entropy} \quad (3.5)$$

where  $k = 1.381 \times 10^{-23} \text{ J K}^{-1}$  and  $W$  is the number of *microstates*, the ways in which the molecules of a system can be arranged while keeping the total energy constant. Each microstate lasts only for an instant and corresponds to a certain distribution of molecules over the available energy levels. When we measure the properties of a system, we are measuring an average taken over the many microstates the system can occupy under the conditions of the experiment. The concept of the number of microstates makes quantitative the ill-defined qualitative concepts of 'disorder' and 'the dispersal of matter and energy' that are used widely to introduce the concept of entropy: a more 'disorderly' distribution of energy and matter corresponds to a greater number of microstates associated with the same total energy.

Equation 3.5 is known as the **Boltzmann formula** and the entropy calculated from it is sometimes called the **statistical entropy**. We see that, if  $W = 1$ , which corresponds to one microstate (only one way of achieving a given energy, all molecules in exactly the same state), then  $S = 0$  because  $\ln 1 = 0$ . However, if the system can exist in more than one microstate, then  $W > 1$  and  $S > 0$ . If the molecules in the system have access to a greater number of energy levels, then there may be more ways of achieving a given total energy, that is, there are more microstates for a given total energy,  $W$  is greater, and the entropy is greater than when fewer states are accessible. Therefore, the statistical view of entropy summarized by the Boltzmann formula is consistent with our previous statement that the entropy is related to the dispersal of energy. In particular, for a gas of particles in a container, the energy levels become closer together as the container expands (Fig. 3.4; this is a conclusion from quantum theory that we shall verify in Chapter 8). As a result, more microstates become possible,  $W$  increases, and the entropy increases, exactly as we inferred from the thermodynamic definition of entropy.

The molecular interpretation of entropy advanced by Boltzmann also suggests the thermodynamic definition given by eqn 3.1. To appreciate this point, consider that molecules in a system at high temperature can occupy a large number of the available energy levels, so a small additional transfer of energy as heat will lead to a relatively small change in the number of accessible energy levels. Consequently, the number of microstates does not increase appreciably and neither does the entropy of the system. In contrast, the molecules in a system at low temperature have access to far fewer energy levels (at  $T = 0$ , only the lowest level is accessible), and the transfer of the same quantity of energy by heating will increase the number of accessible energy levels and the number of microstates significantly. Hence, the change in entropy upon heating will be greater when the energy is transferred to a cold body than when it is transferred to a hot body. This argument suggests that the change in entropy should be inversely proportional to the temperature at which the transfer takes place, as in eqn 3.1.

**Fig. 3.4** When a box expands, the energy levels move closer together and more become accessible to the molecules. As a result the partition function increases and so does the entropy.

**Fig. 3.5** In a thermodynamic cycle, the overall change in a state function (from the initial state to the final state and then back to the initial state again) is zero.

**Fig. 3.6** The basic structure of a Carnot cycle. In Step 1, there is an isothermal reversible expansion at the temperature  $T_h$ . Step 2 is a reversible adiabatic expansion in which the temperature falls from  $T_h$  to  $T_c$ . In Step 3 there is an isothermal reversible compression at  $T_c$ , and that isothermal step is followed by an adiabatic reversible compression, which restores the system to its initial state.

### (c) The entropy as a state function

Entropy is a state function. To prove this assertion, we need to show that the integral of  $dS$  is independent of path. To do so, it is sufficient to prove that the integral of eqn 3.1 around an arbitrary cycle is zero, for that guarantees that the entropy is the same at the initial and final states of the system regardless of the path taken between them (Fig. 3.5). That is, we need to show that

$$\oint \frac{dq_{\text{rev}}}{T_{\text{sur}}} = 0 \quad (3.6)$$

where the symbol  $\oint$  denotes integration around a closed path. There are three steps in the argument:

1. First, to show that eqn 3.6 is true for a special cycle (a ‘Carnot cycle’) involving a perfect gas.
2. Then to show that the result is true whatever the working substance.
3. Finally, to show that the result is true for any cycle.

A **Carnot cycle**, which is named after the French engineer Sadi Carnot, consists of four reversible stages (Fig. 3.6):

1. Reversible isothermal expansion from A to B at  $T_h$ ; the entropy change is  $q_h/T_h$ , where  $q_h$  is the energy supplied to the system as heat from the hot source.
2. Reversible adiabatic expansion from B to C. No energy leaves the system as heat, so the change in entropy is zero. In the course of this expansion, the temperature falls from  $T_h$  to  $T_c$ , the temperature of the cold sink.
3. Reversible isothermal compression from C to D at  $T_c$ . Energy is released as heat to the cold sink; the change in entropy of the system is  $q_c/T_c$ ; in this expression  $q_c$  is negative.
4. Reversible adiabatic compression from D to A. No energy enters the system as heat, so the change in entropy is zero. The temperature rises from  $T_c$  to  $T_h$ .

The total change in entropy around the cycle is the sum of the changes in each of these four steps:

$$\oint dS = \frac{q_h}{T_h} + \frac{q_c}{T_c}$$

However, we show in the following *Justification* that for a perfect gas

$$\frac{q_h}{q_c} = -\frac{T_h}{T_c} \quad (3.7)$$

Substitution of this relation into the preceding equation gives zero on the right, which is what we wanted to prove.

#### Justification 3.1 Heating accompanying reversible adiabatic expansion

This *Justification* is based on two features of the cycle. One feature is that the two temperatures  $T_h$  and  $T_c$  in eqn 3.7 lie on the same adiabat in Fig. 3.6. The second feature is that the energies transferred as heat during the two isothermal stages are

$$q_h = nRT_h \ln \frac{V_B}{V_A} \quad q_c = nRT_c \ln \frac{V_D}{V_C}$$

We now show that the two volume ratios are related in a very simple way. From the relation between temperature and volume for reversible adiabatic processes ( $VT^c = \text{constant}$ , eqn 2.28):

$$V_A T_h^c = V_D T_c^c \quad V_C T_c^c = V_B T_h^c$$

Multiplication of the first of these expressions by the second gives

$$V_A V_C T_h^c T_c^c = V_D V_B T_h^c T_c^c$$

which, on cancellation of the temperatures, simplifies to

$$\frac{V_A}{V_B} = \frac{V_D}{V_C}$$

With this relation established, we can write

$$q_c = nRT_c \ln \frac{V_D}{V_C} = nRT_c \ln \frac{V_A}{V_B} = -nRT_c \ln \frac{V_B}{V_A}$$

and therefore

$$\frac{q_h}{q_c} = \frac{nRT_h \ln(V_B/V_A)}{-nRT_c \ln(V_B/V_A)} = -\frac{T_h}{T_c}$$

as in eqn 3.7.

In the second step we need to show that eqn 3.6 applies to any material, not just a perfect gas (which is why, in anticipation, we have not labelled it with a °). We begin this step of the argument by introducing the **efficiency**,  $\eta$  (eta), of a heat engine:

$$\eta = \frac{\text{work performed}}{\text{heat absorbed from hot source}} = \frac{|w|}{|q_h|} \quad \boxed{\text{Definition of efficiency}} \quad [3.8]$$

We are using modulus signs to avoid complications with signs: all efficiencies are positive numbers. The definition implies that, the greater the work output for a given supply of heat from the hot reservoir, the greater is the efficiency of the engine. We can express the definition in terms of the heat transactions alone, because (as shown in Fig. 3.7), the energy supplied as work by the engine is the difference between the energy supplied as heat by the hot reservoir and returned to the cold reservoir:

$$\eta = \frac{|q_h| - |q_c|}{|q_h|} = 1 - \frac{|q_c|}{|q_h|} \quad (3.9)$$

It then follows from eqn 3.7 (noting that the modulus signs remove the minus sign) that

$$\eta = 1 - \frac{T_c}{T_h} \quad \boxed{\text{Carnot efficiency}} \quad (3.10)_{\text{rev}}$$

Now we are ready to generalize this conclusion. The Second Law of thermodynamics implies that *all reversible engines have the same efficiency regardless of their construction*. To see the truth of this statement, suppose two reversible engines are coupled together and run between the same two reservoirs (Fig. 3.8). The working substances and details of construction of the two engines are entirely arbitrary. Initially, suppose that engine A is more efficient than engine B, and that we choose a setting of the controls that causes engine B to acquire energy as heat  $q_c$  from the cold reservoir and to release a certain quantity of energy as heat into the hot reservoir. However, because engine A is more efficient than engine B, not all the work that A produces is needed for

**Fig. 3.7** Suppose an energy  $q_h$  (for example, 20 kJ) is supplied to the engine and  $q_c$  is lost from the engine (for example,  $q_c = -15$  kJ) and discarded into the cold reservoir. The work done by the engine is equal to  $q_h + q_c$  (for example, 20 kJ + (-15 kJ) = 5 kJ). The efficiency is the work done divided by the energy supplied as heat from the hot source.

**Fig. 3.8** (a) The demonstration of the equivalence of the efficiencies of all reversible engines working between the same thermal reservoirs is based on the flow of energy represented in this diagram. (b) The net effect of the processes is the conversion of heat into work without there being a need for a cold sink: this is contrary to the Kelvin statement of the Second Law.

this process, and the difference can be used to do work. The net result is that the cold reservoir is unchanged, work has been done, and the hot reservoir has lost a certain amount of energy. This outcome is contrary to the Kelvin statement of the Second Law, because some heat has been converted directly into work. In molecular terms, the random thermal motion of the hot reservoir has been converted into ordered motion characteristic of work. Because the conclusion is contrary to experience, the initial assumption that engines A and B can have different efficiencies must be false. It follows that the relation between the heat transfers and the temperatures must also be independent of the working material, and therefore that eqn 3.10 is always true for any substance involved in a Carnot cycle.

For the final step in the argument, we note that any reversible cycle can be approximated as a collection of Carnot cycles and the integral around an arbitrary path is the sum of the integrals around each of the Carnot cycles (Fig. 3.9). This approximation becomes exact as the individual cycles are allowed to become infinitesimal. The entropy change around each individual cycle is zero (as demonstrated above), so the sum of entropy changes for all the cycles is zero. However, in the sum, the entropy change along any individual path is cancelled by the entropy change along the path it shares with the neighbouring cycle. Therefore, all the entropy changes cancel except for those along the perimeter of the overall cycle. That is,

$$\sum_{\text{all}} \frac{q_{\text{rev}}}{T} = \sum_{\text{perimeter}} \frac{q_{\text{rev}}}{T} = 0$$

In the limit of infinitesimal cycles, the non-cancelling edges of the Carnot cycles match the overall cycle exactly, and the sum becomes an integral. Equation 3.6 then follows immediately. This result implies that  $dS$  is an exact differential and therefore that  $S$  is a state function.

#### (d) The thermodynamic temperature

Suppose we have an engine that is working reversibly between a hot source at a temperature  $T_h$  and a cold sink at a temperature  $T$ , then we know from eqn 3.10 that

$$T = (1 - \eta)T_h \quad (3.11)$$

This expression enabled Kelvin to define the **thermodynamic temperature scale** in terms of the efficiency of a heat engine: we construct an engine in which the hot source is at a known temperature and the cold sink is the object of interest. The temperature of the latter can then be inferred from the measured efficiency of the engine. The **Kelvin scale** (which is a special case of the thermodynamic temperature scale) is defined by using water at its triple point as the notional hot source and defining that temperature as 273.16 K exactly. For instance, if it is found that the efficiency of such an engine is 0.20, then the temperature of the cold sink is  $0.80 \times 273.16 \text{ K} = 220 \text{ K}$ . This result is independent of the working substance of the engine.

#### (e) The Clausius inequality

We now show that the definition of entropy is consistent with the Second Law. To begin, we recall that more work is done when a change is reversible than when it is irreversible. That is,  $|dw_{\text{rev}}| \geq |dw|$ . Because  $dw$  and  $dw_{\text{rev}}$  are negative when energy leaves the system as work, this expression is the same as  $-dw_{\text{rev}} \geq -dw$ , and hence  $dw - dw_{\text{rev}} \geq 0$ . Because the internal energy is a state function, its change is the same for irreversible and reversible paths between the same two states, so we can also write:

$$dU = dq + dw = dq_{\text{rev}} + dw_{\text{rev}}$$

It follows that  $dq_{\text{rev}} - dq = dw - dw_{\text{rev}} \geq 0$ , or  $dq_{\text{rev}} \geq dq$ , and therefore that  $dq_{\text{rev}}/T \geq dq/T$ . Now we use the thermodynamic definition of the entropy (eqn 3.1;  $dS = dq_{\text{rev}}/T$ ) to write

$$dS \geq \frac{dq}{T} \quad \text{Clausius inequality} \quad (3.12)$$

This expression is the **Clausius inequality**. It will prove to be of great importance for the discussion of the spontaneity of chemical reactions, as we shall see in Section 3.5.

### • A brief illustration

Consider the transfer of energy as heat from one system—the hot source—at a temperature  $T_h$  to another system—the cold sink—at a temperature  $T_c$  (Fig. 3.10). When  $|dq|$  leaves the hot source (so  $dq_h < 0$ ), the Clausius inequality implies that  $dS \geq dq_h/T_h$ . When  $|dq|$  enters the cold sink the Clausius inequality implies that  $dS \geq dq_c/T_c$  (with  $dq_c > 0$ ). Overall, therefore,

$$dS \geq \frac{dq_h}{T_h} + \frac{dq_c}{T_c}$$

However,  $dq_h = -dq_c$ , so

$$dS \geq -\frac{dq_c}{T_h} + \frac{dq_c}{T_c} = \left( \frac{1}{T_c} - \frac{1}{T_h} \right) dq_c$$

which is positive (because  $dq_c > 0$  and  $T_h > T_c$ ). Hence, cooling (the transfer of heat from hot to cold) is spontaneous, as we know from experience. •

We now suppose that the system is isolated from its surroundings, so that  $dq = 0$ . The Clausius inequality implies that

$$dS \geq 0 \quad (3.13)$$

and we conclude that *in an isolated system the entropy cannot decrease when a spontaneous change occurs*. This statement captures the content of the Second Law.

## IMPACT ON ENGINEERING

### 13.1 Refrigeration

The same argument that we have used to discuss the efficiency of a heat engine can be used to discuss the efficiency of a refrigerator, a device for transferring energy as heat from a cold object (the contents of the refrigerator) to a warm sink (typically, the room in which the refrigerator stands). The less work we have to do to bring this transfer about, the more efficient is the refrigerator.

When an energy  $|q_c|$  migrates from a cool source at a temperature  $T_c$  into a warmer sink at a temperature  $T_h$ , the change in entropy is

$$\Delta S = -\frac{|q_c|}{T_c} + \frac{|q_c|}{T_h} < 0 \quad (3.14)$$

The process is not spontaneous because not enough entropy is generated in the warm sink to overcome the entropy loss from the cold source (Fig. 3.11). To generate more entropy, energy must be added to the stream that enters the warm sink. Our task is to find the minimum energy that needs to be supplied. The outcome is expressed as the **coefficient of performance**,  $c$ :

$$c = \frac{\text{energy transferred as heat}}{\text{energy transferred as work}} = \frac{|q_c|}{|w|} \quad \text{Definition of coefficient of performance} \quad (3.15)$$

**Fig. 3.9** A general cycle can be divided into small Carnot cycles. The match is exact in the limit of infinitesimally small cycles. Paths cancel in the interior of the collection, and only the perimeter, an increasingly good approximation to the true cycle as the number of cycles increases, survives. Because the entropy change around every individual cycle is zero, the integral of the entropy around the perimeter is zero too.

**Fig. 3.10** When energy leaves a hot reservoir as heat, the entropy of the reservoir decreases. When the same quantity of energy enters a cooler reservoir, the entropy increases by a larger amount. Hence, overall there is an increase in entropy and the process is spontaneous. Relative changes in entropy are indicated by the sizes of the arrows.

**Fig. 3.11** (a) The flow of energy as heat from a cold source to a hot sink is not spontaneous. As shown here, the entropy increase of the hot sink is smaller than the entropy decrease of the cold source, so there is a net decrease in entropy. (b) The process becomes feasible if work is provided to add to the energy stream. Then the increase in entropy of the hot sink can be made to cancel the entropy decrease of the cold source.

The less the work that is required to achieve a given transfer, the greater the coefficient of performance and the more efficient is the refrigerator. For some of this development it will prove best to work with  $1/c$ .

Because  $|q_c|$  is removed from the cold source, and the work  $|w|$  is added to the energy stream, the energy deposited as heat in the hot sink is  $|q_h| = |q_c| + |w|$ . Therefore,

$$\frac{1}{c} = \frac{|w|}{|q_c|} = \frac{|q_h| - |q_c|}{|q_c|} = \frac{|q_h|}{|q_c|} - 1$$

We can now use eqn 3.7 to express this result in terms of the temperatures alone, which is possible if the transfer is performed reversibly. This substitution leads to

$$\frac{1}{c} = \frac{T_h}{T_c} - 1 = \frac{T_h - T_c}{T_c}$$

and therefore

$$c = \frac{T_c}{T_h - T_c} \quad (3.16)_{\text{rev}}$$

for the thermodynamically optimum coefficient of performance.

#### • A brief illustration

For a refrigerator withdrawing heat from ice-cold water ( $T_c = 273 \text{ K}$ ) in a typical environment ( $T_h = 293 \text{ K}$ ),  $c = 14$ , so, to remove  $10 \text{ kJ}$  (enough to freeze  $30 \text{ g}$  of water), requires transfer of at least  $0.71 \text{ kJ}$  as work. Practical refrigerators, of course, have a lower coefficient of performance. •

### 3.3 Entropy changes accompanying specific processes

**Key points** (a) The entropy of a perfect gas increases when it expands isothermally. (b) The change in entropy of a substance accompanying a change of state at its transition temperature is calculated from its enthalpy of transition. (c) The increase in entropy when a substance is heated is expressed in terms of its heat capacity. (d) The entropy of a substance at a given temperature is determined from measurements of its heat capacity from  $T = 0$  up to the temperature of interest, allowing for phase transitions in that range.

We now see how to calculate the entropy changes that accompany a variety of basic processes.

#### (a) Expansion

We established in Example 3.1 that the change in entropy of a perfect gas that expands isothermally from  $V_i$  to  $V_f$  is

$$\Delta S = nR \ln \frac{V_f}{V_i} \quad \text{Entropy change for the isothermal expansion of a perfect gas} \quad (3.17)^{\circ}$$

Because  $S$  is a state function, the value of  $\Delta S$  of the system is independent of the path between the initial and final states, so this expression applies whether the change of state occurs reversibly or irreversibly. The logarithmic dependence of entropy on volume is illustrated in Fig. 3.12.

The total change in entropy, however, does depend on how the expansion takes place. For any process the energy lost as heat from the system is acquired by the

surroundings, so  $dq_{\text{sur}} = -dq$ . For a reversible change we use the expression in Example 3.1 ( $q_{\text{rev}} = nRT \ln(V_f/V_i)$ ); consequently, from eqn 3.3b

$$\Delta S_{\text{sur}} = \frac{q_{\text{sur}}}{T} = -\frac{q_{\text{rev}}}{T} = -nR \ln \frac{V_f}{V_i} \quad (3.18)_{\text{rev}}^{\circ}$$

This change is the negative of the change in the system, so we can conclude that  $\Delta S_{\text{tot}} = 0$ , which is what we should expect for a reversible process. If, on the other hand, the isothermal expansion occurs freely ( $w = 0$ ), then  $q = 0$  (because  $\Delta U = 0$ ). Consequently,  $\Delta S_{\text{sur}} = 0$ , and the total entropy change is given by eqn 3.17 itself:

$$\Delta S_{\text{tot}} = nR \ln \frac{V_f}{V_i} \quad (3.19)^{\circ}$$

In this case,  $\Delta S_{\text{tot}} > 0$ , as we expect for an irreversible process.

### (b) Phase transition

The degree of dispersal of matter and energy changes when a substance freezes or boils as a result of changes in the order with which the molecules pack together and the extent to which the energy is localized or dispersed. Therefore, we should expect the transition to be accompanied by a change in entropy. For example, when a substance vaporizes, a compact condensed phase changes into a widely dispersed gas and we can expect the entropy of the substance to increase considerably. The entropy of a solid also increases when it melts to a liquid and when that liquid turns into a gas.

Consider a system and its surroundings at the **normal transition temperature**,  $T_{\text{trs}}$ , the temperature at which two phases are in equilibrium at 1 atm. This temperature is  $0^{\circ}\text{C}$  (273 K) for ice in equilibrium with liquid water at 1 atm, and  $100^{\circ}\text{C}$  (373 K) for liquid water in equilibrium with its vapour at 1 atm. At the transition temperature, any transfer of energy as heat between the system and its surroundings is reversible because the two phases in the system are in equilibrium. Because at constant pressure  $q = \Delta_{\text{trs}}H$ , the change in molar entropy of the system is<sup>3</sup>

$$\Delta_{\text{trs}}S = \frac{\Delta_{\text{trs}}H}{T_{\text{trs}}} \quad \text{Entropy of phase transition} \quad (3.20)$$

If the phase transition is exothermic ( $\Delta_{\text{trs}}H < 0$ , as in freezing or condensing), then the entropy change of the system is negative. This decrease in entropy is consistent with the increased order of a solid compared with a liquid and with the increased order of a liquid compared with a gas. The change in entropy of the surroundings, however, is positive because energy is released as heat into them, and at the transition temperature the total change in entropy is zero. If the transition is endothermic ( $\Delta_{\text{trs}}H > 0$ , as in melting and vaporization), then the entropy change of the system is positive, which is consistent with dispersal of matter in the system. The entropy of the surroundings decreases by the same amount, and overall the total change in entropy is zero.

Table 3.1 lists some experimental entropies of transition. Table 3.2 lists in more detail the standard entropies of vaporization of several liquids at their boiling points. An interesting feature of the data is that a wide range of liquids give approximately the same standard entropy of vaporization (about  $85 \text{ J K}^{-1} \text{ mol}^{-1}$ ): this empirical observation is called **Trouton's rule**. The explanation of Trouton's rule is that a comparable change in volume occurs when any liquid evaporates and becomes a gas. Hence, all

**Fig. 3.12** The logarithmic increase in entropy of a perfect gas as it expands isothermally.

**InterActivity** Evaluate the change in expansion of 1.00 mol  $\text{CO}_2$  (g) from  $0.001 \text{ m}^3$  to  $0.010 \text{ m}^3$  at 298 K, treated as a van der Waals gas.

<sup>3</sup> Recall from Section 2.6 that  $\Delta_{\text{trs}}H$  is an enthalpy change per mole of substance; so  $\Delta_{\text{trs}}S$  is also a molar quantity.

| Water                | 40.7                                                | 100.0                     | 109.1                                                            |

\* More values are given in the *Data section*.

liquids can be expected to have similar standard entropies of vaporization. Liquids that show significant deviations from Trouton's rule do so on account of strong molecular interactions that result in a partial ordering of their molecules. As a result, there is a greater change in disorder when the liquid turns into a vapour than for a fully disordered liquid. An example is water, where the large entropy of vaporization reflects the presence of structure arising from hydrogen-bonding in the liquid. Hydrogen bonds tend to organize the molecules in the liquid so that they are less random than, for example, the molecules in liquid hydrogen sulfide (in which there is no hydrogen bonding). Methane has an unusually low entropy of vaporization. A part of the reason is that the entropy of the gas itself is slightly low ( $186 \text{ J K}^{-1} \text{mol}^{-1}$  at 298 K); the entropy of  $\text{N}_2$  under the same conditions is  $192 \text{ J K}^{-1} \text{mol}^{-1}$ . As we shall see in Chapter 12, fewer rotational states are accessible at room temperature for light molecules than for heavy molecules.

#### • A brief illustration

There is no hydrogen bonding in liquid bromine and  $\text{Br}_2$  is a heavy molecule that is unlikely to display unusual behaviour in the gas phase, so it is safe to use Trouton's rule. To predict the standard molar enthalpy of vaporization of bromine given that it boils at  $59.2^\circ\text{C}$ , we use the rule in the form

$$\Delta_{\text{vap}}H^\ominus = T_b \times (85 \text{ J K}^{-1} \text{mol}^{-1})$$

Substitution of the data then gives

$$\Delta_{\text{vap}}H^\ominus = (332.4 \text{ K}) \times (85 \text{ J K}^{-1} \text{mol}^{-1}) = +2.8 \times 10^3 \text{ J mol}^{-1} = +28 \text{ kJ mol}^{-1}$$

The experimental value is  $+29.45 \text{ kJ mol}^{-1}$ . •

**Self-test 3.3** Predict the enthalpy of vaporization of ethane from its boiling point,  $-88.6^\circ\text{C}$ .  $[16 \text{ kJ mol}^{-1}]$

### (c) Heating

We can use eqn 3.2 to calculate the entropy of a system at a temperature  $T_f$  from a knowledge of its entropy at another temperature  $T_i$  and the heat supplied to change its temperature from one value to the other:

$$S(T_f) = S(T_i) + \int_{T_i}^{T_f} \frac{dq_{\text{rev}}}{T} \quad (3.21)$$

We shall be particularly interested in the entropy change when the system is subjected to constant pressure (such as from the atmosphere) during the heating. Then, from the definition of constant-pressure heat capacity (eqn 2.22, written as  $dq_{\text{rev}} = C_p dT$ ). Consequently, at constant pressure:

$$S(T_f) = S(T_i) + \int_{T_i}^{T_f} \frac{C_p dT}{T} \quad \text{Entropy variation with temperature} \quad (3.22)$$

The same expression applies at constant volume, but with  $C_p$  replaced by  $C_V$ . When  $C_p$  is independent of temperature in the temperature range of interest, it can be taken outside the integral and we obtain

$$S(T_f) = S(T_i) + C_p \int_{T_i}^{T_f} \frac{dT}{T} = S(T_i) + C_p \ln \frac{T_f}{T_i} \quad (3.23)$$

with a similar expression for heating at constant volume. The logarithmic dependence of entropy on temperature is illustrated in Fig. 3.13.

### Example 3.2 Calculating the entropy change

Calculate the entropy change when argon at  $25^\circ\text{C}$  and 1.00 bar in a container of volume  $0.500 \text{ dm}^3$  is allowed to expand to  $1.000 \text{ dm}^3$  and is simultaneously heated to  $100^\circ\text{C}$ .

**Method** Because  $S$  is a state function, we are free to choose the most convenient path from the initial state. One such path is reversible isothermal expansion to the final volume, followed by reversible heating at constant volume to the final temperature. The entropy change in the first step is given by eqn 3.17 and that of the second step, provided  $C_V$  is independent of temperature, by eqn 3.23 (with  $C_V$  in place of  $C_p$ ). In each case we need to know  $n$ , the amount of gas molecules, and can calculate it from the perfect gas equation and the data for the initial state from  $n = p_i V_i / RT_i$ . The molar heat capacity at constant volume is given by the equipartition theorem as  $\frac{3}{2}R$ . (The equipartition theorem is reliable for monatomic gases: for others and, in general, use experimental data like those in Table 2.8, converting to the value at constant volume by using the relation  $C_{p,m} - C_{v,m} = R$ .)

**Answer** From eqn 3.17 the entropy change of the isothermal expansion from  $V_i$  to  $V_f$  is

$$\Delta S(\text{Step 1}) = nR \ln \frac{V_f}{V_i}$$

**Fig. 3.13** The logarithmic increase in entropy of a substance as it is heated at constant volume. Different curves correspond to different values of the constant-volume heat capacity (which is assumed constant over the temperature range) expressed as  $C_{V,m}/R$ .

**interActivity** Plot the change in entropy of a perfect gas of (a) atoms, (b) linear rotors, (c) nonlinear rotors as the sample is heated over the same range under conditions of (i) constant volume, (ii) constant pressure.

From eqn 3.23, the entropy change in the second step, from  $T_i$  to  $T_f$  at constant volume, is

$$\Delta S(\text{Step 2}) = nC_{V,m} \ln \frac{T_f}{T_i} = \frac{3}{2} nR \ln \frac{T_f}{T_i} = nR \ln \left( \frac{T_f}{T_i} \right)^{3/2}$$

The overall entropy change of the system, the sum of these two changes, is

$$\Delta S = nR \ln \frac{V_f}{V_i} + nR \ln \left( \frac{T_f}{T_i} \right)^{3/2} = nR \ln \left\{ \frac{V_f}{V_i} \left( \frac{T_f}{T_i} \right)^{3/2} \right\}$$

(We have used  $\ln x + \ln y = \ln xy$ .) Now we substitute  $n = p_i V_i / RT_i$  and obtain

$$\Delta S = \frac{p_i V_i}{T_i} \ln \left\{ \frac{V_f}{V_i} \left( \frac{T_f}{T_i} \right)^{3/2} \right\}$$

At this point we substitute the data:

$$\begin{aligned} \Delta S &= \frac{(1.00 \times 10^5 \text{ Pa}) \times (0.500 \times 10^{-3} \text{ m}^3)}{298 \text{ K}} \times \ln \left\{ \frac{1.000}{0.500} \left( \frac{373}{298} \right)^{3/2} \right\} \\ &= +0.173 \text{ J K}^{-1} \end{aligned}$$

**A note on good practice** It is sensible to proceed as generally as possible before inserting numerical data so that, if required, the formula can be used for other data and to avoid rounding errors.

**Self-test 3.4** Calculate the entropy change when the same initial sample is compressed to  $0.0500 \text{ dm}^3$  and cooled to  $-25^\circ\text{C}$ . [ $-0.43 \text{ J K}^{-1}$ ]

**Fig. 3.14** The variation of  $C_p/T$  with the temperature for a sample is used to evaluate the entropy, which is equal to the area beneath the upper curve up to the corresponding temperature, plus the entropy of each phase transition passed.

**interActivity** Allow for the temperature dependence of the heat capacity by writing  $C = a + bT + c/T^2$ , and plot the change in entropy for different values of the three coefficients (including negative values of  $c$ ).

#### (d) The measurement of entropy

The entropy of a system at a temperature  $T$  is related to its entropy at  $T = 0$  by measuring its heat capacity  $C_p$  at different temperatures and evaluating the integral in eqn 3.22, taking care to add the entropy of transition ( $\Delta_{\text{trs}} H/T_{\text{trs}}$ ) for each phase transition between  $T = 0$  and the temperature of interest. For example, if a substance melts at  $T_f$  and boils at  $T_b$ , then its molar entropy above its boiling temperature is given by

$$\begin{aligned} S_m(T) &= S_m(0) + \int_0^{T_f} \frac{C_{p,m}(s,T)}{T} dT + \frac{\Delta_{\text{fus}} H}{T_f} + \int_{T_f}^{T_b} \frac{C_{p,m}(l,T)}{T} dT \\ &\quad + \frac{\Delta_{\text{vap}} H}{T_b} + \int_{T_b}^T \frac{C_{p,m}(g,T)}{T} dT \end{aligned} \quad (3.24)$$

All the properties required, except  $S_m(0)$ , can be measured calorimetrically, and the integrals can be evaluated either graphically or, as is now more usual, by fitting a polynomial to the data and integrating the polynomial analytically. The former procedure is illustrated in Fig. 3.14: the area under the curve of  $C_{p,m}/T$  against  $T$  is the integral required. Because  $dT/T = d \ln T$ , an alternative procedure is to evaluate the area under a plot of  $C_{p,m}$  against  $\ln T$ .

One problem with the determination of entropy is the difficulty of measuring heat capacities near  $T = 0$ . There are good theoretical grounds for assuming that the heat capacity is proportional to  $T^3$  when  $T$  is low (see Section 7.1), and this dependence is the basis of the **Debye extrapolation**. In this method,  $C_p$  is measured down to as low a temperature as possible, and a curve of the form  $aT^3$  is fitted to the data. That fit determines the value of  $a$ , and the expression  $C_{p,m} = aT^3$  is assumed valid down to  $T = 0$ .

• **A brief illustration**

The standard molar entropy of nitrogen gas at 25°C has been calculated from the following data:

|                                       | $S_m^\ominus / (\text{J K}^{-1} \text{ mol}^{-1})$ |
|---------------------------------------|----------------------------------------------------|
| Debye extrapolation                   | 1.92                                               |
| Integration, from 10 K to 35.61 K     | 25.25                                              |
| Phase transition at 35.61 K           | 6.43                                               |
| Integration, from 35.61 K to 63.14 K  | 23.38                                              |
| Fusion at 63.14 K                     | 11.42                                              |
| Integration, from 63.14 K to 77.32 K  | 11.41                                              |
| Vaporization at 77.32 K               | 72.13                                              |
| Integration, from 77.32 K to 298.15 K | 39.20                                              |
| Correction for gas imperfection       | 0.92                                               |
| Total                                 | 192.06                                             |

Therefore

$$S_m^\ominus(298.15 \text{ K}) = S_m(0) + 192.1 \text{ J K}^{-1} \text{ mol}^{-1} \quad \bullet$$

**Example 3.3** Calculating the entropy at low temperatures

The molar constant-pressure heat capacity of a certain solid at 4.2 K is  $0.43 \text{ J K}^{-1} \text{ mol}^{-1}$ . What is its molar entropy at that temperature?

**Method** Because the temperature is so low, we can assume that the heat capacity varies with temperature as  $aT^3$ , in which case we can use eqn 3.22 to calculate the entropy at a temperature  $T$  in terms of the entropy at  $T = 0$  and the constant  $a$ . When the integration is carried out, it turns out that the result can be expressed in terms of the heat capacity at the temperature  $T$ , so the data can be used directly to calculate the entropy.

**Answer** The integration required is

$$\begin{aligned} S_m(T) &= S_m(0) + \int_0^T \frac{aT^3}{T} dT = S_m(0) + a \int_0^T T^2 dT \\ &= S_m(0) + \frac{1}{3} aT^3 = S_m(0) + \frac{1}{3} C_{p,m}(T) \end{aligned}$$

from which it follows that

$$S_m(4.2 \text{ K}) = S_m(0) + 0.14 \text{ J K}^{-1} \text{ mol}^{-1}$$

**Self-test 3.5** For metals, there is also a contribution to the heat capacity from the electrons that is linearly proportional to  $T$  when the temperature is low. Find its contribution to the entropy at low temperatures.  $[S(T) = S(0) + C_p(T)]$

### 3.4 The Third Law of thermodynamics

**Key points** (a) The Nernst heat theorem implies the Third Law of thermodynamics. (b) The Third Law allows us to define absolute entropies of substances and to define the standard entropy of a reaction.

At  $T = 0$ , all energy of thermal motion has been quenched, and in a perfect crystal all the atoms or ions are in a regular, uniform array. The localization of matter and the absence of thermal motion suggest that such materials also have zero entropy. This conclusion is consistent with the molecular interpretation of entropy, because  $S = 0$  if there is only one way of arranging the molecules and only one microstate is accessible (all molecules occupy the ground state).

### (a) The Nernst heat theorem

The experimental observation that turns out to be consistent with the view that the entropy of a regular array of molecules is zero at  $T = 0$  is summarized by the **Nernst heat theorem**:

The entropy change accompanying any physical or chemical transformation approaches zero as the temperature approaches zero:  $\Delta S \rightarrow 0$  as  $T \rightarrow 0$  provided all the substances involved are perfectly ordered.

Nernst  
heat  
theorem

#### • A brief illustration

Consider the entropy of the transition between orthorhombic sulfur,  $S(\alpha)$ , and monoclinic sulfur,  $S(\beta)$ , which can be calculated from the transition enthalpy ( $-402 \text{ J mol}^{-1}$ ) at the transition temperature (369 K):

$$\Delta_{\text{trs}} S = S_{\text{m}}(\beta) - S_{\text{m}}(\alpha) = \frac{(-402 \text{ J mol}^{-1})}{369 \text{ K}} = -1.09 \text{ J K}^{-1} \text{ mol}^{-1}$$

The two individual entropies can also be determined by measuring the heat capacities from  $T = 0$  up to  $T = 369 \text{ K}$ . It is found that  $S_{\text{m}}(\alpha) = S_{\text{m}}(\alpha, 0) + 37 \text{ J K}^{-1} \text{ mol}^{-1}$  and  $S_{\text{m}}(\beta) = S_{\text{m}}(\beta, 0) + 38 \text{ J K}^{-1} \text{ mol}^{-1}$ . These two values imply that at the transition temperature

$$\Delta_{\text{trs}} S = S_{\text{m}}(\alpha, 0) - S_{\text{m}}(\beta, 0) = -1 \text{ J K}^{-1} \text{ mol}^{-1}$$

On comparing this value with the one above, we conclude that  $S_{\text{m}}(\alpha, 0) - S_{\text{m}}(\beta, 0) \approx 0$ , in accord with the theorem. •

It follows from the Nernst theorem that, if we arbitrarily ascribe the value zero to the entropies of elements in their perfect crystalline form at  $T = 0$ , then all perfect crystalline compounds also have zero entropy at  $T = 0$  (because the change in entropy that accompanies the formation of the compounds, like the entropy of all transformations at that temperature, is zero). This conclusion is summarized by the **Third Law of thermodynamics**:

The entropy of all perfect crystalline substances is zero at  $T = 0$ .

Third Law of  
thermodynamics

As far as thermodynamics is concerned, choosing this common value as zero is a matter of convenience. The molecular interpretation of entropy, however, justifies the value  $S = 0$  at  $T = 0$ . We saw in Section 3.2b that, according to the Boltzmann formula, the entropy is zero if there is only one accessible microstate ( $W = 1$ ). In most cases,  $W = 1$  at  $T = 0$  because there is only one way of achieving the lowest total energy: put all the molecules into the same, lowest state. Therefore,  $S = 0$  at  $T = 0$ , in accord with the Third Law of thermodynamics. In certain cases, though,  $W$  may differ from 1 at  $T = 0$ . This is the case if there is no energy advantage in adopting a particular orientation even at absolute zero. For instance, for a diatomic molecule AB there may

be almost no energy difference between the arrangements ... AB AB AB ... and ... BA AB BA ..., so  $W > 1$  even at  $T = 0$ . If  $S > 0$  at  $T = 0$  we say that the substance has a **residual entropy**. Ice has a residual entropy of  $3.4 \text{ J K}^{-1} \text{ mol}^{-1}$ . It stems from the arrangement of the hydrogen bonds between neighbouring water molecules: a given O atom has two short O–H bonds and two long O...H bonds to its neighbours, but there is a degree of randomness in which two bonds are short and which two are long.

### (b) Third-Law entropies

Entropies reported on the basis that  $S(0) = 0$  are called **Third-Law entropies** (and often just ‘entropies’). When the substance is in its standard state at the temperature  $T$ , the **standard (Third-Law) entropy** is denoted  $S^\circ(T)$ . A list of values at 298 K is given in Table 3.3.

The **standard reaction entropy**,  $S^\circ(T)$ , is defined, like the standard reaction enthalpy, as the difference between the molar entropies of the pure, separated products and the pure, separated reactants, all substances being in their standard states at the specified temperature:

$$\Delta_r S^\circ = \sum_{\text{Products}} \nu S_m^\circ - \sum_{\text{Reactants}} \nu S_m^\circ \quad \text{Definition of standard reaction entropy} \quad (3.25a)$$

In this expression, each term is weighted by the appropriate stoichiometric coefficient. A more sophisticated approach is to adopt the notation introduced in Section 2.8 and to write

$$\Delta_r S^\circ = \sum_j \nu_j S_m^\circ(\text{J}) \quad (3.25b)$$

Standard reaction entropies are likely to be positive if there is a net formation of gas in a reaction, and are likely to be negative if there is a net consumption of gas.

#### • A brief illustration

To calculate the standard reaction entropy of  $\text{H}_2(\text{g}) + \frac{1}{2} \text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{l})$  at  $25^\circ\text{C}$ , we use the data in Table 2.8 of the *Data section* to write

$$\begin{aligned} \Delta_r S^\circ &= S_m^\circ(\text{H}_2\text{O}, \text{l}) - \{S_m^\circ(\text{H}_2, \text{g}) + \frac{1}{2} S_m^\circ(\text{O}_2, \text{g})\} \\ &= 69.9 \text{ J K}^{-1} \text{ mol}^{-1} - \{130.7 + \frac{1}{2}(205.0)\} \text{ J K}^{-1} \text{ mol}^{-1} \\ &= -163.4 \text{ J K}^{-1} \text{ mol}^{-1} \end{aligned}$$

The negative value is consistent with the conversion of two gases to a compact liquid. •

**Self-test 3.6** Calculate the standard reaction entropy for the combustion of methane to carbon dioxide and liquid water at  $25^\circ\text{C}$ .  $[-243 \text{ J K}^{-1} \text{ mol}^{-1}]$

Just as in the discussion of enthalpies in Section 2.8, where we acknowledged that solutions of cations cannot be prepared in the absence of anions, the standard molar entropies of ions in solution are reported on a scale in which the standard entropy of the  $\text{H}^+$  ions in water is taken as zero at all temperatures:

$$S^\circ(\text{H}^+, \text{aq}) = 0 \quad \text{Convention for ions in solution} \quad [3.26]$$

**Table 3.3\*** Standard Third-Law entropies at 298 K

|                                                              | $S_m^\circ / (\text{J K}^{-1} \text{ mol}^{-1})$ |
|--------------------------------------------------------------|--------------------------------------------------|
| <i>Solids</i>                                                |                                                  |

| <i>Gases</i>                                                 |                                                  |
| Methane, $\text{CH}_4(\text{g})$                             | 186.3                                            |
| Carbon dioxide, $\text{CO}_2(\text{g})$                      | 213.7                                            |
| Hydrogen, $\text{H}_2(\text{g})$                             | 130.7                                            |
| Helium, He                                                   | 126.2                                            |
| Ammonia, $\text{NH}_3(\text{g})$                             | 192.4                                            |

\* More values are given in the *Data section*.

**A note on good practice** Do not make the mistake of setting the standard molar entropies of elements equal to zero: they have non-zero values (provided  $T > 0$ ), as we have already discussed.

The values based on this choice are listed in Table 2.8 in the *Data section*.<sup>4</sup> Because the entropies of ions in water are values relative to the hydrogen ion in water, they may be either positive or negative. A positive entropy means that an ion has a higher molar entropy than  $\text{H}^+$  in water and a negative entropy means that the ion has a lower molar entropy than  $\text{H}^+$  in water. For instance, the standard molar entropy of  $\text{Cl}^-(\text{aq})$  is  $+57 \text{ J K}^{-1} \text{ mol}^{-1}$  and that of  $\text{Mg}^{2+}(\text{aq})$  is  $-128 \text{ J K}^{-1} \text{ mol}^{-1}$ . Ion entropies vary as expected on the basis that they are related to the degree to which the ions order the water molecules around them in the solution. Small, highly charged ions induce local structure in the surrounding water, and the disorder of the solution is decreased more than in the case of large, singly charged ions. The absolute, Third-Law standard molar entropy of the proton in water can be estimated by proposing a model of the structure it induces, and there is some agreement on the value  $-21 \text{ J K}^{-1} \text{ mol}^{-1}$ . The negative value indicates that the proton induces order in the solvent.

#### IMPACT ON MATERIALS CHEMISTRY

##### 13.2 Crystal defects

The Third Law implies that at  $T = 0$  the entropies of perfect crystalline substances are characterized by long-range, regularly repeating arrangements of atoms, ions, or molecules. This regularity, and the accompanying inter- and intramolecular interactions between the subunits of the crystal, govern the physical, optical, and electronic properties of the solid. In reality, however, all crystalline solids possess one or more defects that affect the physical and chemical properties of the substance. In fact, impurities are often introduced to achieve particular desirable properties, such as the colour of a gemstone or enhanced strength of a metal.

One of the main types of crystalline imperfection is a **point defect**, a location where an atom is missing or irregularly placed in the lattice structure. Other terms used to describe point defects include *voids*, or *lattice vacancies*, *substitutional impurity atoms*, *dopant sites*, and *interstitial impurity atoms*. Many gemstones feature substitutional solids, such as in rubies and blue sapphires where the  $\text{Al}^{3+}$  ions in the corundum structure of alumina are replaced with  $\text{Cr}^{3+}$  and  $\text{Fe}^{3+}$  ions, respectively. Interstitial solids can result from the random diffusion of dopants in interstices (voids) or from self-diffusion, as in ionic crystals, where a lattice ion can migrate into an interstitial position and leave behind a vacancy known as a Frenkel defect.

Figure 3.15 illustrates the impact of impurities on the heat capacity and thus entropy of a pure crystal. Niobium has become the dominant metal in low-temperature superconductor alloys because it can be manufactured economically in a ductile form that is needed for the high critical current of a superconductor. The purity of the metal, however, is essential to yield superconducting properties. Close to 1 K the heat capacity of pure niobium follows the Debye  $T^3$  law. However, when niobium is treated by allowing  $\text{H}_2$  or  $\text{D}_2$  to diffuse over the sample at  $700^\circ\text{C}$  impurities are introduced and the heat capacity diverges from that of the pure metal. To identify the role of the defects the values of  $C_p$  for the pure metal are subtracted from those of the doped samples, divided by  $T$ , and plotted against temperature. The area under the resulting curves then represents the contributions to the entropy from the presence of the impurities.

**Fig. 3.15** Molar heat capacity contributions of the defects in hydrogen- and deuterium doped niobium. The area under each curve is used to calculate the entropy due to the presence of the defects. (Based on G.J. Sellers and A.C. Anderson, *Phys. Rev. B*, 10, 2771 (1974).)

<sup>4</sup> In terms of the language to be introduced in Section 5.1, the entropies of ions in solution are actually *partial molar entropies*, for their values include the consequences of their presence on the organization of the solvent molecules around them.

## Concentrating on the system

Entropy is the basic concept for discussing the direction of natural change, but to use it we have to analyse changes in both the system and its surroundings. We have seen that it is always very simple to calculate the entropy change in the surroundings, and we shall now see that it is possible to devise a simple method for taking that contribution into account automatically. This approach focuses our attention on the system and simplifies discussions. Moreover, it is the foundation of all the applications of chemical thermodynamics that follow.

### 3.5 The Helmholtz and Gibbs energies

---

**Key points** (a) The Clausius inequality implies a number of criteria for spontaneous change under a variety of conditions that may be expressed in terms of the properties of the system alone; they are summarized by introducing the Helmholtz and Gibbs energies. (b) A spontaneous process at constant temperature and volume is accompanied by a decrease in the Helmholtz energy. (c) The change in the Helmholtz energy is equal to the maximum work accompanying a process at constant temperature. (d) A spontaneous process at constant temperature and pressure is accompanied by a decrease in the Gibbs energy. (e) The change in the Gibbs energy is equal to the maximum non-expansion work accompanying a process at constant temperature and pressure.

---

Consider a system in thermal equilibrium with its surroundings at a temperature  $T$ . When a change in the system occurs and there is a transfer of energy as heat between the system and the surroundings, the Clausius inequality ( $dS \geq dq/T$ , eqn 3.12) reads

$$dS - \frac{dq}{T} \geq 0 \quad (3.27)$$

We can develop this inequality in two ways according to the conditions (of constant volume or constant pressure) under which the process occurs.

#### (a) Criteria for spontaneity

First, consider heating at constant volume. Then, in the absence of non-expansion work, we can write  $dq_V = dU$ ; consequently

$$dS - \frac{dU}{T} \geq 0 \quad (3.28)$$

The importance of the inequality in this form is that it expresses the criterion for spontaneous change solely in terms of the state functions of the system. The inequality is easily rearranged into

$$TdS \geq dU \quad (\text{constant } V, \text{ no additional work})^5 \quad (3.29)$$

At either constant internal energy ( $dU = 0$ ) or constant entropy ( $dS = 0$ ), this expression becomes, respectively,

$$dS_{U,V} \geq 0 \quad dU_{S,V} \leq 0 \quad (3.30)$$

where the subscripts indicate the constant conditions.

Equation 3.30 expresses the criteria for spontaneous change in terms of properties relating to the system. The first inequality states that, in a system at constant volume

<sup>5</sup> Recall that 'additional work' is work other than expansion work.

and constant internal energy (such as an isolated system), the entropy increases in a spontaneous change. That statement is essentially the content of the Second Law. The second inequality is less obvious, for it says that, if the entropy and volume of the system are constant, then the internal energy must decrease in a spontaneous change. Do not interpret this criterion as a tendency of the system to sink to lower energy. It is a disguised statement about entropy and should be interpreted as implying that, if the entropy of the system is unchanged, then there must be an increase in entropy of the surroundings, which can be achieved only if the energy of the system decreases as energy flows out as heat.

When energy is transferred as heat at constant pressure, and there is no work other than expansion work, we can write  $dq_p = dH$  and obtain

$$TdS \geq dH \quad (\text{constant } p, \text{ no additional work}) \quad (3.31)$$

At either constant enthalpy or constant entropy this inequality becomes, respectively,

$$dS_{H,p} \geq 0 \quad dH_{S,p} \leq 0 \quad (3.32)$$

The interpretations of these inequalities are similar to those of eqn 3.30. The entropy of the system at constant pressure must increase if its enthalpy remains constant (for there can then be no change in entropy of the surroundings). Alternatively, the enthalpy must decrease if the entropy of the system is constant, for then it is essential to have an increase in entropy of the surroundings.

Because eqns 3.29 and 3.31 have the forms  $dU - TdS \leq 0$  and  $dH - TdS \leq 0$ , respectively, they can be expressed more simply by introducing two more thermodynamic quantities. One is the **Helmholtz energy**,  $A$ , which is defined as

$$A = U - TS \quad \text{Definition of Helmholtz energy} \quad [3.33]$$

The other is the **Gibbs energy**,  $G$ :

$$G = H - TS \quad \text{Definition of Gibbs energy} \quad [3.34]$$

All the symbols in these two definitions refer to the system.

When the state of the system changes at constant temperature, the two properties change as follows:

$$(a) dA = dU - TdS \quad (b) dG = dH - TdS \quad (3.35)$$

When we introduce eqns 3.29 and 3.31, respectively, we obtain the criteria of spontaneous change as

$$(a) dA_{T,V} \leq 0 \quad (b) dG_{T,p} \leq 0 \quad (3.36)$$

These inequalities are the most important conclusions from thermodynamics for chemistry. They are developed in subsequent sections and chapters.

### (b) Some remarks on the Helmholtz energy

A change in a system at constant temperature and volume is spontaneous if  $dA_{T,V} \leq 0$ . That is, a change under these conditions is spontaneous if it corresponds to a decrease in the Helmholtz energy. Such systems move spontaneously towards states of lower  $A$  if a path is available. The criterion of equilibrium, when neither the forward nor reverse process has a tendency to occur, is

$$dA_{T,V} = 0 \quad (3.37)$$

The expressions  $dA = dU - TdS$  and  $dA < 0$  are sometimes interpreted as follows. A negative value of  $dA$  is favoured by a negative value of  $dU$  and a positive value of  $TdS$ . This observation suggests that the tendency of a system to move to lower  $A$  is due to its tendency to move towards states of lower internal energy and higher entropy. However, this interpretation is false (even though it is a good rule of thumb for remembering the expression for  $dA$ ) because the tendency to lower  $A$  is solely a tendency towards states of greater overall entropy. Systems change spontaneously if in doing so the total entropy of the system and its surroundings increases, not because they tend to lower internal energy. The form of  $dA$  may give the impression that systems favour lower energy, but that is misleading:  $dS$  is the entropy change of the system,  $-dU/T$  is the entropy change of the surroundings (when the volume of the system is constant), and their total tends to a maximum.

### (c) Maximum work

It turns out, as we show in the following *Justification*, that  $A$  carries a greater significance than being simply a signpost of spontaneous change: *the change in the Helmholtz function is equal to the maximum work accompanying a process at constant temperature*:

$$dw_{\max} = dA \quad (3.38)$$

As a result,  $A$  is sometimes called the ‘maximum work function’, or the ‘work function’.<sup>6</sup>

#### Justification 3.2 Maximum work

To demonstrate that maximum work can be expressed in terms of the changes in Helmholtz energy, we combine the Clausius inequality  $dS \geq dq/T$  in the form  $TdS \geq dq$  with the First Law,  $dU = dq + dw$ , and obtain

$$dU \leq TdS + dw$$

( $dU$  is smaller than the term of the right because we are replacing  $dq$  by  $TdS$ , which in general is larger.) This expression rearranges to

$$dw \geq dU - TdS$$

It follows that the most negative value of  $dw$ , and therefore the maximum energy that can be obtained from the system as work, is given by

$$dw_{\max} = dU - TdS$$

and that this work is done only when the path is traversed reversibly (because then the equality applies). Because at constant temperature  $dA = dU - TdS$ , we conclude that  $dw_{\max} = dA$ .

When a macroscopic isothermal change takes place in the system, eqn 3.38 becomes

$$w_{\max} = \Delta A$$

Relation between  $A$   
and maximum work

$$(3.39)$$

with

$$\Delta A = \Delta U - T\Delta S \quad (3.40)$$

<sup>6</sup> *Arbeit* is the German word for work; hence the symbol  $A$ .

**Fig. 3.16** In a system not isolated from its surroundings, the work done may be different from the change in internal energy. Moreover, the process is spontaneous if overall the entropy of the system and its surroundings increases. In the process depicted here, the entropy of the system decreases, so that of the surroundings must increase in order for the process to be spontaneous, which means that energy must pass from the system to the surroundings as heat. Therefore, less work than  $\Delta U$  can be obtained.

**Fig. 3.17** In this process, the entropy of the system increases; hence we can afford to lose some entropy of the surroundings. That is, some of their energy may be lost as heat to the system. This energy can be returned to them as work. Hence the work done can exceed  $\Delta U$ .

This expression shows that in some cases, depending on the sign of  $T\Delta S$ , not all the change in internal energy may be available for doing work. If the change occurs with a decrease in entropy (of the system), in which case  $T\Delta S < 0$ , then the right-hand side of this equation is not as negative as  $\Delta U$  itself, and consequently the maximum work is less than  $\Delta U$ . For the change to be spontaneous, some of the energy must escape as heat in order to generate enough entropy in the surroundings to overcome the reduction in entropy in the system (Fig. 3.16). In this case, Nature is demanding a tax on the internal energy as it is converted into work. This is the origin of the alternative name ‘Helmholtz free energy’ for  $A$ , because  $\Delta A$  is that part of the change in internal energy that we are free to use to do work.

Further insight into the relation between the work that a system can do and the Helmholtz energy is to recall that work is energy transferred to the surroundings as the uniform motion of atoms. We can interpret the expression  $A = U - TS$  as showing that  $A$  is the total internal energy of the system,  $U$ , less a contribution that is stored as energy of thermal motion (the quantity  $TS$ ). Because energy stored in random thermal motion cannot be used to achieve uniform motion in the surroundings, only the part of  $U$  that is not stored in that way, the quantity  $U - TS$ , is available for conversion into work.

If the change occurs with an increase of entropy of the system (in which case  $T\Delta S > 0$ ), the right-hand side of the equation is more negative than  $\Delta U$ . In this case, the maximum work that can be obtained from the system is greater than  $\Delta U$ . The explanation of this apparent paradox is that the system is not isolated and energy may flow in as heat as work is done. Because the entropy of the system increases, we can afford a reduction of the entropy of the surroundings yet still have, overall, a spontaneous process. Therefore, some energy (no more than the value of  $T\Delta S$ ) may leave the surroundings as heat and contribute to the work the change is generating (Fig. 3.17). Nature is now providing a tax refund.

#### Example 3.4 Calculating the maximum available work

When 1.000 mol  $\text{C}_6\text{H}_{12}\text{O}_6$  (glucose) is oxidized to carbon dioxide and water at 25°C according to the equation  $\text{C}_6\text{H}_{12}\text{O}_6(\text{s}) + 6 \text{O}_2(\text{g}) \rightarrow 6 \text{CO}_2(\text{g}) + 6 \text{H}_2\text{O}(\text{l})$ , calorimetric measurements give  $\Delta_r U^\circ = -2808 \text{ kJ mol}^{-1}$  and  $\Delta_r S^\circ = +259.1 \text{ J K}^{-1} \text{ mol}^{-1}$  at 25°C. How much of this energy change can be extracted as (a) heat at constant pressure, (b) work?

**Method** We know that the heat released at constant pressure is equal to the value of  $\Delta H$ , so we need to relate  $\Delta_r H^\circ$  to  $\Delta_r U^\circ$ , which is given. To do so, we suppose that all the gases involved are perfect, and use eqn 2.21 in the form  $\Delta_r H = \Delta_r U + \Delta v_g RT$ . For the maximum work available from the process we use eqn 3.39.

**Answer** (a) Because  $\Delta v_g = 0$ , we know that  $\Delta_r H^\circ = \Delta_r U^\circ = -2808 \text{ kJ mol}^{-1}$ . Therefore, at constant pressure, the energy available as heat is  $2808 \text{ kJ mol}^{-1}$ . (b) Because  $T = 298 \text{ K}$ , the value of  $\Delta_r A^\circ$  is

$$\Delta_r A^\circ = \Delta_r U^\circ - T\Delta_r S^\circ = -2885 \text{ kJ mol}^{-1}$$

Therefore, the combustion of 1.000 mol  $\text{C}_6\text{H}_{12}\text{O}_6$  can be used to produce up to 2885 kJ of work. The maximum work available is greater than the change in internal energy on account of the positive entropy of reaction (which is partly due to the generation of a large number of small molecules from one big one). The system can therefore draw in energy from the surroundings (so reducing their entropy) and make it available for doing work.

**Self-test 3.7** Repeat the calculation for the combustion of 1.000 mol  $\text{CH}_4(\text{g})$  under the same conditions, using data from Tables 2.6 and 2.8.

$$[|q_p| = 890 \text{ kJ}, |w_{\text{max}}| = 818 \text{ kJ}]$$

#### (d) Some remarks on the Gibbs energy

The Gibbs energy (the ‘free energy’) is more common in chemistry than the Helmholtz energy because, at least in laboratory chemistry, we are usually more interested in changes occurring at constant pressure than at constant volume. The criterion  $dG_{T,p} \leq 0$  carries over into chemistry as the observation that, *at constant temperature and pressure, chemical reactions are spontaneous in the direction of decreasing Gibbs energy*. Therefore, if we want to know whether a reaction is spontaneous, the pressure and temperature being constant, we assess the change in the Gibbs energy. If  $G$  decreases as the reaction proceeds, then the reaction has a spontaneous tendency to convert the reactants into products. If  $G$  increases, then the reverse reaction is spontaneous.

The existence of spontaneous endothermic reactions provides an illustration of the role of  $G$ . In such reactions,  $H$  increases, the system rises spontaneously to states of higher enthalpy, and  $dH > 0$ . Because the reaction is spontaneous we know that  $dG < 0$  despite  $dH > 0$ ; it follows that the entropy of the system increases so much that  $TdS$  outweighs  $dH$  in  $dG = dH - TdS$ . Endothermic reactions are therefore driven by the increase of entropy of the system, and this entropy change overcomes the reduction of entropy brought about in the surroundings by the inflow of heat into the system ( $dS_{\text{sur}} = -dH/T$  at constant pressure).

#### (e) Maximum non-expansion work

The analogue of the maximum work interpretation of  $\Delta A$ , and the origin of the name ‘free energy’, can be found for  $\Delta G$ . In the following *Justification*, we show that at constant temperature and pressure, the maximum additional (non-expansion) work,  $w_{\text{add,max}}$ , is given by the change in Gibbs energy:

$$dw_{\text{add,max}} = dG \quad (3.41a)$$

The corresponding expression for a measurable change is

$$w_{\text{add,max}} = \Delta G \quad (3.41b)$$

Relation between  $G$  and maximum non-expansion work

This expression is particularly useful for assessing the electrical work that may be produced by fuel cells and electrochemical cells, and we shall see many applications of it.

#### Justification 3.3 Maximum non-expansion work

Because  $H = U + pV$ , for a general change in conditions, the change in enthalpy is

$$dH = dq + dw + d(pV)$$

The corresponding change in Gibbs energy ( $G = H - TS$ ) is

$$dG = dH - TdS - SdT = dq + dw + d(pV) - TdS - SdT$$

When the change is isothermal we can set  $dT = 0$ ; then

$$dG = dq + dw + d(pV) - TdS$$

When the change is reversible,  $dw = dw_{\text{rev}}$  and  $dq = dq_{\text{rev}} = TdS$ , so for a reversible, isothermal process

$$dG = TdS + dw_{\text{rev}} + d(pV) - TdS = dw_{\text{rev}} + d(pV)$$

The work consists of expansion work, which for a reversible change is given by  $-pdV$ , and possibly some other kind of work (for instance, the electrical work of pushing electrons through a circuit or of raising a column of liquid); this additional work we denote  $dw_{\text{add}}$ . Therefore, with  $d(pV) = pdV + Vdp$ ,

$$dG = (-pdV + dw_{\text{add,rev}}) + pdV + Vdp = dw_{\text{add,rev}} + Vdp$$

If the change occurs at constant pressure (as well as constant temperature), we can set  $dp = 0$  and obtain  $dG = dw_{\text{add,rev}}$ . Therefore, at constant temperature and pressure,  $dw_{\text{add,rev}} = dG$ . However, because the process is reversible, the work done must now have its maximum value, so eqn 3.41 follows.

### Example 3.5 Calculating the maximum non-expansion work of a reaction

How much energy is available for sustaining muscular and nervous activity from the combustion of 1.00 mol of glucose molecules under standard conditions at 37°C (blood temperature)? The standard entropy of reaction is  $+259.1 \text{ J K}^{-1} \text{ mol}^{-1}$ .

**Method** The non-expansion work available from the reaction is equal to the change in standard Gibbs energy for the reaction ( $\Delta_r G^\circ$ , a quantity defined more fully below). To calculate this quantity, it is legitimate to ignore the temperature-dependence of the reaction enthalpy, to obtain  $\Delta_r H^\circ$  from Tables 2.6 and 2.8, and to substitute the data into  $\Delta_r G^\circ = \Delta_r H^\circ - T\Delta_r S^\circ$ .

**Answer** Because the standard reaction enthalpy is  $-2808 \text{ kJ mol}^{-1}$ , it follows that the standard reaction Gibbs energy is

$$\Delta_r G^\circ = -2808 \text{ kJ mol}^{-1} - (310 \text{ K}) \times (259.1 \text{ J K}^{-1} \text{ mol}^{-1}) = -2888 \text{ kJ mol}^{-1}$$

Therefore,  $w_{\text{add,max}} = -2888 \text{ kJ}$  for the combustion of 1 mol glucose molecules, and the reaction can be used to do up to 2888 kJ of non-expansion work. To place this result in perspective, consider that a person of mass 70 kg needs to do 2.1 kJ of work to climb vertically through 3.0 m; therefore, at least 0.13 g of glucose is needed to complete the task (and in practice significantly more).

**Self-test 3.8** How much non-expansion work can be obtained from the combustion of 1.00 mol  $\text{CH}_4(\text{g})$  under standard conditions at 298 K? Use  $\Delta_r S^\circ = -243 \text{ J K}^{-1} \text{ mol}^{-1}$ . [818 kJ]

## 3.6 Standard molar Gibbs energies

**Key points** Standard Gibbs energies of formation are used to calculate the standard Gibbs energies of reactions. The Gibbs energies of formation of ions may be estimated from a thermodynamic cycle and the Born equation.

Standard entropies and enthalpies of reaction can be combined to obtain the **standard Gibbs energy of reaction** (or ‘standard reaction Gibbs energy’),  $\Delta_r G^\circ$ :

$$\Delta_r G^\circ = \Delta_r H^\circ - T\Delta_r S^\circ \quad \text{Definition of standard Gibbs energy of reaction} \quad [3.42]$$

The standard Gibbs energy of reaction is the difference in standard molar Gibbs energies of the products and reactants in their standard states at the temperature specified for the reaction as written. As in the case of standard reaction enthalpies, it is convenient to define the **standard Gibbs energies of formation**,  $\Delta_f G^\circ$ , the standard

reaction Gibbs energy for the formation of a compound from its elements in their reference states.<sup>7</sup> Standard Gibbs energies of formation of the elements in their reference states are zero, because their formation is a ‘null’ reaction. A selection of values for compounds is given in Table 3.4. From the values there, it is a simple matter to obtain the standard Gibbs energy of reaction by taking the appropriate combination:

$$\Delta_r G^\ominus = \sum_{\text{Products}} \nu \Delta_f G^\ominus - \sum_{\text{Reactants}} \nu \Delta_f G^\ominus \quad (3.43a)$$

Procedure for calculating the standard Gibbs energy of reaction

In the notation introduced in Section 2.8,

$$\Delta_r G^\ominus = \sum_J \nu_J \Delta_f G^\ominus(J) \quad (3.43b)$$

#### • A brief illustration

To calculate the standard Gibbs energy of the reaction  $\text{CO(g)} + \frac{1}{2} \text{O}_2\text{(g)} \rightarrow \text{CO}_2\text{(g)}$  at 25°C, we write

$$\begin{aligned} \Delta_r G^\ominus &= \Delta_f G^\ominus(\text{CO}_2\text{g}) - \{\Delta_f G^\ominus(\text{COg}) + \tfrac{1}{2} \Delta_f G^\ominus(\text{O}_2\text{g})\} \\ &= -394.4 \text{ kJ mol}^{-1} - \{(-137.2) + \tfrac{1}{2}(0)\} \text{ kJ mol}^{-1} \\ &= -257.2 \text{ kJ mol}^{-1} \quad \bullet \end{aligned}$$

**Self-test 3.9** Calculate the standard reaction Gibbs energy for the combustion of  $\text{CH}_4\text{(g)}$  at 298 K. [−818 kJ mol<sup>−1</sup>]

Just as we did in Section 2.8, where we acknowledged that solutions of cations cannot be prepared without their accompanying anions, we define one ion, conventionally the hydrogen ion, to have zero standard Gibbs energy of formation at all temperatures:

$$\Delta_f G^\ominus(\text{H}^+, \text{aq}) = 0 \quad (3.44)$$

Convention for ions in solution

In essence, this definition adjusts the actual values of the Gibbs energies of formation of ions by a fixed amount that is chosen so that the standard value for one of them,  $\text{H}^+(\text{aq})$ , has the value zero.

#### • A brief illustration

For the reaction

we can write

$$\Delta_r G^\ominus = \Delta_f G^\ominus(\text{H}^+, \text{aq}) + \Delta_f G^\ominus(\text{Cl}^-, \text{aq}) = \Delta_f G^\ominus(\text{Cl}^-, \text{aq})$$

and hence identify  $\Delta_f G^\ominus(\text{Cl}^-, \text{aq})$  as  $-131.23 \text{ kJ mol}^{-1}$ . With the value of  $\Delta_f G^\ominus(\text{Cl}^-, \text{aq})$  established, we can find the value of  $\Delta_f G^\ominus(\text{Ag}^+, \text{aq})$  from

which leads to  $\Delta_f G^\ominus(\text{Ag}^+, \text{aq}) = +77.11 \text{ kJ mol}^{-1}$ . All the Gibbs energies of formation of ions tabulated in the *Data section* were calculated in the same way. •

**Table 3.4\*** Standard Gibbs energies of formation (at 298 K)

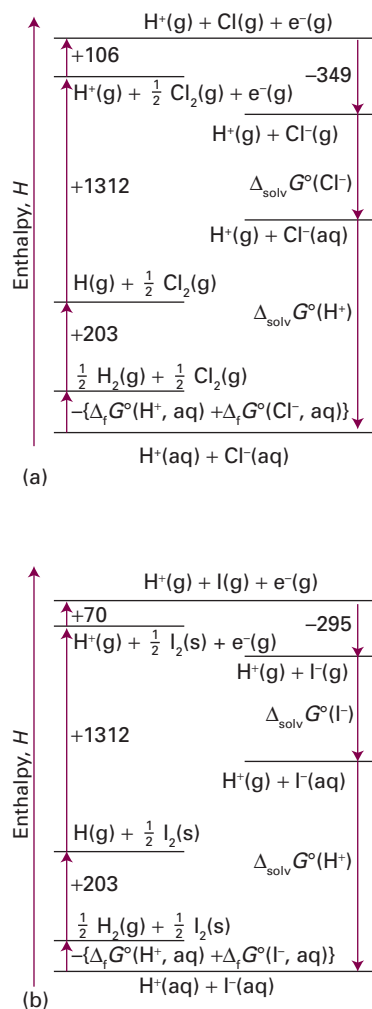

|                                            | $\Delta_f G^\ominus / (\text{kJ mol}^{-1})$ |
|--------------------------------------------|---------------------------------------------|
| Diamond, C(s)                              | +2.9                                        |
| Benzene, C <sub>6</sub> H <sub>6</sub> (l) | +124.3                                      |
| Methane, CH <sub>4</sub> (g)               | −50.7                                       |
| Carbon dioxide, CO <sub>2</sub> (g)        | −394.4                                      |
| Water, H <sub>2</sub> O(l)                 | −237.1                                      |
| Ammonia, NH <sub>3</sub> (g)               | −16.5                                       |
| Sodium chloride, NaCl(s)                   | −384.1                                      |

\* More values are given in the *Data section*.

<sup>7</sup> The reference state of an element was defined in Section 2.8.

**A brief comment**

The standard Gibbs energies of formation of the gas-phase ions are unknown. We have therefore used ionization energies and electron affinities and have assumed that any differences from the Gibbs energies arising from conversion to enthalpy and the inclusion of entropies to obtain Gibbs energies in the formation of  $H^+$  are cancelled by the corresponding terms in the electron gain of  $X$ . The conclusions from the cycles are therefore only approximate.

**Fig. 3.18** The thermodynamic cycles for the discussion of the Gibbs energies of solvation (hydration) and formation of (a) chloride ions, (b) iodide ions in aqueous solution. The sum of the changes in Gibbs energies around the cycle sum to zero because  $G$  is a state function.

The factors responsible for the magnitude of the Gibbs energy of formation of an ion in solution can be identified by analysing it in terms of a thermodynamic cycle. As an illustration, we consider the standard Gibbs energy of formation of  $Cl^-$  in water, which is  $-131 \text{ kJ mol}^{-1}$ . We do so by treating the formation reaction

as the outcome of the sequence of steps shown in Fig. 3.18 (with values taken from the *Data section*). The sum of the Gibbs energies for all the steps around a closed cycle is zero, so

$$\Delta_f G^\ominus(Cl^-, aq) = 1272 \text{ kJ mol}^{-1} + \Delta_{\text{solv}} G^\ominus(H^+) + \Delta_{\text{solv}} G^\ominus(Cl^-)$$

An important point to note is that the value of  $\Delta_f G^\ominus$  of an ion  $X$  is not determined by the properties of  $X$  alone but includes contributions from the dissociation, ionization, and hydration of hydrogen.

Gibbs energies of solvation of individual ions may be estimated from an equation derived by Max Born, who identified  $\Delta_{\text{solv}} G^\ominus$  with the electrical work of transferring an ion from a vacuum into the solvent treated as a continuous dielectric of relative permittivity  $\epsilon_r$ . The resulting **Born equation**, which is derived in *Further information* 3.1, is

$$\Delta_{\text{solv}} G^\ominus = -\frac{z_i^2 e^2 N_A}{8\pi\epsilon_0 r_i} \left(1 - \frac{1}{\epsilon_r}\right) \quad \text{Born equation} \quad (3.45a)$$

where  $z_i$  is the charge number of the ion and  $r_i$  its radius ( $N_A$  is Avogadro's constant). Note that  $\Delta_{\text{solv}} G^\ominus < 0$ , and that  $\Delta_{\text{solv}} G^\ominus$  is strongly negative for small, highly charged ions in media of high relative permittivity. For water for which  $\epsilon_r = 78.54$  at  $25^\circ\text{C}$ ,

$$\Delta_{\text{solv}} G^\ominus = -\frac{z_i^2}{(r_i/\text{pm})} \times (6.86 \times 10^4 \text{ kJ mol}^{-1}) \quad (3.45b)$$

• **A brief illustration**

To see how closely the Born equation reproduces the experimental data, we calculate the difference in the values of  $\Delta_f G^\ominus$  for  $Cl^-$  and  $I^-$  in water at  $25^\circ\text{C}$ , given their radii as 181 pm and 220 pm (Table 19.3), respectively, is

$$\begin{aligned} \Delta_{\text{solv}} G^\ominus(Cl^-) - \Delta_{\text{solv}} G^\ominus(I^-) &= -\left(\frac{1}{181} - \frac{1}{220}\right) \times (6.86 \times 10^4 \text{ kJ mol}^{-1}) \\ &= -67 \text{ kJ mol}^{-1} \end{aligned}$$

This estimated difference is in good agreement with the experimental difference, which is  $-61 \text{ kJ mol}^{-1}$ . •

**Self-test 3.10** Estimate the value of  $\Delta_{\text{solv}} G^\ominus(Cl^-) - \Delta_{\text{solv}} G^\ominus(Br^-)$  in water from experimental data and from the Born equation.

[ $-26 \text{ kJ mol}^{-1}$  experimental;  $-29 \text{ kJ mol}^{-1}$  calculated]

Calorimetry (for  $\Delta H$  directly, and for  $S$  via heat capacities) is only one of the ways of determining Gibbs energies. They may also be obtained from equilibrium constants and electrochemical measurements (Chapter 6), and for gases they may be calculated using data from spectroscopic observations (Chapter 16).

## Combining the First and Second Laws

The First and Second Laws of thermodynamics are both relevant to the behaviour of matter, and we can bring the whole force of thermodynamics to bear on a problem by setting up a formulation that combines them.

### 3.7 The fundamental equation

**Key point** The fundamental equation, a combination of the First and Second Laws, is an expression for the change in internal energy that accompanies changes in the volume and entropy of a system.

We have seen that the First Law of thermodynamics may be written  $dU = dq + dw$ . For a reversible change in a closed system of constant composition, and in the absence of any additional (non-expansion) work, we may set  $dw_{\text{rev}} = -pdV$  and (from the definition of entropy)  $dq_{\text{rev}} = TdS$ , where  $p$  is the pressure of the system and  $T$  its temperature. Therefore, for a reversible change in a closed system,

$$dU = TdS - pdV \quad \text{The fundamental equation} \quad (3.46)$$

However, because  $dU$  is an exact differential, its value is independent of path. Therefore, the same value of  $dU$  is obtained whether the change is brought about irreversibly or reversibly. Consequently, *eqn 3.46 applies to any change—reversible or irreversible—of a closed system that does no additional (non-expansion) work*. We shall call this combination of the First and Second Laws the **fundamental equation**.

The fact that the fundamental equation applies to both reversible and irreversible changes may be puzzling at first sight. The reason is that only in the case of a reversible change may  $TdS$  be identified with  $dq$  and  $-pdV$  with  $dw$ . When the change is irreversible,  $TdS > dq$  (the Clausius inequality) and  $-pdV > dw$ . The sum of  $dw$  and  $dq$  remains equal to the sum of  $TdS$  and  $-pdV$ , provided the composition is constant.

### 3.8 Properties of the internal energy

**Key points** Relations between thermodynamic properties are generated by combining thermodynamic and mathematical expressions for changes in their values. (a) The Maxwell relations are a series of relations between derivatives of thermodynamic properties based on criteria for changes in the properties being exact differentials. (b) The Maxwell relations are used to derive the thermodynamic equation of state and to determine how the internal energy of a substance varies with volume.

Equation 3.46 shows that the internal energy of a closed system changes in a simple way when either  $S$  or  $V$  is changed ( $dU \propto dS$  and  $dU \propto dV$ ). These simple proportionalities suggest that  $U$  is best regarded as a function of  $S$  and  $V$ . We could regard  $U$  as a function of other variables, such as  $S$  and  $p$  or  $T$  and  $V$ , because they are all inter-related; but the simplicity of the fundamental equation suggests that  $U(S, V)$  is the best choice.

The *mathematical* consequence of  $U$  being a function of  $S$  and  $V$  is that we can express an infinitesimal change  $dU$  in terms of changes  $dS$  and  $dV$  by

$$dU = \left( \frac{\partial U}{\partial S} \right)_V dS + \left( \frac{\partial U}{\partial V} \right)_S dV \quad (3.47)$$

#### A brief comment

Partial derivatives were introduced in *Mathematical background 2*. The type of result in eqn 3.47 was first obtained in Section 2.11, where we treated  $U$  as a function of  $T$  and  $V$ .

The two partial derivatives are the slopes of the plots of  $U$  against  $S$  and  $V$ , respectively. When this expression is compared to the *thermodynamic* relation, eqn 3.46, we see that, for systems of constant composition,

$$\left(\frac{\partial U}{\partial S}\right)_V = T \quad \left(\frac{\partial U}{\partial V}\right)_S = -p \quad (3.48)$$

The first of these two equations is a purely thermodynamic definition of temperature (a Zeroth-Law concept) as the ratio of the changes in the internal energy (a First-Law concept) and entropy (a Second-Law concept) of a constant-volume, closed, constant-composition system. We are beginning to generate relations between the properties of a system and to discover the power of thermodynamics for establishing unexpected relations.

### (a) The Maxwell relations

An infinitesimal change in a function  $f(x,y)$  can be written  $df = gdx + hdy$  where  $g$  and  $h$  are functions of  $x$  and  $y$ . The mathematical criterion for  $df$  being an exact differential (in the sense that its integral is independent of path) is that

$$\left(\frac{\partial g}{\partial y}\right)_x = \left(\frac{\partial h}{\partial x}\right)_y \quad (3.49)$$

This criterion is discussed in *Mathematical background 2*. Because the fundamental equation, eqn 3.46, is an expression for an exact differential, the functions multiplying  $dS$  and  $dV$  (namely  $T$  and  $-p$ ) must pass this test. Therefore, it must be the case that

$$\left(\frac{\partial T}{\partial V}\right)_S = -\left(\frac{\partial p}{\partial S}\right)_V \quad \text{A Maxwell relation} \quad (3.50)$$

We have generated a relation between quantities that, at first sight, would not seem to be related.

Equation 3.50 is an example of a **Maxwell relation**. However, apart from being unexpected, it does not look particularly interesting. Nevertheless, it does suggest that there may be other similar relations that are more useful. Indeed, we can use the fact that  $H$ ,  $G$ , and  $A$  are all state functions to derive three more Maxwell relations. The argument to obtain them runs in the same way in each case: because  $H$ ,  $G$ , and  $A$  are state functions, the expressions for  $dH$ ,  $dG$ , and  $dA$  satisfy relations like eqn 3.49. All four relations are listed in Table 3.5 and we put them to work later in the chapter.

**Table 3.5** The Maxwell relations

|            |                                                                                                |
|------------|------------------------------------------------------------------------------------------------|
| From $U$ : | $\left(\frac{\partial T}{\partial V}\right)_S = -\left(\frac{\partial p}{\partial S}\right)_V$ |
| From $H$ : | $\left(\frac{\partial T}{\partial p}\right)_S = \left(\frac{\partial V}{\partial S}\right)_p$  |
| From $A$ : | $\left(\frac{\partial p}{\partial T}\right)_V = \left(\frac{\partial S}{\partial V}\right)_T$  |
| From $G$ : | $\left(\frac{\partial V}{\partial T}\right)_p = -\left(\frac{\partial S}{\partial p}\right)_T$ |

### (b) The variation of internal energy with volume

The quantity  $\pi_T = (\partial U/\partial V)_T$ , which represents how the internal energy changes as the volume of a system is changed isothermally, played a central role in the manipulation of the First Law, and in *Further information 2.2* we used the relation

$$\pi_T = T\left(\frac{\partial p}{\partial T}\right)_V - p \quad \text{A thermodynamic equation of state} \quad (3.51)$$

This relation is called a **thermodynamic equation of state** because it is an expression for pressure in terms of a variety of thermodynamic properties of the system. We are now ready to derive it by using a Maxwell relation.

**Justification 3.4** *The thermodynamic equation of state*

We obtain an expression for the coefficient  $\pi_T$  by dividing both sides of eqn 3.47 by  $dV$ , imposing the constraint of constant temperature, which gives

$$\left(\frac{\partial U}{\partial V}\right)_T = \left(\frac{\partial U}{\partial S}\right)_V \left(\frac{\partial S}{\partial V}\right)_T + \left(\frac{\partial U}{\partial V}\right)_S$$

Next, we introduce the two relations in eqn 3.48 and the definition of  $\pi_T$  to obtain

$$\pi_T = T \left(\frac{\partial S}{\partial V}\right)_T - p$$

The third Maxwell relation in Table 3.5 turns  $(\partial S/\partial V)_T$  into  $(\partial p/\partial T)_V$ , which completes the proof of eqn 3.51.

**Example 3.6** *Deriving a thermodynamic relation*

Show thermodynamically that  $\pi_T = 0$  for a perfect gas, and compute its value for a van der Waals gas.

**Method** Proving a result ‘thermodynamically’ means basing it entirely on general thermodynamic relations and equations of state, without drawing on molecular arguments (such as the existence of intermolecular forces). We know that for a perfect gas,  $p = nRT/V$ , so this relation should be used in eqn 3.51. Similarly, the van der Waals equation is given in Table 1.7, and for the second part of the question it should be used in eqn 3.51.

**Answer** For a perfect gas we write

$$\left(\frac{\partial p}{\partial T}\right)_V = \left(\frac{\partial(nRT/V)}{\partial T}\right)_V = \frac{nR}{V}$$

Then, eqn 3.51 becomes

$$\pi_T = \frac{nRT}{V} - p = 0$$

The equation of state of a van der Waals gas is

$$p = \frac{nRT}{V - nb} - a \frac{n^2}{V^2}$$

Because  $a$  and  $b$  are independent of temperature,

$$\left(\frac{\partial p}{\partial T}\right)_V = \left(\frac{\partial(nRT/(V - nb))}{\partial T}\right)_V = \frac{nR}{V - nb}$$

Therefore, from eqn 3.51,

$$\pi_T = \frac{nRT}{V - nb} - p = \frac{nRT}{V - nb} - \left(\frac{nRT}{V - nb} - a \frac{n^2}{V^2}\right) = a \frac{n^2}{V^2}$$

This result for  $\pi_T$  implies that the internal energy of a van der Waals gas increases when it expands isothermally (that is,  $(\partial U/\partial V)_T > 0$ ), and that the increase is related to the parameter  $a$ , which models the attractive interactions between the

particles. A larger molar volume, corresponding to a greater average separation between molecules, implies weaker mean intermolecular attractions, so the total energy is greater.

**Self-test 3.11** Calculate  $\pi_T$  for a gas that obeys the virial equation of state (Table 1.7).  $[\pi_T = RT^2(\partial B/\partial T)_V/V_m^2 + \dots]$

### 3.9 Properties of the Gibbs energy

**Key points** (a) The variation of the Gibbs energy of a system suggests that it is best regarded as a function of pressure and temperature. The Gibbs energy of a substance decreases with temperature and increases with pressure. (b) The variation of Gibbs energy with temperature is related to the enthalpy by the Gibbs–Helmholtz equation. (c) The Gibbs energies of solids and liquids are almost independent of pressure; those of gases vary linearly with the logarithm of the pressure.

The same arguments that we have used for  $U$  can be used for the Gibbs energy  $G = H - TS$ . They lead to expressions showing how  $G$  varies with pressure and temperature that are important for discussing phase transitions and chemical reactions.

#### (a) General considerations

When the system undergoes a change of state,  $G$  may change because  $H$ ,  $T$ , and  $S$  all change. As in *Justification 2.1*, we write for infinitesimal changes in each property

$$dG = dH - d(TS) = dH - TdS - SdT$$

Because  $H = U + pV$ , we know that

$$dH = dU + d(pV) = dU + pdV + Vdp$$

and therefore

$$dG = dU + pdV + Vdp - TdS - SdT$$

For a closed system doing no non-expansion work, we can replace  $dU$  by the fundamental equation  $dU = TdS - pdV$  and obtain

$$dG = TdS - pdV + pdV + Vdp - TdS - SdT$$

Four terms now cancel on the right, and we conclude that for a closed system in the absence of non-expansion work and at constant composition

$$dG = Vdp - SdT$$

The fundamental equation of chemical thermodynamics

 (3.52)

This expression, which shows that a change in  $G$  is proportional to a change in  $p$  or  $T$ , suggests that  $G$  may be best regarded as a function of  $p$  and  $T$ . It may be regarded as the **fundamental equation of chemical thermodynamics** as it is so central to the application of thermodynamics to chemistry: it suggests that  $G$  is an important quantity in chemistry because the pressure and temperature are usually the variables under our control. In other words,  $G$  carries around the combined consequences of the First and Second Laws in a way that makes it particularly suitable for chemical applications.

The same argument that led to eqn 3.48, when applied to the exact differential  $dG = Vdp - SdT$ , now gives

$$\left(\frac{\partial G}{\partial T}\right)_p = -S \quad \left(\frac{\partial G}{\partial p}\right)_T = V$$

The variation of  $G$  with  $T$  and  $p$

 (3.53)

These relations show how the Gibbs energy varies with temperature and pressure (Fig. 3.19). The first implies that:

- Because  $S > 0$  for all substances,  $G$  always *decreases* when the temperature is raised (at constant pressure and composition).
- Because  $(\partial G/\partial T)_p$  becomes more negative as  $S$  increases,  $G$  decreases most sharply when the entropy of the system is large.

Therefore, the Gibbs energy of the gaseous phase of a substance, which has a high molar entropy, is more sensitive to temperature than its liquid and solid phases (Fig. 3.20). Similarly, the second relation implies that:

- Because  $V > 0$  for all substances,  $G$  always *increases* when the pressure of the system is increased (at constant temperature and composition).
- Because  $(\partial G/\partial p)_T$  increases with  $V$ ,  $G$  is more sensitive to pressure when the volume of the system is large.

Because the molar volume of the gaseous phase of a substance is greater than that of its condensed phases, the molar Gibbs energy of a gas is more sensitive to pressure than its liquid and solid phases (Fig. 3.21).

### (b) The variation of the Gibbs energy with temperature

As we remarked in the introduction, because the equilibrium composition of a system depends on the Gibbs energy, to discuss the response of the composition to temperature we need to know how  $G$  varies with temperature.

The first relation in eqn 3.53,  $(\partial G/\partial T)_p = -S$ , is our starting point for this discussion. Although it expresses the variation of  $G$  in terms of the entropy, we can express it in terms of the enthalpy by using the definition of  $G$  to write  $S = (H - G)/T$ . Then

$$\left(\frac{\partial G}{\partial T}\right)_p = \frac{G - H}{T} \quad (3.54)$$

We shall see later that the equilibrium constant of a reaction is related to  $G/T$  rather than to  $G$  itself,<sup>8</sup> and it is easy to deduce from the last equation (see the following *Justification*) that

$$\left(\frac{\partial(G/T)}{\partial T}\right)_p = -\frac{H}{T^2} \quad \text{Gibbs–Helmholtz equation} \quad (3.55)$$

This expression is called the **Gibbs–Helmholtz equation**. It shows that, if we know the enthalpy of the system, then we know how  $G/T$  varies with temperature.

#### Justification 3.5 The Gibbs–Helmholtz equation

First, we note that

$$\left(\frac{\partial(G/T)}{\partial T}\right)_p = \frac{1}{T} \left(\frac{\partial G}{\partial T}\right)_p + G \frac{d(1/T)}{dT} = \frac{1}{T} \left(\frac{\partial G}{\partial T}\right)_p - \frac{G}{T^2} = \frac{1}{T} \left\{ \left(\frac{\partial G}{\partial T}\right)_p - \frac{G}{T} \right\}$$

Then we use eqn 3.54 to write

$$\left(\frac{\partial G}{\partial T}\right)_p - \frac{G}{T} = \frac{G - H}{T} - \frac{G}{T} = -\frac{H}{T}$$

When this expression is substituted in the preceding one, we obtain eqn 3.55.

**Fig. 3.19** The variation of the Gibbs energy of a system with (a) temperature at constant pressure and (b) pressure at constant temperature. The slope of the former is equal to the negative of the entropy of the system and that of the latter is equal to the volume.

**Fig. 3.20** The variation of the Gibbs energy with the temperature is determined by the entropy. Because the entropy of the gaseous phase of a substance is greater than that of the liquid phase, and the entropy of the solid phase is smallest, the Gibbs energy changes most steeply for the gas phase, followed by the liquid phase, and then the solid phase of the substance.

<sup>8</sup> In Section 6.2b we derive the result that the equilibrium constant for a reaction is related to its standard reaction Gibbs energy by  $\Delta_r G^\circ/T = -R \ln K$ .

**Fig. 3.21** The variation of the Gibbs energy with the pressure is determined by the volume of the sample. Because the volume of the gaseous phase of a substance is greater than that of the same amount of liquid phase, and the entropy of the solid phase is smallest (for most substances), the Gibbs energy changes most steeply for the gas phase, followed by the liquid phase, and then the solid phase of the substance. Because the volumes of the solid and liquid phases of a substance are similar, their molar Gibbs energies vary by similar amounts as the pressure is changed.

**Fig. 3.22** The difference in Gibbs energy of a solid or liquid at two pressures is equal to the rectangular area shown. We have assumed that the variation of volume with pressure is negligible.

The Gibbs–Helmholtz equation is most useful when it is applied to changes, including changes of physical state and chemical reactions at constant pressure. Then, because  $\Delta G = G_f - G_i$  for the change of Gibbs energy between the final and initial states and because the equation applies to both  $G_f$  and  $G_i$ , we can write

$$\left( \frac{\partial(\Delta G/T)}{\partial T} \right)_p = -\frac{\Delta H}{T^2} \quad (3.56)$$

This equation shows that, if we know the change in enthalpy of a system that is undergoing some kind of transformation (such as vaporization or reaction), then we know how the corresponding change in Gibbs energy varies with temperature. As we shall see, this is a crucial piece of information in chemistry.

### (c) The variation of the Gibbs energy with pressure

To find the Gibbs energy at one pressure in terms of its value at another pressure, the temperature being constant, we set  $dT = 0$  in eqn 3.52, which gives  $dG = V dp$ , and integrate:

$$G(p_f) = G(p_i) + \int_{p_i}^{p_f} V dp \quad (3.57a)$$

For molar quantities,

$$G_m(p_f) = G_m(p_i) + \int_{p_i}^{p_f} V_m dp \quad (3.57b)$$

This expression is applicable to any phase of matter, but to evaluate it we need to know how the molar volume,  $V_m$ , depends on the pressure.

The molar volume of a condensed phase changes only slightly as the pressure changes (Fig. 3.22), so we can treat  $V_m$  as a constant and take it outside the integral:

$$G_m(p_f) = G_m(p_i) + V_m \int_{p_i}^{p_f} dp = G_m(p_i) + (p_f - p_i) V_m \quad (3.58)$$

**Self-test 3.12** Calculate the change in  $G_m$  for ice at  $-10^\circ\text{C}$ , with density  $917 \text{ kg m}^{-3}$ , when the pressure is increased from 1.0 bar to 2.0 bar. [+2.0 J mol<sup>-1</sup>]

Under normal laboratory conditions  $(p_f - p_i) V_m$  is very small and may be neglected. Hence, we may usually suppose that the Gibbs energies of solids and liquids are independent of pressure. However, if we are interested in geophysical problems, then, because pressures in the Earth's interior are huge, their effect on the Gibbs energy cannot be ignored. If the pressures are so great that there are substantial volume changes over the range of integration, then we must use the complete expression, eqn 3.57.

#### • A brief illustration

Suppose that for a certain phase transition of a solid  $\Delta_{\text{trs}} V = +1.0 \text{ cm}^3 \text{ mol}^{-1}$  independent of pressure. Then for an increase in pressure to 3.0 Mbar ( $3.0 \times 10^{11} \text{ Pa}$ ) from 1.0 bar ( $1.0 \times 10^5 \text{ Pa}$ ), the Gibbs energy of the transition changes from  $\Delta_{\text{trs}} G(1 \text{ bar})$  to

$$\begin{aligned} \Delta_{\text{trs}} G(3 \text{ Mbar}) &= \Delta_{\text{trs}} G(1 \text{ bar}) + (1.0 \times 10^{-6} \text{ m}^3 \text{ mol}^{-1}) \times (3.0 \times 10^{11} \text{ Pa} - 1.0 \times 10^5 \text{ Pa}) \\ &= \Delta_{\text{trs}} G(1 \text{ bar}) + 3.0 \times 10^2 \text{ kJ mol}^{-1} \end{aligned}$$

where we have used  $1 \text{ Pa m}^3 = 1 \text{ J}$ . •

The molar volumes of gases are large, so the Gibbs energy of a gas depends strongly on the pressure. Furthermore, because the volume also varies markedly with the pressure, we cannot treat it as a constant in the integral in eqn 3.57b (Fig. 3.23). For a perfect gas we substitute  $V_m = RT/p$  into the integral, treat  $RT$  as a constant, and find

$$G_m(p_f) = G_m(p_i) + RT \int_{p_i}^{p_f} \frac{1}{p} dp = G_m(p_i) + RT \ln \frac{p_f}{p_i} \quad (3.59)^\circ$$

This expression shows that, when the pressure is increased tenfold at room temperature, the molar Gibbs energy increases by  $RT \ln 10 \approx 6 \text{ kJ mol}^{-1}$ . It also follows from this equation that, if we set  $p_i = p^\ominus$  (the standard pressure of 1 bar), then the molar Gibbs energy of a perfect gas at a pressure  $p$  (set  $p_f = p$ ) is related to its standard value by

$$G_m(p) = G_m^\ominus + RT \ln \frac{p}{p^\ominus} \quad (3.60)^\circ$$

The molar Gibbs energy of a perfect gas

**Self-test 3.13** Calculate the change in the molar Gibbs energy of water vapour (treated as a perfect gas) when the pressure is increased isothermally from 1.0 bar to 2.0 bar at 298 K. Note that, whereas the change in molar Gibbs energy for a condensed phase (Self-test 3.12) is a few joules per mole, the answer you should get for a gas is of the order of kilojoules per mole [+1.7 kJ mol<sup>-1</sup>]

The logarithmic dependence of the molar Gibbs energy on the pressure predicted by eqn 3.60 is illustrated in Fig. 3.24. This very important expression, the consequences of which we unfold in the following chapters, applies to perfect gases (which is usually a good enough approximation). *Further information 3.2* describes how to take into account gas imperfections.

**Fig. 3.23** The difference in Gibbs energy for a perfect gas at two pressures is equal to the area shown below the perfect-gas isotherm.

**Fig. 3.24** The molar Gibbs energy of a perfect gas is proportional to  $\ln p$ , and the standard state is reached at  $p^\ominus$ . Note that, as  $p \rightarrow 0$ , the molar Gibbs energy becomes negatively infinite.

**InterActivity** Show how the first derivative of  $G$ ,  $(\partial G/\partial p)_T$ , varies with pressure, and plot the resulting expression over a pressure range. What is the physical significance of  $(\partial G/\partial p)_T$ ?

## Checklist of key equations

## Further information

### Further information 3.1 The Born equation

The strategy of the calculation is to identify the Gibbs energy of solvation with the work of transferring an ion from a vacuum into the solvent. That work is calculated by taking the difference of the work of charging an ion when it is in the solution and the work of charging the same ion when it is in a vacuum.

The Coulomb interaction between two charges  $Q_1$  and  $Q_2$  separated by a distance  $r$  is described by the *Coulombic potential energy*:

$$V = \frac{Q_1 Q_2}{4\pi\epsilon r}$$

where  $\epsilon$  is the medium's permittivity. The permittivity of vacuum is  $\epsilon_0 = 8.854 \times 10^{-12} \text{ J}^{-1} \text{ C}^2 \text{ m}^{-1}$ . The relative permittivity (formerly called the 'dielectric constant') of a substance is defined as  $\epsilon_r = \epsilon/\epsilon_0$ . Ions do not interact as strongly in a solvent of high relative permittivity (such as water, with  $\epsilon_r = 80$  at 293 K) as they do in a solvent of lower relative permittivity (such as ethanol, with  $\epsilon_r = 25$  at 293 K). See Chapter 17 for more details. The potential energy of a

charge  $Q_1$  in the presence of a charge  $Q_2$  can be expressed in terms of the *Coulomb potential*,  $\phi$ :

$$V = Q_1 \phi \quad \phi = \frac{Q_2}{4\pi\epsilon r}$$

We model an ion as a sphere of radius  $r_i$  immersed in a medium of permittivity  $\epsilon$ . It turns out that, when the charge of the sphere is  $Q$ , the electric potential,  $\phi$ , at its surface is the same as the potential due to a point charge at its centre, so we can use the last expression and write

$$\phi = \frac{Q}{4\pi\epsilon r_i}$$

The work of bringing up a charge  $dQ$  to the sphere is  $\phi dQ$ . Therefore, the total work of charging the sphere from 0 to  $z_i e$  is

$$w = \int_0^{z_i e} \phi dQ = \frac{1}{4\pi\epsilon r_i} \int_0^{z_i e} Q dQ = \frac{z_i^2 e^2}{8\pi\epsilon r_i}$$

This electrical work of charging, when multiplied by Avogadro's constant, is the molar Gibbs energy for charging the ions.

The work of charging an ion in a vacuum is obtained by setting  $\epsilon = \epsilon_0$ , the vacuum permittivity. The corresponding value for charging the ion in a medium is obtained by setting  $\epsilon = \epsilon_r \epsilon_0$ , where  $\epsilon_r$  is the relative permittivity of the medium. It follows that the change in molar Gibbs energy that accompanies the transfer of ions from a vacuum to a solvent is the difference of these two quantities:

$$\Delta_{\text{solv}} G^\ominus = \frac{z_i^2 e^2 N_A}{8\pi\epsilon_r r_i} - \frac{z_i^2 e^2 N_A}{8\pi\epsilon_0 r_i} = \frac{z_i^2 e^2 N_A}{8\pi\epsilon_r \epsilon_0 r_i} - \frac{z_i^2 e^2 N_A}{8\pi\epsilon_0 r_i} = -\frac{z_i^2 e^2 N_A}{8\pi\epsilon_0 r_i} \left(1 - \frac{1}{\epsilon_r}\right)$$

which is eqn 3.45.

### Further information 3.2 The fugacity

At various stages in the development of physical chemistry it is necessary to switch from a consideration of idealized systems to real systems. In many cases it is desirable to preserve the form of the expressions that have been derived for an idealized system. Then deviations from the idealized behaviour can be expressed most simply. For instance, the pressure dependence of the molar Gibbs energy of a real gas might resemble that shown in Fig. 3.25. To adapt eqn 3.60 to this case, we replace the true pressure,  $p$ , by an effective pressure, called the **fugacity**,<sup>9</sup>  $f$ , and write

$$G_m = G_m^\ominus + RT \ln \frac{f}{p^\ominus} \quad [3.61]$$

The fugacity, a function of the pressure and temperature, is defined so that this relation is exactly true. Although thermodynamic expressions

**Fig. 3.25** The molar Gibbs energy of a real gas. As  $p \rightarrow 0$ , the molar Gibbs energy coincides with the value for a perfect gas (shown by the black line). When attractive forces are dominant (at intermediate pressures), the molar Gibbs energy is less than that of a perfect gas and the molecules have a lower ‘escaping tendency’. At high pressures, when repulsive forces are dominant, the molar Gibbs energy of a real gas is greater than that of a perfect gas. Then the ‘escaping tendency’ is increased.

<sup>9</sup> The name ‘fugacity’ comes from the Latin for ‘fleetness’ in the sense of ‘escaping tendency’; fugacity has the same dimensions as pressure.

in terms of fugacities derived from this expression are exact, they are useful only if we know how to interpret fugacities in terms of actual pressures. To develop this relation we write the fugacity as

$$f = \phi p \quad [3.62]$$

where  $\phi$  is the dimensionless **fugacity coefficient**, which in general depends on the temperature, the pressure, and the identity of the gas.

Equation 3.57b is true for all gases whether real or perfect.

Expressing it in terms of the fugacity by using eqn 3.61 turns it into

$$\int_{p'}^p V_m dp = G_m(p) - G_m(p') = \left\{ G_m^\ominus + RT \ln \frac{f}{p^\ominus} \right\} - \left\{ G_m^\ominus + RT \ln \frac{f'}{p^\ominus} \right\}$$

In this expression,  $f$  is the fugacity when the pressure is  $p$  and  $f'$  is the fugacity when the pressure is  $p'$ . If the gas were perfect, we would write

$$\int_{p'}^p V_{\text{perfect},m} dp = RT \int_{p'}^p \frac{1}{p} dp = RT \ln \frac{p}{p'}$$

The difference between the two equations is

$$\int_{p'}^p (V_m - V_{\text{perfect},m}) dp = RT \left( \ln \frac{f}{f'} - \ln \frac{p}{p'} \right) = RT \ln \left( \frac{f/f'}{p/p'} \right)$$

which can be rearranged into

$$\ln \left( \frac{f}{p} \times \frac{p'}{f'} \right) = \frac{1}{RT} \int_{p'}^p (V_m - V_{\text{perfect},m}) dp$$

When  $p' \rightarrow 0$ , the gas behaves perfectly and  $f'$  becomes equal to the pressure,  $p'$ . Therefore,  $f'/p' \rightarrow 1$  as  $p' \rightarrow 0$ . If we take this limit, which means setting  $f'/p' = 1$  on the left and  $p' = 0$  on the right, the last equation becomes

$$\ln \frac{f}{p} = \frac{1}{RT} \int_0^p (V_m - V_{\text{perfect},m}) dp$$

Then, with  $\phi = f/p$ ,

$$\ln \phi = \frac{1}{RT} \int_0^p (V_m - V_{\text{perfect},m}) dp$$

For a perfect gas,  $V_{\text{perfect},m} = RT/p$ . For a real gas,  $V_m = RTZ/p$ , where  $Z$  is the compression factor of the gas (Section 1.3a). With these two substitutions, we obtain

$$\ln \phi = \int_0^p \frac{Z - 1}{p} dp \quad (3.63)$$

Provided we know how  $Z$  varies with pressure up to the pressure of interest, this expression enables us to determine the fugacity coefficient and hence, through eqn 3.62, to relate the fugacity to the pressure of the gas.

We see from Fig. 1.14 that for most gases  $Z < 1$  up to moderate pressures, but that  $Z > 1$  at higher pressures. If  $Z < 1$  throughout the range of integration, then the integrand in eqn 3.63 is negative and  $\phi < 1$ . This value implies that  $f < p$  (the molecules tend to stick

**Fig. 3.26** The fugacity coefficient of a van der Waals gas plotted using the reduced variables of the gas. The curves are labelled with the reduced temperature  $T_r = T/T_c$ .

**interActivity** Evaluate the fugacity coefficient as a function of the reduced volume of a van der Waals gas and plot the outcome for a selection of reduced temperatures over the range  $0.8 \leq V_r \leq 3$ .

together) and that the molar Gibbs energy of the gas is less than that of a perfect gas. At higher pressures, the range over which  $Z > 1$  may dominate the range over which  $Z < 1$ . The integral is then positive,  $\phi > 1$ , and  $f > p$  (the repulsive interactions are dominant and tend to drive the particles apart). Now the molar Gibbs energy of the gas is greater than that of the perfect gas at the same pressure.

Figure 3.26, which has been calculated using the full van der Waals equation of state, shows how the fugacity coefficient depends on the pressure in terms of the reduced variables (Section 1.4). Because critical constants are available in Table 1.5, the graphs can be used for quick estimates of the fugacities of a wide range of gases. Table 3.6 gives some explicit values for nitrogen.

**Table 3.6\*** The fugacity of nitrogen at 273 K

| $p/\text{atm}$ | $f/\text{atm}$ |
|----------------|----------------|
| 1              | 0.999 55       |
| 10             | 9.9560         |
| 100            | 97.03          |
| 1000           | 1839           |

## Discussion questions

**3.1** The evolution of life requires the organization of a very large number of molecules into biological cells. Does the formation of living organisms violate the Second Law of thermodynamics? State your conclusion clearly and present detailed arguments to support it.

**3.2** You received an unsolicited proposal from a self-declared inventor who is seeking investors for the development of his latest idea: a device that uses heat extracted from the ground by a heat pump to boil water into steam that is used to heat a home and to power a steam engine that drives the heat pump. This procedure is potentially very lucrative because, after an initial extraction of energy from the ground, no fossil fuels would be required to keep the device running indefinitely. Would you invest in this idea? State your conclusion clearly and present detailed arguments to support it.

**3.3** The following expressions have been used to establish criteria for spontaneous change:  $\Delta S_{\text{tot}} > 0$ ,  $dS_{U,V} \geq 0$  and  $dU_{S,V} \leq 0$ ,  $dA_{T,V} \leq 0$ , and  $dG_{T,p} \leq 0$ . Discuss the origin, significance, and applicability of each criterion.

**3.4** The following expressions have been used to establish criteria for spontaneous change:  $dA_{T,V} < 0$  and  $dG_{T,p} < 0$ . Discuss the origin, significance, and applicability of each criterion.

**3.5** Discuss the physical interpretation of any one Maxwell relation.

**3.6** Account for the dependence of  $\pi_T$  of a van der Waals gas in terms of the significance of the parameters  $a$  and  $b$ .

**3.7** Suggest a physical interpretation of the dependence of the Gibbs energy on the pressure.

**3.8** Suggest a physical interpretation of the dependence of the Gibbs energy on the temperature.

## Exercises

Assume that all gases are perfect and that data refer to 298.15 K unless otherwise stated.

**3.1(a)** Calculate the change in entropy when 25 kJ of energy is transferred reversibly and isothermally as heat to a large block of iron at (a) 0°C, (b) 100°C.

**3.1(b)** Calculate the change in entropy when 50 kJ of energy is transferred reversibly and isothermally as heat to a large block of copper at (a) 0°C, (b) 70°C.

**3.2(a)** Calculate the molar entropy of a constant-volume sample of neon at 500 K given that it is  $146.22 \text{ J K}^{-1} \text{ mol}^{-1}$  at 298 K.

**3.2(b)** Calculate the molar entropy of a constant-volume sample of argon at 250 K given that it is  $154.84 \text{ J K}^{-1} \text{ mol}^{-1}$  at 298 K.

**3.3(a)** Calculate  $\Delta S$  (for the system) when the state of 3.00 mol of perfect gas atoms, for which  $C_{p,m} = \frac{5}{2}R$ , is changed from 25°C and 1.00 atm to 125°C and 5.00 atm. How do you rationalize the sign of  $\Delta S$ ?

**3.3(b)** Calculate  $\Delta S$  (for the system) when the state of 2.00 mol diatomic perfect gas molecules, for which  $C_{p,m} = \frac{7}{2}R$ , is changed from 25°C and 1.50 atm to 135°C and 7.00 atm. How do you rationalize the sign of  $\Delta S$ ?

**3.4(a)** A sample consisting of 3.00 mol of diatomic perfect gas molecules at 200 K is compressed reversibly and adiabatically until its temperature reaches 250 K. Given that  $C_{V,m} = 27.5 \text{ J K}^{-1} \text{ mol}^{-1}$ , calculate  $q$ ,  $w$ ,  $\Delta U$ ,  $\Delta H$ , and  $\Delta S$ .

**3.4(b)** A sample consisting of 2.00 mol of diatomic perfect gas molecules at 250 K is compressed reversibly and adiabatically until its temperature reaches 300 K. Given that  $C_{V,m} = 27.5 \text{ J K}^{-1} \text{ mol}^{-1}$ , calculate  $q$ ,  $w$ ,  $\Delta U$ ,  $\Delta H$ , and  $\Delta S$ .

**3.5(a)** Calculate  $\Delta H$  and  $\Delta S_{\text{tot}}$  when two copper blocks, each of mass 10.0 kg, one at 100°C and the other at 0°C, are placed in contact in an isolated container. The specific heat capacity of copper is  $0.385 \text{ J K}^{-1} \text{ g}^{-1}$  and may be assumed constant over the temperature range involved.

**3.5(b)** Calculate  $\Delta H$  and  $\Delta S_{\text{tot}}$  when two iron blocks, each of mass 1.00 kg, one at 200°C and the other at 25°C, are placed in contact in an isolated container. The specific heat capacity of iron is  $0.449 \text{ J K}^{-1} \text{ g}^{-1}$  and may be assumed constant over the temperature range involved.

**3.6(a)** Consider a system consisting of 2.0 mol  $\text{CO}_2(\text{g})$ , initially at 25°C and 10 atm and confined to a cylinder of cross-section  $10.0 \text{ cm}^2$ . It is allowed to expand adiabatically against an external pressure of 1.0 atm until the piston has moved outwards through 20 cm. Assume that carbon dioxide may be considered a perfect gas with  $C_{V,m} = 28.8 \text{ J K}^{-1} \text{ mol}^{-1}$  and calculate (a)  $q$ , (b)  $w$ , (c)  $\Delta U$ , (d)  $\Delta T$ , (e)  $\Delta S$ .

**3.6(b)** Consider a system consisting of 1.5 mol  $\text{CO}_2(\text{g})$ , initially at 15°C and 9.0 atm and confined to a cylinder of cross-section  $100.0 \text{ cm}^2$ . The sample is allowed to expand adiabatically against an external pressure of 1.5 atm until the piston has moved outwards through 15 cm. Assume that carbon dioxide may be considered a perfect gas with  $C_{V,m} = 28.8 \text{ J K}^{-1} \text{ mol}^{-1}$ , and calculate (a)  $q$ , (b)  $w$ , (c)  $\Delta U$ , (d)  $\Delta T$ , (e)  $\Delta S$ .

**3.7(a)** The enthalpy of vaporization of chloroform ( $\text{CHCl}_3$ ) is  $29.4 \text{ kJ mol}^{-1}$  at its normal boiling point of 334.88 K. Calculate (a) the entropy of vaporization of chloroform at this temperature and (b) the entropy change of the surroundings.

**3.7(b)** The enthalpy of vaporization of methanol is  $35.27 \text{ kJ mol}^{-1}$  at its normal boiling point of 64.1°C. Calculate (a) the entropy of vaporization of methanol at this temperature and (b) the entropy change of the surroundings.

**3.8(a)** Calculate the standard reaction entropy at 298 K of

**3.8(b)** Calculate the standard reaction entropy at 298 K of

**3.9(a)** Combine the reaction entropies calculated in Exercise 3.8a with the reaction enthalpies, and calculate the standard reaction Gibbs energies at 298 K.

**3.9(b)** Combine the reaction entropies calculated in Exercise 3.8b with the reaction enthalpies, and calculate the standard reaction Gibbs energies at 298 K.

**3.10(a)** Use standard Gibbs energies of formation to calculate the standard reaction Gibbs energies at 298 K of the reactions in Exercise 3.8a.

**3.10(b)** Use standard Gibbs energies of formation to calculate the standard reaction Gibbs energies at 298 K of the reactions in Exercise 3.8b.

**3.11(a)** Calculate the standard Gibbs energy of the reaction  $4 \text{ HCl}(\text{g}) + \text{O}_2(\text{g}) \rightarrow 2 \text{ Cl}_2(\text{g}) + 2 \text{ H}_2\text{O}(\text{l})$  at 298 K, from the standard entropies and enthalpies of formation given in the *Data section*.

**3.11(b)** Calculate the standard Gibbs energy of the reaction  $\text{CO}(\text{g}) + \text{CH}_3\text{OH}(\text{l}) \rightarrow \text{CH}_3\text{COOH}(\text{l})$  at 298 K, from the standard entropies and enthalpies of formation given in the *Data section*.

**3.12(a)** The standard enthalpy of combustion of solid phenol ( $\text{C}_6\text{H}_5\text{OH}$ ) is  $-3054 \text{ kJ mol}^{-1}$  at 298 K and its standard molar entropy is  $144.0 \text{ J K}^{-1} \text{ mol}^{-1}$ . Calculate the standard Gibbs energy of formation of phenol at 298 K.

**3.12(b)** The standard enthalpy of combustion of solid urea ( $\text{CO}(\text{NH}_2)_2$ ) is  $-632 \text{ kJ mol}^{-1}$  at 298 K and its standard molar entropy is  $104.60 \text{ J K}^{-1} \text{ mol}^{-1}$ . Calculate the standard Gibbs energy of formation of urea at 298 K.

**3.13(a)** Calculate the change in the entropies of the system and the surroundings, and the total change in entropy, when a sample of nitrogen gas of mass 14 g at 298 K and 1.00 bar doubles its volume in (a) an isothermal reversible expansion, (b) an isothermal irreversible expansion against  $p_{\text{ex}} = 0$ , and (c) an adiabatic reversible expansion.

**3.13(b)** Calculate the change in the entropies of the system and the surroundings, and the total change in entropy, when the volume of a sample of argon gas of mass 21 g at 298 K and 1.50 bar increases from  $1.20 \text{ dm}^3$  to  $4.60 \text{ dm}^3$  in (a) an isothermal reversible expansion, (b) an isothermal irreversible expansion against  $p_{\text{ex}} = 0$ , and (c) an adiabatic reversible expansion.

**3.14(a)** Calculate the maximum non-expansion work per mole that may be obtained from a fuel cell in which the chemical reaction is the combustion of methane at 298 K.

**3.14(b)** Calculate the maximum non-expansion work per mole that may be obtained from a fuel cell in which the chemical reaction is the combustion of propane at 298 K.

**3.15(a)** (a) Calculate the Carnot efficiency of a primitive steam engine operating on steam at 100°C and discharging at 60°C. (b) Repeat the calculation for a modern steam turbine that operates with steam at 300°C and discharges at 80°C.

**3.15(b)** A certain heat engine operates between 1000 K and 500 K. (a) What is the maximum efficiency of the engine? (b) Calculate the maximum work that

can be done by for each 1.0 kJ of heat supplied by the hot source. (c) How much heat is discharged into the cold sink in a reversible process for each 1.0 kJ supplied by the hot source?

**3.16(a)** Suppose that 3.0 mmol  $\text{N}_2(\text{g})$  occupies  $36 \text{ cm}^3$  at 300 K and expands to  $60 \text{ cm}^3$ . Calculate  $\Delta G$  for the process.

**3.16(b)** Suppose that 2.5 mmol  $\text{Ar}(\text{g})$  occupies  $72 \text{ dm}^3$  at 298 K and expands to  $100 \text{ dm}^3$ . Calculate  $\Delta G$  for the process.

**3.17(a)** The change in the Gibbs energy of a certain constant-pressure process was found to fit the expression  $\Delta G/J = -85.40 + 36.5(T/K)$ . Calculate the value of  $\Delta S$  for the process.

**3.17(b)** The change in the Gibbs energy of a certain constant-pressure process was found to fit the expression  $\Delta G/J = -73.1 + 42.8(T/K)$ . Calculate the value of  $\Delta S$  for the process.

**3.18(a)** Calculate the change in Gibbs energy of 35 g of ethanol (mass density  $0.789 \text{ g cm}^{-3}$ ) when the pressure is increased isothermally from 1 atm to 3000 atm.

**3.18(b)** Calculate the change in Gibbs energy of 25 g of methanol (mass density  $0.791 \text{ g cm}^{-3}$ ) when the pressure is increased isothermally from 100 kPa to 100 MPa. Take  $k_T = 1.26 \times 10^{-9} \text{ Pa}^{-1}$ .

**3.19(a)** Calculate the change in chemical potential of a perfect gas when its pressure is increased isothermally from 1.8 atm to 29.5 atm at  $40^\circ\text{C}$ .

**3.19(b)** Calculate the change in chemical potential of a perfect gas that its pressure is increased isothermally from 92.0 kPa to 252.0 kPa at  $50^\circ\text{C}$ .

**3.20(a)** The fugacity coefficient of a certain gas at 200 K and 50 bar is 0.72. Calculate the difference of its molar Gibbs energy from that of a perfect gas in the same state.

**3.20(b)** The fugacity coefficient of a certain gas at 290 K and 2.1 MPa is 0.68. Calculate the difference of its molar Gibbs energy from that of a perfect gas in the same state.

**3.21(a)** Estimate the change in the Gibbs energy of  $1.0 \text{ dm}^3$  of benzene when the pressure acting on it is increased from 1.0 atm to 100 atm.

**3.21(b)** Estimate the change in the Gibbs energy of  $1.0 \text{ dm}^3$  of water when the pressure acting on it is increased from 100 kPa to 300 kPa.

**3.22(a)** Calculate the change in the molar Gibbs energy of hydrogen gas when its pressure is increased isothermally from 1.0 atm to 100.0 atm at 298 K.

**3.22(b)** Calculate the change in the molar Gibbs energy of oxygen when its pressure is increased isothermally from 50.0 kPa to 100.0 kPa at 500 K.

## Problems\*

Assume that all gases are perfect and that data refer to 298 K unless otherwise stated.

### Numerical problems

**3.1** Calculate the difference in molar entropy (a) between liquid water and ice at  $-5^\circ\text{C}$ , (b) between liquid water and its vapour at  $95^\circ\text{C}$  and 1.00 atm. The differences in heat capacities on melting and on vaporization are  $37.3 \text{ J K}^{-1} \text{ mol}^{-1}$  and  $-41.9 \text{ J K}^{-1} \text{ mol}^{-1}$ , respectively. Distinguish between the entropy changes of the sample, the surroundings, and the total system, and discuss the spontaneity of the transitions at the two temperatures.

**3.2** The heat capacity of chloroform (trichloromethane,  $\text{CHCl}_3$ ) in the range 240 K to 330 K is given by  $C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1}) = 91.47 + 7.5 \times 10^{-2} (T/\text{K})$ . In a particular experiment, 1.00 mol  $\text{CHCl}_3$  is heated from 273 K to 300 K. Calculate the change in molar entropy of the sample.

**3.3** A block of copper of mass 2.00 kg ( $C_{p,m} = 24.44 \text{ J K}^{-1} \text{ mol}^{-1}$ ) and temperature  $0^\circ\text{C}$  is introduced into an insulated container in which there is 1.00 mol  $\text{H}_2\text{O}(\text{g})$  at  $100^\circ\text{C}$  and 1.00 atm. (a) Assuming all the steam is condensed to water, what will be the final temperature of the system, the heat transferred from water to copper, and the entropy change of the water, copper, and the total system? (b) In fact, some water vapour is present at equilibrium. From the vapour pressure of water at the temperature calculated in (a), and assuming that the heat capacities of both gaseous and liquid water are constant and given by their values at that temperature, obtain an improved value of the final temperature, the heat transferred, and the various entropies. (Hint. You will need to make plausible approximations.)

**3.4** Consider a perfect gas contained in a cylinder and separated by a frictionless adiabatic piston into two sections A and B. All changes in B are isothermal, that is, a thermostat surrounds B to keep its temperature constant. There is 2.00 mol of the gas in each section. Initially  $T_A = T_B = 300 \text{ K}$ ,  $V_A = V_B$

$= 2.00 \text{ dm}^3$ . Energy is supplied as heat to Section A and the piston moves to the right reversibly until the final volume of Section B is  $1.00 \text{ dm}^3$ . Calculate (a)  $\Delta S_A$  and  $\Delta S_B$ , (b)  $\Delta A_A$  and  $\Delta A_B$ , (c)  $\Delta G_A$  and  $\Delta G_B$ , (d)  $\Delta S$  of the total system and its surroundings. If numerical values cannot be obtained, indicate whether the values should be positive, negative, or zero or are indeterminate from the information given. (Assume  $C_{V,m} = 20 \text{ J K}^{-1} \text{ mol}^{-1}$ .)

**3.5** A Carnot cycle uses 1.00 mol of a monatomic perfect gas as the working substance from an initial state of 10.0 atm and 600 K. It expands isothermally to a pressure of 1.00 atm (Step 1), and then adiabatically to a temperature of 300 K (Step 2). This expansion is followed by an isothermal compression (Step 3), and then an adiabatic compression (Step 4) back to the initial state. Determine the values of  $q$ ,  $w$ ,  $\Delta U$ ,  $\Delta H$ ,  $\Delta S$ ,  $\Delta S_{\text{tot}}$ , and  $\Delta G$  for each stage of the cycle and for the cycle as a whole. Express your answer as a table of values.

**3.6** 1.00 mol of perfect gas molecules at  $27^\circ\text{C}$  is expanded isothermally from an initial pressure of 3.00 atm to a final pressure of 1.00 atm in two ways: (a) reversibly, and (b) against a constant external pressure of 1.00 atm. Determine the values of  $q$ ,  $w$ ,  $\Delta U$ ,  $\Delta H$ ,  $\Delta S$ ,  $\Delta S_{\text{sur}}$ ,  $\Delta S_{\text{tot}}$  for each path.

**3.7** The standard molar entropy of  $\text{NH}_3(\text{g})$  is  $192.45 \text{ J K}^{-1} \text{ mol}^{-1}$  at 298 K, and its heat capacity is given by eqn 2.25 with the coefficients given in Table 2.2. Calculate the standard molar entropy at (a)  $100^\circ\text{C}$  and (b)  $500^\circ\text{C}$ .

**3.8** A block of copper of mass 500 g and initially at 293 K is in thermal contact with an electric heater of resistance  $1.00 \text{ k}\Omega$  and negligible mass. A current of 1.00 A is passed for 15.0 s. Calculate the change in entropy of the copper, taking  $C_{p,m} = 24.4 \text{ J K}^{-1} \text{ mol}^{-1}$ . The experiment is then repeated with the copper immersed in a stream of water that maintains its temperature at 293 K. Calculate the change in entropy of the copper and the water in this case.

**3.9** Find an expression for the change in entropy when two blocks of the same substance and of equal mass, one at the temperature  $T_h$  and the other at  $T_c$ , are brought into thermal contact and allowed to reach equilibrium. Evaluate the

\* Problems denoted with the symbol ‡ were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

change for two blocks of copper, each of mass 500 g, with  $C_{p,m} = 24.4 \text{ J K}^{-1} \text{ mol}^{-1}$ , taking  $T_h = 500 \text{ K}$  and  $T_c = 250 \text{ K}$ .

**3.10** A gaseous sample consisting of 1.00 mol molecules is described by the equation of state  $pV_m = RT(1 + Bp)$ . Initially at 373 K, it undergoes Joule–Thomson expansion from 100 atm to 1.00 atm. Given that  $C_{p,m} = \frac{5}{2}R$ ,  $\mu = 0.21 \text{ K atm}^{-1}$ ,  $B = -0.525(\text{K/T}) \text{ atm}^{-1}$ , and that these are constant over the temperature range involved, calculate  $\Delta T$  and  $\Delta S$  for the gas.

**3.11** The molar heat capacity of lead varies with temperature as follows:

|                                              |      |      |      |      |      |      |
|----------------------------------------------|------|------|------|------|------|------|
| $T/\text{K}$                                 | 10   | 15   | 20   | 25   | 30   | 50   |
| $C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$ | 2.8  | 7.0  | 10.8 | 14.1 | 16.5 | 21.4 |
| $T/\text{K}$                                 | 70   | 100  | 150  | 200  | 250  | 298  |
| $C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$ | 23.3 | 24.5 | 25.3 | 25.8 | 26.2 | 26.6 |

Calculate the standard Third-Law entropy of lead at (a)  $0^\circ\text{C}$  and (b)  $25^\circ\text{C}$ .

**3.12** From standard enthalpies of formation, standard entropies, and standard heat capacities available from tables in the *Data section*, calculate the standard enthalpies and entropies at 298 K and 398 K for the reaction  $\text{CO}_2(\text{g}) + \text{H}_2(\text{g}) \rightarrow \text{CO}(\text{g}) + \text{H}_2\text{O}(\text{g})$ . Assume that the heat capacities are constant over the temperature range involved.

**3.13** The heat capacity of anhydrous potassium hexacyanoferrate(II) varies with temperature as follows:

|              |                                              |              |                                              |
|--------------|----------------------------------------------|--------------|----------------------------------------------|
| $T/\text{K}$ | $C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$ | $T/\text{K}$ | $C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$ |
| 10           | 2.09                                         | 100          | 179.6                                        |
| 20           | 14.43                                        | 110          | 192.8                                        |
| 30           | 36.44                                        | 150          | 237.6                                        |
| 40           | 62.55                                        | 160          | 247.3                                        |
| 50           | 87.03                                        | 170          | 256.5                                        |
| 60           | 111.0                                        | 180          | 265.1                                        |
| 70           | 131.4                                        | 190          | 273.0                                        |
| 80           | 149.4                                        | 200          | 280.3                                        |
| 90           | 165.3                                        |              |                                              |

Calculate the molar enthalpy relative to its value at  $T = 0$  and the Third-Law entropy at each of these temperatures.

**3.14** The compound 1,3,5-trichloro-2,4,6-trifluorobenzene is an intermediate in the conversion of hexachlorobenzene to hexafluorobenzene, and its thermodynamic properties have been examined by measuring its heat capacity over a wide temperature range (R.L. Andon and J.F. Martin, *J. Chem. Soc. Faraday Trans. I*, 871 (1973)). Some of the data are as follows:

|                                              |        |        |        |        |        |        |
|----------------------------------------------|--------|--------|--------|--------|--------|--------|
| $T/\text{K}$                                 | 14.14  | 16.33  | 20.03  | 31.15  | 44.08  | 64.81  |
| $C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$ | 9.492  | 12.70  | 18.18  | 32.54  | 46.86  | 66.36  |
| $T/\text{K}$                                 | 100.90 | 140.86 | 183.59 | 225.10 | 262.99 | 298.06 |
| $C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$ | 95.05  | 121.3  | 144.4  | 163.7  | 180.2  | 196.4  |

Calculate the molar enthalpy relative to its value at  $T = 0$  and the Third-Law molar entropy of the compound at these temperatures.

**3.15†** Given that  $S_m^\circ = 29.79 \text{ J K}^{-1} \text{ mol}^{-1}$  for bismuth at 100 K and the following tabulated heat capacities data (D.G. Archer, *J. Chem. Eng. Data* **40**, 1015 (1995)), compute the standard molar entropy of bismuth at 200 K.

|                                              |       |       |       |       |       |       |       |
|----------------------------------------------|-------|-------|-------|-------|-------|-------|-------|
| $T/\text{K}$                                 | 100   | 120   | 140   | 150   | 160   | 180   | 200   |
| $C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$ | 23.00 | 23.74 | 24.25 | 24.44 | 24.61 | 24.89 | 25.11 |

Compare the value to the value that would be obtained by taking the heat capacity to be constant at  $24.44 \text{ J K}^{-1} \text{ mol}^{-1}$  over this range.

**3.16** Calculate  $\Delta_r G^\circ(375 \text{ K})$  for the reaction  $2 \text{CO}(\text{g}) + \text{O}_2(\text{g}) \rightarrow 2 \text{CO}_2(\text{g})$  from the value of  $\Delta_r G^\circ(298 \text{ K})$ ,  $\Delta_r H^\circ(298 \text{ K})$ , and the Gibbs–Helmholtz equation.

**3.17** Estimate the standard reaction Gibbs energy of  $\text{N}_2(\text{g}) + 3 \text{H}_2(\text{g}) \rightarrow 2 \text{NH}_3(\text{g})$  at (a) 500 K, (b) 1000 K from their values at 298 K.

**3.18** At 200 K, the compression factor of oxygen varies with pressure as shown below. Evaluate the fugacity of oxygen at this temperature and 100 atm.

|                |        |         |         |         |        |        |        |
|----------------|--------|---------|---------|---------|--------|--------|--------|
| $p/\text{atm}$ | 1.0000 | 4.00000 | 7.00000 | 10.0000 | 40.00  | 70.00  | 100.0  |
| $Z$            | 0.9971 | 0.98796 | 0.97880 | 0.96956 | 0.8734 | 0.7764 | 0.6871 |

## Theoretical problems

**3.19** Represent the Carnot cycle on a temperature–entropy diagram and show that the area enclosed by the cycle is equal to the work done.

**3.20** Prove that two reversible adiabatic paths can never cross. Assume that the energy of the system under consideration is a function of temperature only. (*Hint*. Suppose that two such paths can intersect, and complete a cycle with the two paths plus one isothermal path. Consider the changes accompanying each stage of the cycle and show that they conflict with the Kelvin statement of the Second Law.)

**3.21** Prove that the perfect gas temperature scale and the thermodynamic temperature scale based on the Second Law of thermodynamics differ from each other by at most a constant numerical factor.

**3.22** The molar Gibbs energy of a certain gas is given by  $G_m = RT \ln p + A + Bp + \frac{1}{2}Cp^2 + \frac{1}{3}Dp^3$ , where  $A$ ,  $B$ ,  $C$ , and  $D$  are constants. Obtain the equation of state of the gas.

**3.23** Evaluate  $(\partial S/\partial V)_T$  for (a) a van der Waals gas, (b) a Dieterici gas (Table 1.7). For an isothermal expansion, for which kind of gas (and a perfect gas) will  $\Delta S$  be greatest? Explain your conclusion.

**3.24** Show that, for a perfect gas,  $(\partial U/\partial S)_V = T$  and  $(\partial U/\partial V)_S = -p$ .

**3.25** Two of the four Maxwell relations were derived in the text, but two were not. Complete their derivation by showing that  $(\partial S/\partial V)_T = (\partial p/\partial T)_V$  and  $(\partial T/\partial p)_S = (\partial V/\partial S)_p$ .

**3.26** Use the Maxwell relations to express the derivatives (a)  $(\partial S/\partial V)_T$  and  $(\partial V/\partial S)_p$  and (b)  $(\partial p/\partial S)_V$  and  $(\partial V/\partial S)_p$  in terms of the heat capacities, the expansion coefficient  $\alpha$ , and the isothermal compressibility,  $\kappa_T$ .

**3.27** Use the Maxwell relations to show that the entropy of a perfect gas depends on the volume as  $S \propto R \ln V$ .

**3.28** Derive the thermodynamic equation of state

$$\left(\frac{\partial H}{\partial p}\right)_T = V - T\left(\frac{\partial V}{\partial T}\right)_p$$

Derive an expression for  $(\partial H/\partial p)_T$  for (a) a perfect gas and (b) a van der Waals gas. In the latter case, estimate its value for 1.0 mol Ar(g) at 298 K and 10 atm. By how much does the enthalpy of the argon change when the pressure is increased isothermally to 11 atm?

**3.29** Show that, if  $B(T)$  is the second virial coefficient of a gas, and  $\Delta B = B(T'') - B(T')$ ,  $\Delta T = T'' - T'$ , and  $T$  is the mean of  $T''$  and  $T'$ , then  $\pi_T \approx RT^2 \Delta B/V_m^2 \Delta T$ . Estimate  $\pi_T$  for argon given that  $B(250 \text{ K}) = -28.0 \text{ cm}^3 \text{ mol}^{-1}$  and  $B(300 \text{ K}) = -15.6 \text{ cm}^3 \text{ mol}^{-1}$  at 275 K at (a) 1.0 atm, (b) 10.0 atm.

**3.30** The Joule coefficient,  $\mu_J$ , is defined as  $\mu_J = (\partial T/\partial V)_U$ . Show that  $\mu_J C_V = p - \alpha T/\kappa_T$ .

**3.31** Evaluate  $\pi_T$  for a Dieterici gas (Table 1.7). Justify physically the form of the expression obtained.

**3.32** The adiabatic compressibility,  $\kappa_S$ , is defined like  $\kappa_T$  (eqn 2.43) but at constant entropy. Show that for a perfect gas  $p\gamma\kappa_S = 1$  (where  $\gamma$  is the ratio of heat capacities).

**3.33** Suppose that  $S$  is regarded as a function of  $p$  and  $T$ . Show that  $TdS = C_p dT - \alpha TV dp$ . Hence, show that the energy transferred as heat when the pressure on an incompressible liquid or solid is increased by  $\Delta p$  is equal to  $-\alpha TV \Delta p$ . Evaluate  $q$  when the pressure acting on 100 cm<sup>3</sup> of mercury at 0°C is increased by 1.0 kbar. ( $\alpha = 1.82 \times 10^{-4} \text{ K}^{-1}$ .)

**3.34** Suppose that (a) the attractive interactions between gas particles can be neglected, (b) the attractive interaction is dominant in a van der Waals gas, and the pressure is low enough to make the approximation  $4ap/(RT)^2 \ll 1$ . Find expressions for the fugacity of a van der Waals gas in terms of the pressure and estimate its value for ammonia at 10.00 atm and 298.15 K in each case.

**3.35** Find an expression for the fugacity coefficient of a gas that obeys the equation of state  $pV_m = RT(1 + B/V_m + C/V_m^2)$ . Use the resulting expression to estimate the fugacity of argon at 1.00 atm and 100 K using  $B = -21.13 \text{ cm}^3 \text{ mol}^{-1}$  and  $C = 1054 \text{ cm}^6 \text{ mol}^{-2}$ .

### Applications: to biology, environmental science, polymer science, and engineering

**3.36** The protein lysozyme unfolds at a transition temperature of 75.5°C and the standard enthalpy of transition is 509 kJ mol<sup>-1</sup>. Calculate the entropy of unfolding of lysozyme at 25.0°C, given that the difference in the constant-pressure heat capacities upon unfolding is 6.28 kJ K<sup>-1</sup> mol<sup>-1</sup> and can be assumed to be independent of temperature. *Hint.* Imagine that the transition at 25.0°C occurs in three steps: (i) heating of the folded protein from 25.0°C to the transition temperature, (ii) unfolding at the transition temperature, and (iii) cooling of the unfolded protein to 25.0°C. Because the entropy is a state function, the entropy change at 25.0°C is equal to the sum of the entropy changes of the steps.

**3.37** At 298 K the standard enthalpy of combustion of sucrose is -5797 kJ mol<sup>-1</sup> and the standard Gibbs energy of the reaction is -6333 kJ mol<sup>-1</sup>. Estimate the additional non-expansion work that may be obtained by raising the temperature to blood temperature, 37°C.

**3.38** In biological cells, the energy released by the oxidation of foods (*Impact I2.2*) is stored in adenosine triphosphate (ATP or ATP<sup>4-</sup>). The essence of ATP's action is its ability to lose its terminal phosphate group by hydrolysis and to form adenosine diphosphate (ADP or ADP<sup>3-</sup>):

At pH = 7.0 and 37°C (310 K, blood temperature) the enthalpy and Gibbs energy of hydrolysis are  $\Delta_r H = -20 \text{ kJ mol}^{-1}$  and  $\Delta_r G = -31 \text{ kJ mol}^{-1}$ , respectively. Under these conditions, the hydrolysis of 1 mol ATP<sup>4-</sup>(aq) results in the extraction of up to 31 kJ of energy that can be used to do non-expansion work, such as the synthesis of proteins from amino acids, muscular contraction, and the activation of neuronal circuits in our brains. (a) Calculate and account for the sign of the entropy of hydrolysis of ATP at pH = 7.0 and 310 K. (b) Suppose that the radius of a typical biological cell is 10 μm and that inside it 10<sup>6</sup> ATP molecules are hydrolysed each second. What is the power density of the cell in watts per cubic metre (1 W = 1 J s<sup>-1</sup>)? A computer battery delivers about 15 W and has a volume of 100 cm<sup>3</sup>. Which has the greater power density, the cell or the battery? (c) The formation of glutamine from glutamate and ammonium ions requires 14.2 kJ mol<sup>-1</sup> of energy input. It is driven by the hydrolysis of ATP to ADP mediated by the enzyme glutamine synthetase. How many moles of ATP must be hydrolysed to form 1 mol glutamine?

**3.39†** In 1995, the Intergovernmental Panel on Climate Change (IPCC) considered a global average temperature rise of 1.0–3.5°C likely by the year 2100, with 2.0°C its best estimate. Because water vapour is itself a greenhouse gas, the increase in water vapour content of the atmosphere is of some

concern to climate change experts. Predict the relative increase in water vapour in the atmosphere based on a temperature rises of 2.0 K, assuming that the relative humidity remains constant. (The present global mean temperature is 290 K, and the equilibrium vapour pressure of water at that temperature is 0.0189 bar.)

**3.40†** Nitric acid hydrates have received much attention as possible catalysts for heterogeneous reactions that bring about the Antarctic ozone hole. Worsnop *et al.* investigated the thermodynamic stability of these hydrates under conditions typical of the polar winter stratosphere (*Science* 259, 71 (1993)). They report thermodynamic data for the sublimation of mono-, di-, and trihydrates to nitric acid and water vapours,  $\text{HNO}_3 \cdot n\text{H}_2\text{O}(\text{s}) \rightarrow \text{HNO}_3(\text{g}) + n\text{H}_2\text{O}(\text{g})$ , for  $n = 1, 2$ , and 3. Given  $\Delta_r G^\circ$  and  $\Delta_r H^\circ$  for these reactions at 220 K, use the Gibbs–Helmholtz equation to compute  $\Delta_r G^\circ$  at 190 K.

| $n$                                     | 1    | 2    | 3    |
|-----------------------------------------|------|------|------|
| $\Delta_r G^\circ/(\text{kJ mol}^{-1})$ | 46.2 | 69.4 | 93.2 |
| $\Delta_r H^\circ/(\text{kJ mol}^{-1})$ | 127  | 188  | 237  |

**3.41†** J. Gao and J. H. Weiner in their study of the origin of stress on the atomic level in dense polymer systems (*Science* 266, 748 (1994)), observe that the tensile force required to maintain the length,  $l$ , of a long linear chain of  $N$  freely jointed links each of length  $a$ , can be interpreted as arising from an entropic spring. For such a chain,  $S(l) = -3kl^2/2Na^2 + C$ , where  $k$  is the Boltzmann constant and  $C$  is a constant. Using thermodynamic relations of this and previous chapters, show that the tensile force obeys Hooke's law,  $f = -k_t l$ , if we assume that the energy  $U$  is independent of  $l$ .

**3.42** Suppose that an internal combustion engine runs on octane, for which the enthalpy of combustion is -5512 kJ mol<sup>-1</sup> and take the mass of 1 gallon of fuel as 3 kg. What is the maximum height, neglecting all forms of friction, to which a car of mass 1000 kg can be driven on 1.00 gallon of fuel given that the engine cylinder temperature is 2000°C and the exit temperature is 800°C?

**3.43** The cycle involved in the operation of an internal combustion engine is called the *Otto cycle*. Air can be considered to be the working substance and can be assumed to be a perfect gas. The cycle consists of the following steps: (1) reversible adiabatic compression from A to B, (2) reversible constant-volume pressure increase from B to C due to the combustion of a small amount of fuel, (3) reversible adiabatic expansion from C to D, and (4) reversible and constant-volume pressure decrease back to state A. Determine the change in entropy (of the system and of the surroundings) for each step of the cycle and determine an expression for the efficiency of the cycle, assuming that the heat is supplied in Step 2. Evaluate the efficiency for a compression ratio of 10:1. Assume that in state A,  $V = 4.00 \text{ dm}^3$ ,  $p = 1.00 \text{ atm}$ , and  $T = 300 \text{ K}$ , that  $V_A = 10V_B$ ,  $p_C/p_B = 5$ , and that  $C_{p,m} = \frac{7}{2}R$ .

**3.44** To calculate the work required to lower the temperature of an object, we need to consider how the coefficient of performance changes with the temperature of the object. (a) Find an expression for the work of cooling an object from  $T_i$  to  $T_f$  when the refrigerator is in a room at a temperature  $T_h$ . *Hint.* Write  $dw = dq/c(T)$ , relate  $dq$  to  $dT$  through the heat capacity  $C_p$ , and integrate the resulting expression. Assume that the heat capacity is independent of temperature in the range of interest. (b) Use the result in part (a) to calculate the work needed to freeze 250 g of water in a refrigerator at 293 K. How long will it take when the refrigerator operates at 100 W?

**3.45** The expressions that apply to the treatment of refrigerators also describe the behaviour of heat pumps, where warmth is obtained from the back of a refrigerator while its front is being used to cool the outside world. Heat pumps are popular home heating devices because they are very efficient. Compare heating of a room at 295 K by each of two methods: (a) direct conversion of 1.00 kJ of electrical energy in an electrical heater, and (b) use of 1.00 kJ of electrical energy to run a reversible heat pump with the outside at 260 K. Discuss the origin of the difference in the energy delivered to the interior of the house by the two methods.

# Physical transformations of pure substances

The discussion of the phase transitions of pure substances is among the simplest applications of thermodynamics to chemistry. We shall see that one type of phase diagram is a map of the pressures and temperatures at which each phase of a substance is the most stable. The thermodynamic criterion of phase stability enables us to deduce a very general result, the phase rule, that summarizes the constraints on the equilibria between phases. In preparation for later chapters, we express the rule in a general way that can be applied to systems of more than one component. Then, we describe the interpretation of empirically determined phase diagrams for a selection of substances. We then consider the factors that determine the positions and shapes of the boundaries between the regions on a phase diagram. The practical importance of the expressions we derive is that they show how the vapour pressure of a substance varies with temperature and how the melting point varies with pressure. Transitions between phases are classified by noting how various thermodynamic functions change when the transition occurs. This chapter also introduces the chemical potential, a property that will be at the centre of our discussions of mixtures and chemical reactions.

Vaporization, melting (fusion), and the conversion of graphite to diamond are all examples of changes of phase without change of chemical composition. In this chapter we describe such processes thermodynamically, using as the guiding principle the tendency of systems at constant temperature and pressure to minimize their Gibbs energy.

## Phase diagrams

One of the most succinct ways of presenting the physical changes of state that a substance can undergo is in terms of its 'phase diagram'. This material is also the basis of the discussion of mixtures in Chapter 5.

### 4.1 The stabilities of phases

**Key points** (a) A phase is a form of matter that is uniform throughout in chemical composition and physical state. (b) A phase transition is the spontaneous conversion of one phase into another and may be studied by techniques that include thermal analysis. (c) The thermodynamic analysis of phases is based on the fact that, at equilibrium, the chemical potential of a substance is the same throughout a sample.

Thermodynamics provides a powerful language for describing and understanding the stabilities and transformations of phases, but to apply it we need to employ definitions carefully.

Problems

**A note on good practice** An *allotrope* is a particular form of an element (such as  $O_2$  and  $O_3$ ) and may be solid, liquid, or gas. A *polymorph* is one of a number of solid phases of an element or compound.

**Fig. 4.1** The difference between (a) a single-phase solution, in which the composition is uniform on a microscopic scale, and (b) a dispersion, in which regions of one component are embedded in a matrix of a second component.

**Fig. 4.2** A cooling curve at constant pressure. The halt corresponds to the pause in the fall of temperature while the first-order exothermic transition (freezing) occurs. This pause enables  $T_f$  to be located even if the transition cannot be observed visually.

### (a) The number of phases

A **phase** is a form of matter that is uniform throughout in chemical composition and physical state. Thus, we speak of solid, liquid, and gas phases of a substance, and of its various solid phases, such as the white and black allotropes of phosphorus or the aragonite and calcite polymorphs of calcium carbonate.

The number of phases in a system is denoted  $P$ . A gas, or a gaseous mixture, is a single phase ( $P = 1$ ), a crystal of a substance is a single phase, and two fully miscible liquids form a single phase. A solution of sodium chloride in water is a single phase. Ice is a single phase even though it might be chipped into small fragments. A slurry of ice and water is a two-phase system ( $P = 2$ ) even though it is difficult to map the physical boundaries between the phases. A system in which calcium carbonate undergoes the thermal decomposition

consists of two solid phases (one consisting of calcium carbonate and the other of calcium oxide) and one gaseous phase (consisting of carbon dioxide).

Two metals form a two-phase system ( $P = 2$ ) if they are immiscible, but a single-phase system ( $P = 1$ ), an alloy, if they are miscible. This example shows that it is not always easy to decide whether a system consists of one phase or of two. A solution of solid B in solid A—a homogeneous mixture of the two substances—is uniform on a molecular scale. In a solution, atoms of A are surrounded by atoms of A and B, and any sample cut from the sample, even microscopically small, is representative of the composition of the whole.

A dispersion is uniform on a macroscopic scale but not on a microscopic scale, for it consists of grains or droplets of one substance in a matrix of the other. A small sample could come entirely from one of the minute grains of pure A and would not be representative of the whole (Fig. 4.1). Dispersions are important because, in many advanced materials (including steels), heat treatment cycles are used to achieve the precipitation of a fine dispersion of particles of one phase (such as a carbide phase) within a matrix formed by a saturated solid solution phase. The ability to control this microstructure resulting from phase equilibria makes it possible to tailor the mechanical properties of the materials to a particular application.

### (b) Phase transitions

A **phase transition**, the spontaneous conversion of one phase into another phase, occurs at a characteristic temperature for a given pressure. Thus, at 1 atm, ice is the stable phase of water below  $0^\circ\text{C}$ , but above  $0^\circ\text{C}$  liquid water is more stable. This difference indicates that below  $0^\circ\text{C}$  the Gibbs energy decreases as liquid water changes into ice and that above  $0^\circ\text{C}$  the Gibbs energy decreases as ice changes into liquid water. The **transition temperature**,  $T_{\text{trs}}$ , is the temperature at which the two phases are in equilibrium and the Gibbs energy of the system is minimized at the prevailing pressure.

Detecting a phase transition is not always as simple as seeing water boil in a kettle, so special techniques have been developed. One technique is **thermal analysis**, which takes advantage of the heat that is evolved or absorbed during any transition. The transition is detected by noting that the temperature does not change even though heat is being supplied or removed from the sample (Fig. 4.2). Differential scanning calorimetry is also used (see *Impact I2.1*). Thermal techniques are useful for solid–solid transitions, where simple visual inspection of the sample may be inadequate. X-ray diffraction (Section 19.3) also reveals the occurrence of a phase transition in a solid, for different structures are found on either side of the transition temperature.

As always, it is important to distinguish between the thermodynamic description of a process and the rate at which the process occurs. A phase transition that is predicted from thermodynamics to be spontaneous may occur too slowly to be significant in practice. For instance, at normal temperatures and pressures the molar Gibbs energy of graphite is lower than that of diamond, so there is a thermodynamic tendency for diamond to change into graphite. However, for this transition to take place, the C atoms must change their locations, which is an immeasurably slow process in a solid except at high temperatures. The discussion of the rate of attainment of equilibrium is a kinetic problem and is outside the range of thermodynamics. In gases and liquids the mobilities of the molecules allow phase transitions to occur rapidly, but in solids thermodynamic instability may be frozen in. Thermodynamically unstable phases that persist because the transition is kinetically hindered are called **metastable phases**. Diamond is a metastable phase of carbon under normal conditions.

### (c) Thermodynamic criteria of phase stability

All our considerations will be based on the Gibbs energy of a substance, and in particular on its molar Gibbs energy,  $G_m$ . In fact, this quantity will play such an important role in this chapter and the rest of the text that we give it a special name and symbol, the **chemical potential**,  $\mu$  (mu). For a one-component system, ‘molar Gibbs energy’ and ‘chemical potential’ are synonyms, so  $\mu = G_m$ , but in Chapter 5 we shall see that chemical potential has a broader significance and a more general definition. The name ‘chemical potential’ is also instructive: as we develop the concept, we shall see that  $\mu$  is a measure of the potential that a substance has for undergoing change in a system. In this chapter, it reflects the potential of a substance to undergo physical change. In Chapter 6 we shall see that  $\mu$  is the potential of a substance to undergo chemical change.

We base the entire discussion on the following consequence of the Second Law (Fig. 4.3):

At equilibrium, the chemical potential of a substance is the same throughout a sample, regardless of how many phases are present.

Criterion of  
phase  
equilibrium

To see the validity of this remark, consider a system in which the chemical potential of a substance is  $\mu_1$  at one location and  $\mu_2$  at another location. The locations may be in the same or in different phases. When an infinitesimal amount  $dn$  of the substance is transferred from one location to the other, the Gibbs energy of the system changes by  $-\mu_1 dn$  when material is removed from location 1, and it changes by  $+\mu_2 dn$  when that material is added to location 2. The overall change is therefore  $dG = (\mu_2 - \mu_1)dn$ . If the chemical potential at location 1 is higher than that at location 2, the transfer is accompanied by a decrease in  $G$ , and so has a spontaneous tendency to occur. Only if  $\mu_1 = \mu_2$  is there no change in  $G$ , and only then is the system at equilibrium.

**Fig. 4.3** When two or more phases are in equilibrium, the chemical potential of a substance (and, in a mixture, a component) is the same in each phase and is the same at all points in each phase.

**Fig. 4.4** The general regions of pressure and temperature where solid, liquid, or gas is stable (that is, has minimum molar Gibbs energy) are shown on this phase diagram. For example, the solid phase is the most stable phase at low temperatures and high pressures. In the following paragraphs we locate the precise boundaries between the regions.

## 4.2 Phase boundaries

**Key points** (a) A substance is characterized by a variety of parameters that can be identified on its phase diagram. (b) The phase rule relates the number of variables that may be changed while the phases of a system remain in mutual equilibrium.

The **phase diagram** of a pure substance shows the regions of pressure and temperature at which its various phases are thermodynamically stable (Fig. 4.4). In fact, any two intensive variables may be used (such as temperature and magnetic field; in Chapter 5 mole fraction is another variable), but in this chapter we concentrate on pressure and

**Fig. 4.5** The vapour pressure of a liquid or solid is the pressure exerted by the vapour in equilibrium with the condensed phase.

temperature. The lines separating the regions, which are called **phase boundaries** (or *coexistence curves*), show the values of  $p$  and  $T$  at which two phases coexist in equilibrium and their chemical potentials are equal.

#### (a) Characteristic properties related to phase transitions

Consider a liquid sample of a pure substance in a closed vessel. The pressure of a vapour in equilibrium with the liquid is called the **vapour pressure** of the substance (Fig. 4.5). Therefore, the liquid–vapour phase boundary in a phase diagram shows how the vapour pressure of the liquid varies with temperature. Similarly, the solid–vapour phase boundary shows the temperature variation of the **sublimation vapour pressure**, the vapour pressure of the solid phase. The vapour pressure of a substance increases with temperature because at higher temperatures more molecules have sufficient energy to escape from their neighbours.

When a liquid is heated in an open vessel, the liquid vaporizes from its surface. When the vapour pressure is equal to the external pressure, vaporization can occur throughout the bulk of the liquid and the vapour can expand freely into the surroundings. The condition of free vaporization throughout the liquid is called **boiling**. The temperature at which the vapour pressure of a liquid is equal to the external pressure is called the **boiling temperature** at that pressure. For the special case of an external pressure of 1 atm, the boiling temperature is called the **normal boiling point**,  $T_b$ . With the replacement of 1 atm by 1 bar as standard pressure, there is some advantage in using the **standard boiling point** instead: this is the temperature at which the vapour pressure reaches 1 bar. Because 1 bar is slightly less than 1 atm (1.00 bar = 0.987 atm), the standard boiling point of a liquid is slightly lower than its normal boiling point. The normal boiling point of water is 100.0°C; its standard boiling point is 99.6°C. We need to distinguish normal and standard properties only for precise work in thermodynamics because any thermodynamic properties that we intend to add together must refer to the same conditions.

Boiling does not occur when a liquid is heated in a rigid, closed vessel. Instead, the vapour pressure, and hence the density of the vapour, rise as the temperature is raised (Fig. 4.6). At the same time, the density of the liquid decreases slightly as a result of its expansion. There comes a stage when the density of the vapour is equal to that of the remaining liquid and the surface between the two phases disappears. The temperature at which the surface disappears is the **critical temperature**,  $T_c$ , of the substance. We first encountered this property in Section 1.3d. The vapour pressure at the critical temperature is called the **critical pressure**,  $p_c$ . At and above the critical temperature, a single uniform phase called a **supercritical fluid** fills the container and an interface no longer exists. That is, above the critical temperature, the liquid phase of the substance does not exist.

The temperature at which, under a specified pressure, the liquid and solid phases of a substance coexist in equilibrium is called the **melting temperature**. Because a substance melts at exactly the same temperature as it freezes, the melting temperature of a substance is the same as its **freezing temperature**. The freezing temperature when the pressure is 1 atm is called the **normal freezing point**,  $T_f$ , and its freezing point when the pressure is 1 bar is called the **standard freezing point**. The normal and standard freezing points are negligibly different for most purposes. The normal freezing point is also called the **normal melting point**.

There is a set of conditions under which three different phases of a substance (typically solid, liquid, and vapour) all simultaneously coexist in equilibrium. These conditions are represented by the **triple point**, a point at which the three phase boundaries meet. The temperature at the triple point is denoted  $T_3$ . The triple point of a pure substance is outside our control: it occurs at a single definite pressure and temperature characteristic of the substance. The triple point of water lies at 273.16 K

**Fig. 4.6** (a) A liquid in equilibrium with its vapour. (b) When a liquid is heated in a sealed container, the density of the vapour phase increases and that of the liquid decreases slightly. There comes a stage, (c), at which the two densities are equal and the interface between the fluids disappears. This disappearance occurs at the critical temperature. The container needs to be strong: the critical temperature of water is 374°C and the vapour pressure is then 218 atm.

and 611 Pa (6.11 mbar, 4.58 Torr), and the three phases of water (ice, liquid water, and water vapour) coexist in equilibrium at no other combination of pressure and temperature. This invariance of the triple point is the basis of its use in the definition of the thermodynamic temperature scale (Section 3.2d).

As we can see from Fig. 4.4, the triple point marks the lowest pressure at which a liquid phase of a substance can exist. If (as is common) the slope of the solid–liquid phase boundary is as shown in the diagram, then the triple point also marks the lowest temperature at which the liquid can exist; the critical temperature is the upper limit.

### (b) The phase rule

In one of the most elegant arguments of the whole of chemical thermodynamics, which is presented in the following *Justification*, J.W. Gibbs deduced the **phase rule**, which gives the number of parameters that can be varied independently (at least to a small extent) while the number of phases in equilibrium is preserved. The phase rule is a general relation between the variance,  $F$ , the number of components,  $C$ , and the number of phases at equilibrium,  $P$ , for a system of any composition:

$$F = C - P + 2 \quad \text{The phase rule} \quad (4.1)$$

A **component** is a *chemically independent* constituent of a system. The number of components,  $C$ , in a system is the minimum number of types of independent species (ions or molecules) necessary to define the composition of all the phases present in the system. In this chapter we deal only with one-component systems ( $C = 1$ ). By a **constituent** of a system we mean a chemical species that is present. Thus, a mixture of ethanol and water has two constituents. A solution of sodium chloride has three constituents—water,  $\text{Na}^+$  ions, and  $\text{Cl}^-$  ions—but only two components because the numbers of  $\text{Na}^+$  and  $\text{Cl}^-$  ions are constrained to be equal by the requirement of charge neutrality. The **variance** (or *number of degrees of freedom*),  $F$ , of a system is the number of intensive variables that can be changed independently without disturbing the number of phases in equilibrium.

In a single-component, single-phase system ( $C = 1$ ,  $P = 1$ ), the pressure and temperature may be changed independently without changing the number of phases, so  $F = 2$ . We say that such a system is **bivariant**, or that it has two **degrees of freedom**. On the other hand, if two phases are in equilibrium (a liquid and its vapour, for instance) in a single-component system ( $C = 1$ ,  $P = 2$ ), the temperature (or the pressure) can be changed at will, but the change in temperature (or pressure) demands an accompanying change in pressure (or temperature) to preserve the number of phases in equilibrium. That is, the variance of the system has fallen to 1.

#### Justification 4.1 The phase rule

Consider first the special case of a one-component system for which the phase rule is  $F = 3 - P$ . For two phases  $\alpha$  and  $\beta$  in equilibrium ( $P = 2$ ,  $F = 1$ ) at a given pressure and temperature, we can write

$$\mu(\alpha; p, T) = \mu(\beta; p, T)$$

(For instance, when ice and water are in equilibrium, we have  $\mu(s; p, T) = \mu(l; p, T)$  for  $\text{H}_2\text{O}$ .) This is an equation relating  $p$  and  $T$ , so only one of these variables is independent (just as the equation  $x + y = xy$  is a relation for  $y$  in terms of  $x$ :  $y = x/(x - 1)$ ). That conclusion is consistent with  $F = 1$ . For three phases of a one-component system in mutual equilibrium ( $P = 3$ ,  $F = 0$ ),

$$\mu(\alpha; p, T) = \mu(\beta; p, T) = \mu(\gamma; p, T)$$

This relation is actually two equations for two unknowns,  $\mu(\alpha; p, T) = \mu(\beta; p, T)$  and  $\mu(\beta; p, T) = \mu(\gamma; p, T)$ , and therefore has a solution only for a single value of  $p$  and  $T$  (just as the pair of equations  $x + y = xy$  and  $3x - y = xy$  has the single solution  $x = 2$  and  $y = 2$ ). That conclusion is consistent with  $F = 0$ . Four phases cannot be in mutual equilibrium in a one-component system because the three equalities

$$\mu(\alpha; p, T) = \mu(\beta; p, T) \quad \mu(\beta; p, T) = \mu(\gamma; p, T) \quad \mu(\gamma; p, T) = \mu(\delta; p, T)$$

are three equations for two unknowns ( $p$  and  $T$ ) and are not consistent (just as  $x + y = xy$ ,  $3x - y = xy$ , and  $x + y = 2xy^2$  have no solution).

Now consider the general case. We begin by counting the total number of intensive variables. The pressure,  $p$ , and temperature,  $T$ , count as 2. We can specify the composition of a phase by giving the mole fractions of  $C - 1$  components. We need specify only  $C - 1$  and not all  $C$  mole fractions because  $x_1 + x_2 + \dots + x_C = 1$ , and all mole fractions are known if all except one are specified. Because there are  $P$  phases, the total number of composition variables is  $P(C - 1)$ . At this stage, the total number of intensive variables is  $P(C - 1) + 2$ .

At equilibrium, the chemical potential of a component  $J$  must be the same in every phase (Section 4.4):

$$\mu(\alpha; p, T) = \mu(\beta; p, T) = \dots \text{ for } P \text{ phases}$$

That is, there are  $P - 1$  equations of this kind to be satisfied for each component  $J$ . As there are  $C$  components, the total number of equations is  $C(P - 1)$ . Each equation reduces our freedom to vary one of the  $P(C - 1) + 2$  intensive variables. It follows that the total number of degrees of freedom is

$$F = P(C - 1) + 2 - C(P - 1) = C - P + 2$$

which is eqn 4.1.

### 4.3 Three representative phase diagrams

**Key points** (a) Carbon dioxide is a typical substance but shows features that can be traced to its weak intermolecular forces. (b) Water shows anomalies that can be traced to its extensive hydrogen bonding. (c) Helium shows anomalies, including superfluidity, that can be traced to its low mass and weak interactions.

**Fig. 4.7** The typical regions of a one-component phase diagram. The lines represent conditions under which the two adjoining phases are in equilibrium. A point represents the unique set of conditions under which three phases coexist in equilibrium. Four phases cannot mutually coexist in equilibrium.

For a one-component system, such as pure water,  $F = 3 - P$ . When only one phase is present,  $F = 2$  and both  $p$  and  $T$  can be varied independently (at least over a small range) without changing the number of phases. In other words, a single phase is represented by an *area* on a phase diagram. When two phases are in equilibrium  $F = 1$ , which implies that pressure is not freely variable if the temperature is set; indeed, at a given temperature, a liquid has a characteristic vapour pressure. It follows that the equilibrium of two phases is represented by a *line* in the phase diagram. Instead of selecting the temperature, we could select the pressure, but having done so the two phases would be in equilibrium at a single definite temperature. Therefore, freezing (or any other phase transition) occurs at a definite temperature at a given pressure.

When three phases are in equilibrium,  $F = 0$  and the system is invariant. This special condition can be established only at a definite temperature and pressure that is characteristic of the substance and outside our control. The equilibrium of three phases is therefore represented by a *point*, the triple point, on a phase diagram. Four phases cannot be in equilibrium in a one-component system because  $F$  cannot be negative. These features are summarized in Fig. 4.7 and should be kept in mind when considering the form of the phase diagrams of the three pure substances treated here.

**(a) Carbon dioxide**

The phase diagram for carbon dioxide is shown in Fig. 4.8. The features to notice include the positive slope (up from left to right) of the solid–liquid boundary; the direction of this line is characteristic of most substances. This slope indicates that the melting temperature of solid carbon dioxide rises as the pressure is increased. Notice also that, as the triple point lies above 1 atm, the liquid cannot exist at normal atmospheric pressures whatever the temperature. As a result, the solid sublimates when left in the open (hence the name ‘dry ice’). To obtain the liquid, it is necessary to exert a pressure of at least 5.11 atm. Cylinders of carbon dioxide generally contain the liquid or compressed gas; at 25°C that implies a vapour pressure of 67 atm if both gas and liquid are present in equilibrium. When the gas squirts through the throttle it cools by the Joule–Thomson effect, so, when it emerges into a region where the pressure is only 1 atm, it condenses into a finely divided snow-like solid. That carbon dioxide gas cannot be liquefied except by applying high pressure reflects the weakness of the intermolecular forces between the nonpolar carbon dioxide molecules (Section 17.5).

**Fig. 4.8** The experimental phase diagram for carbon dioxide. Note that, as the triple point lies at pressures well above atmospheric, liquid carbon dioxide does not exist under normal conditions (a pressure of at least 5.11 atm must be applied).

**(b) Water**

Figure 4.9 is the phase diagram for water. The liquid–vapour boundary in the phase diagram summarizes how the vapour pressure of liquid water varies with temperature. It also summarizes how the boiling temperature varies with pressure: we simply read off the temperature at which the vapour pressure is equal to the prevailing atmospheric pressure. The solid–liquid boundary shows how the melting temperature varies with the pressure. Its very steep slope indicates that enormous pressures are needed to bring about significant changes. The line has a steep negative slope (down from left to right) up to 2 kbar, which means that the melting temperature falls as the pressure is raised. The reason for this almost unique behaviour can be traced to the decrease in volume that occurs on melting: it is more favourable for the solid to transform into the liquid as the pressure is raised. The decrease in volume is a result of the very open structure of ice: as shown in Fig. 4.10, the water molecules are held apart, as well as together, by the hydrogen bonds between them but the hydrogen-bonded structure partially collapses on melting and the liquid is denser than the solid. Other consequences of its extensive hydrogen bonding are the anomalously high boiling point of water for a molecule of its molar mass and its high critical temperature and pressure.

Figure 4.9 shows that water has one liquid phase but many different solid phases other than ordinary ice (‘ice I’). Some of these phases melt at high temperatures. Ice VII, for instance, melts at 100°C but exists only above 25 kbar. Two further phases, Ice XIII and XIV, were identified in 2006 at –160°C but have not yet been allocated regions in the phase diagram. Note that many more triple points occur in the diagram other than the one where vapour, liquid, and ice I coexist. Each one occurs at a definite pressure and temperature that cannot be changed. The solid phases of ice differ in the arrangement of the water molecules: under the influence of very high pressures, hydrogen bonds buckle and the H<sub>2</sub>O molecules adopt different arrangements. These polymorphs of ice may contribute to the advance of glaciers, for ice at the bottom of glaciers experiences very high pressures where it rests on jagged rocks.

**Fig. 4.9** The experimental phase diagram for water showing the different solid phases.

**(c) Helium**

When considering helium at low temperatures it is necessary to distinguish between the isotopes <sup>3</sup>He and <sup>4</sup>He. Figure 4.11 shows the phase diagram of helium-4. Helium behaves unusually at low temperatures because the mass of its atoms is so low and their small number of electrons results in them interacting only very weakly with their

**Fig. 4.10** A fragment of the structure of ice (ice-I). Each O atom is linked by two covalent bonds to H atoms and by two hydrogen bonds to a neighbouring O atom, in a tetrahedral array.

#### A brief comment

The difference stems from the different nuclear spins of the isotopes and the role of the Pauli exclusion principle: helium-4 has  $I=0$  and is a boson; helium-3 has  $I=\frac{1}{2}$  and is a fermion.

**Fig. 4.11** The phase diagram for helium ( $^4\text{He}$ ). The  $\lambda$ -line marks the conditions under which the two liquid phases are in equilibrium. Helium-II is the superfluid phase. Note that a pressure of over 20 bar must be exerted before solid helium can be obtained. The labels hcp and bcc denote different solid phases in which the atoms pack together differently: hcp denotes hexagonal closed packing and bcc denotes body-centred cubic (see Section 19.5 for a description of these structures).

neighbours. For instance, the solid and gas phases of helium are never in equilibrium however low the temperature: the atoms are so light that they vibrate with a large-amplitude motion even at very low temperatures and the solid simply shakes itself apart. Solid helium can be obtained, but only by holding the atoms together by applying pressure. The isotopes of helium behave differently for quantum mechanical reasons that will become clear in Part 2.

Pure helium-4 has two liquid phases. The phase marked He-I in the diagram behaves like a normal liquid; the other phase, He-II, is a **superfluid**; it is so called because it flows without viscosity.<sup>1</sup> Provided we discount the liquid crystalline substances discussed in *Impact 15.2*, helium is the only known substance with a liquid–liquid boundary, shown as the  $\lambda$ -line (lambda line) in Fig. 4.11.

The phase diagram of helium-3 differs from the phase diagram of helium-4, but it also possesses a superfluid phase. Helium-3 is unusual in that melting is exothermic ( $\Delta_{\text{fus}}H < 0$ ) and therefore (from  $\Delta_{\text{fus}}S = \Delta_{\text{fus}}H/T_f$ ) at the melting point the entropy of the liquid is lower than that of the solid.

#### IMPACT ON TECHNOLOGY

##### 14.1 Supercritical fluids

Supercritical carbon dioxide,  $\text{scCO}_2$ , is the centre of attention for an increasing number of solvent-based processes. The critical temperature of  $\text{CO}_2$ , 304.2 K (31.0°C), and its critical pressure, 72.9 atm, are readily accessible, it is cheap, and it can readily be recycled. The density of  $\text{scCO}_2$  at its critical point is  $0.45 \text{ g cm}^{-3}$ . However, the transport properties of any supercritical fluid (its diffusion behaviour, viscosity, and thermal conductivity) depend strongly on its density, which in turn is sensitive to the pressure and temperature. For instance, densities may be adjusted from a gas-like  $0.1 \text{ g cm}^{-3}$  to a liquid-like  $1.2 \text{ g cm}^{-3}$ . A useful rule of thumb is that the solubility of a solute is an exponential function of the density of the supercritical fluid, so small increases in pressure, particularly close to the critical point, can have very large effects on solubility. Because the relative permittivity (dielectric constant) of a supercritical fluid is highly sensitive to the pressure and temperature, it is possible to run a reaction in polar and nonpolar conditions without changing the solvent, so solvent effects can be studied.

A great advantage of  $\text{scCO}_2$  is that there are no noxious residues once the solvent has been allowed to evaporate, so, coupled with its low critical temperature,  $\text{scCO}_2$  is ideally suited to food processing and the production of pharmaceuticals. It is used, for instance, to remove caffeine from coffee or fats from milk. The supercritical fluid is also increasingly being used for dry cleaning, which avoids the use of carcinogenic and environmentally damaging chlorinated hydrocarbons.

Supercritical  $\text{CO}_2$  has been used since the 1960s as a mobile phase in *supercritical fluid chromatography* (SFC), but it fell out of favour when the more convenient technique of high-performance liquid chromatography (HPLC) was introduced. However, interest in SFC has returned, and there are separations possible in SFC that cannot easily be achieved by HPLC, such as the separation of lipids and of phospholipids. Samples as small as 1 pg can be analysed. The essential advantage of SFC is that diffusion coefficients in supercritical fluids are an order of magnitude greater than in liquids. As a result, there is less resistance to the transfer of solutes through the column and separations may be effected rapidly or with high resolution.

The principal problem with  $\text{scCO}_2$  is that it is not a very good solvent and surfactants are needed to induce many potentially interesting solutes to dissolve. Indeed,

<sup>1</sup> Recent work has suggested that water may also have a superfluid liquid phase.

scCO<sub>2</sub>-based dry cleaning depends on the availability of cheap surfactants; so too does the use of scCO<sub>2</sub> as a solvent for homogeneous catalysts, such as d-metal complexes. There appear to be two principal approaches to solving the solubilization problem. One solution is to use fluorinated and siloxane-based polymeric stabilizers, which allow polymerization reactions to proceed in scCO<sub>2</sub>. The disadvantage of these stabilizers for commercial use is their great expense. An alternative and much cheaper approach is poly(ether-carbonate) copolymers. The copolymers can be made more soluble in scCO<sub>2</sub> by adjusting the ratio of ether and carbonate groups.

The critical temperature of water is 374°C and its pressure is 218 atm. The conditions for using scH<sub>2</sub>O are therefore much more demanding than for scCO<sub>2</sub> and the properties of the fluid are highly sensitive to pressure. Thus, as the density of scH<sub>2</sub>O decreases, the characteristics of a solution change from those of an aqueous solution through those of a non-aqueous solution and eventually to those of a gaseous solution. One consequence is that reaction mechanisms may change from those involving ions to those involving radicals.

## Thermodynamic aspects of phase transitions

As we have seen, the thermodynamic criterion of phase equilibrium is the equality of the chemical potentials of each phase. For a one-component system, the chemical potential is the same as the molar Gibbs energy of the phase. As we already know how the Gibbs energy varies with temperature and pressure (Section 3.9); we can expect to be able to deduce how phase equilibria vary as the conditions are changed.

### 4.4 The dependence of stability on the conditions

**Key points** (a) The chemical potential of a substance decreases with increasing temperature at a rate determined by its molar entropy. (b) The chemical potential of a substance increases with increasing pressure at a rate determined by its molar volume. (c) When pressure is applied to a condensed phase, its vapour pressure rises.

At very low temperatures and provided the pressure is not too low, the solid phase of a substance has the lowest chemical potential and is therefore the most stable phase. However, the chemical potentials of different phases change with temperature in different ways, and above a certain temperature the chemical potential of another phase (perhaps another solid phase, a liquid, or a gas) may turn out to be the lowest. When that happens, a transition to the second phase is spontaneous and occurs if it is kinetically feasible to do so.

#### (a) The temperature dependence of phase stability

The temperature dependence of the Gibbs energy is expressed in terms of the entropy of the system by eqn 3.53 ( $(\partial G/\partial T)_p = -S$ ). Because the chemical potential of a pure substance is just another name for its molar Gibbs energy, it follows that

$$\left(\frac{\partial \mu}{\partial T}\right)_p = -S_m \quad \text{Variation of chemical potential with } T \quad (4.2)$$

This relation shows that, as the temperature is raised, the chemical potential of a pure substance decreases:  $S_m > 0$  for all substances, so the slope of a plot of  $\mu$  against  $T$  is negative.

**Fig. 4.12** The schematic temperature dependence of the chemical potential of the solid, liquid, and gas phases of a substance (in practice, the lines are curved). The phase with the lowest chemical potential at a specified temperature is the most stable one at that temperature. The transition temperatures, the melting and boiling temperatures ( $T_f$  and  $T_b$ , respectively), are the temperatures at which the chemical potentials of the two phases are equal.

Equation 4.2 implies that, because  $S_m(g) > S_m(l)$ , the slope of a plot of  $\mu$  against temperature is steeper for gases than for liquids. Because  $S_m(l) > S_m(s)$  almost always, the slope is also steeper for a liquid than the corresponding solid. These features are illustrated in Fig. 4.12. The steep negative slope of  $\mu(l)$  results in it falling below  $\mu(s)$  when the temperature is high enough, and then the liquid becomes the stable phase: the solid melts. The chemical potential of the gas phase plunges steeply downwards as the temperature is raised (because the molar entropy of the vapour is so high), and there comes a temperature at which it lies lowest. Then the gas is the stable phase and vaporization is spontaneous.

### (b) The response of melting to applied pressure

Most substances melt at a higher temperature when subjected to pressure. It is as though the pressure is preventing the formation of the less dense liquid phase. Exceptions to this behaviour include water, for which the liquid is denser than the solid. Application of pressure to water encourages the formation of the liquid phase. That is, water freezes and ice melts at a lower temperature when it is under pressure.

We can rationalize the response of melting temperatures to pressure as follows. The variation of the chemical potential with pressure is expressed (from the second of eqns 3.53) by

$$\left(\frac{\partial \mu}{\partial p}\right)_T = V_m \quad \text{Variation of chemical potential with } p \quad (4.3)$$

This equation shows that the slope of a plot of chemical potential against pressure is equal to the molar volume of the substance. An increase in pressure raises the chemical potential of any pure substance (because  $V_m > 0$ ). In most cases,  $V_m(l) > V_m(s)$  and the equation predicts that an increase in pressure increases the chemical potential of the liquid more than that of the solid. As shown in Fig. 4.13a, the effect of pressure in such a case is to raise the melting temperature slightly. For water, however,  $V_m(l) < V_m(s)$ , and an increase in pressure increases the chemical potential of the solid more than that of the liquid. In this case, the melting temperature is lowered slightly (Fig. 4.13b).

#### Example 4.1 Assessing the effect of pressure on the chemical potential

Calculate the effect on the chemical potentials of ice and water of increasing the pressure from 1.00 bar to 2.00 bar at 0°C. The density of ice is 0.917 g cm<sup>-3</sup> and that of liquid water is 0.999 g cm<sup>-3</sup> under these conditions.

**Method** From eqn 4.3, we know that the change in chemical potential of an incompressible substance when the pressure is changed by  $\Delta p$  is  $\Delta \mu = V_m \Delta p$ . Therefore, to answer the question, we need to know the molar volumes of the two phases of water. These values are obtained from the mass density,  $\rho$ , and the molar mass,  $M$ , by using  $V_m = M/\rho$ . We therefore use the expression  $\Delta \mu = M \Delta p / \rho$ .

**Answer** The molar mass of water is 18.02 g mol<sup>-1</sup> ( $1.802 \times 10^{-2}$  kg mol<sup>-1</sup>); therefore,

$$\Delta \mu(\text{ice}) = \frac{(1.802 \times 10^{-2} \text{ kg mol}^{-1}) \times (1.00 \times 10^5 \text{ Pa})}{917 \text{ kg m}^{-3}} = +1.97 \text{ J mol}^{-1}$$

$$\Delta \mu(\text{water}) = \frac{(1.802 \times 10^{-2} \text{ kg mol}^{-1}) \times (1.00 \times 10^5 \text{ Pa})}{999 \text{ kg m}^{-3}} = +1.80 \text{ J mol}^{-1}$$

We interpret the numerical results as follows: the chemical potential of ice rises more sharply than that of water so, if they are initially in equilibrium at 1 bar, then there will be a tendency for the ice to melt at 2 bar.

**Self-test 4.1** Calculate the effect of an increase in pressure of 1.00 bar on the liquid and solid phases of carbon dioxide (of molar mass  $44.0 \text{ g mol}^{-1}$ ) in equilibrium with densities  $2.35 \text{ g cm}^{-3}$  and  $2.50 \text{ g cm}^{-3}$ , respectively.

$$[\Delta\mu(\text{l}) = +1.87 \text{ J mol}^{-1}, \Delta\mu(\text{s}) = +1.76 \text{ J mol}^{-1}; \text{solid forms}]$$

### (c) The vapour pressure of a liquid subjected to pressure

When pressure is applied to a condensed phase, its vapour pressure rises: in effect, molecules are squeezed out of the phase and escape as a gas. Pressure can be exerted on the condensed phase mechanically or by subjecting it to the applied pressure of an inert gas (Fig. 4.14). In the latter case, the vapour pressure is the partial pressure of the vapour in equilibrium with the condensed phase. We then speak of the **partial vapour pressure** of the substance. One complication (which we ignore here) is that, if the condensed phase is a liquid, then the pressurizing gas might dissolve and change the properties of the liquid. Another complication is that the gas phase molecules might attract molecules out of the liquid by the process of **gas solvation**, the attachment of molecules to gas-phase species.

As shown in the following *Justification*, the quantitative relation between the vapour pressure,  $p$ , when a pressure  $\Delta P$  is applied and the vapour pressure,  $p^*$ , of the liquid in the absence of an additional pressure is

$$p = p^* e^{V_{\text{m}}(\text{l})\Delta P/RT} \quad (4.4)$$

Effect of applied pressure  $\Delta P$  on vapour pressure  $p$

This equation shows how the vapour pressure increases when the pressure acting on the condensed phase is increased.

#### Justification 4.2 The vapour pressure of a pressurized liquid

We calculate the vapour pressure of a pressurized liquid by using the fact that at equilibrium the chemical potentials of the liquid and its vapour are equal:  $\mu(\text{l}) = \mu(\text{g})$ . It follows that, for any change that preserves equilibrium, the resulting change in  $\mu(\text{l})$  must be equal to the change in  $\mu(\text{g})$ ; therefore, we can write  $d\mu(\text{g}) = d\mu(\text{l})$ . When the pressure  $P$  on the liquid is increased by  $dP$ , the chemical potential of the liquid changes by  $d\mu(\text{l}) = V_{\text{m}}(\text{l})dP$ . The chemical potential of the vapour changes by  $d\mu(\text{g}) = V_{\text{m}}(\text{g})dp$  where  $dp$  is the change in the vapour pressure we are trying to find. If we treat the vapour as a perfect gas, the molar volume can be replaced by  $V_{\text{m}}(\text{g}) = RT/p$ , and we obtain  $d\mu(\text{g}) = RTdp/p$ . Next, we equate the changes in chemical potentials of the vapour and the liquid:

$$\frac{RTdp}{p} = V_{\text{m}}(\text{l})dP$$

We can integrate this expression once we know the limits of integration.

When there is no additional pressure acting on the liquid,  $P$  (the pressure experienced by the liquid) is equal to the normal vapour pressure  $p^*$ , so when  $P = p^*$ ,  $p = p^*$  too. When there is an additional pressure  $\Delta P$  on the liquid, with the result that  $P = p^* + \Delta P$ , the vapour pressure is  $p$  (the value we want to find). Provided the effect of pressure on the vapour pressure is small (as will turn out to be the case) a good approximation is to replace the  $p$  in  $p^* + \Delta P$  by  $p^*$  itself, and to set the upper limit of the integral to  $p^* + \Delta P$ . The integrations required are therefore as follows:

$$RT \int_{p^*}^p \frac{dp}{p} = \int_{p^*}^{p^* + \Delta P} V_{\text{m}}(\text{l})dP$$

**Fig. 4.13** The pressure dependence of the chemical potential of a substance depends on the molar volume of the phase. The lines show schematically the effect of increasing pressure on the chemical potential of the solid and liquid phases (in practice, the lines are curved), and the corresponding effects on the freezing temperatures. (a) In this case the molar volume of the solid is smaller than that of the liquid and  $\mu(\text{s})$  increases less than  $\mu(\text{l})$ . As a result, the freezing temperature rises. (b) Here the molar volume is greater for the solid than the liquid (as for water),  $\mu(\text{s})$  increases more strongly than  $\mu(\text{l})$ , and the freezing temperature is lowered.

**Fig. 4.14** Pressure may be applied to a condensed phases either (a) by compressing the condensed phase or (b) by subjecting it to an inert pressurizing gas. When pressure is applied, the vapour pressure of the condensed phase increases.

We now divide both sides by  $RT$  and assume that the molar volume of the liquid is the same throughout the small range of pressures involved:

$$\int_{p^*}^p \frac{dp}{p} = \frac{V_m(l)}{RT} \int_{p^*}^{p^*+\Delta P} dp$$

Then both integrations are straightforward, and lead to

$$\ln \frac{p}{p^*} = \frac{V_m(l)}{RT} \Delta P$$

which rearranges to eqn 4.4 because  $e^{\ln x} = x$ .

#### • A brief illustration

For water, which has density  $0.997 \text{ g cm}^{-3}$  at  $25^\circ\text{C}$  and therefore molar volume  $18.1 \text{ cm}^3 \text{ mol}^{-1}$ , when the pressure is increased by 10 bar (that is,  $\Delta P = 1.0 \times 10^6 \text{ Pa}$ )

$$\frac{V_m(l)\Delta P}{RT} = \frac{(1.81 \times 10^{-5} \text{ m}^3 \text{ mol}^{-1}) \times (1.0 \times 10^6 \text{ Pa})}{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})} = \frac{1.81 \times 1.0 \times 10}{8.3145 \times 298}$$

where we have used  $1 \text{ J} = 1 \text{ Pa m}^3$ . It follows that  $p = 1.0073p^*$ , an increase of 0.73 per cent. •

**Self-test 4.2** Calculate the effect of an increase in pressure of 100 bar on the vapour pressure of benzene at  $25^\circ\text{C}$ , which has density  $0.879 \text{ g cm}^{-3}$ . [43 per cent]

## 4.5 The location of phase boundaries

**Key points** (a) The Clapeyron equation is an expression for the slope of a phase boundary. (b) The Clapeyron equation gives an expression for the slope of the solid–liquid phase boundary in terms of the enthalpy of fusion. (c) The Clausius–Clapeyron equation is an approximation that relates the slope of the liquid–vapour boundary to the enthalpy of vaporization. (d) The slope of the solid–vapour boundary is similarly related to the enthalpy of sublimation.

**Fig. 4.15** When pressure is applied to a system in which two phases are in equilibrium (at  $a$ ), the equilibrium is disturbed. It can be restored by changing the temperature, so moving the state of the system to  $b$ . It follows that there is a relation between  $dp$  and  $dT$  that ensures that the system remains in equilibrium as either variable is changed.

We can find the precise locations of the phase boundaries—the pressures and temperatures at which two phases can coexist—by making use of the fact that, when two phases are in equilibrium, their chemical potentials must be equal. Therefore, where the phases  $\alpha$  and  $\beta$  are in equilibrium,

$$\mu(\alpha; p, T) = \mu(\beta; p, T) \quad (4.5)$$

By solving this equation for  $p$  in terms of  $T$ , we get an equation for the phase boundary.

### (a) The slopes of the phase boundaries

It turns out to be simplest to discuss the phase boundaries in terms of their slopes,  $dp/dT$ . Let  $p$  and  $T$  be changed infinitesimally, but in such a way that the two phases  $\alpha$  and  $\beta$  remain in equilibrium. The chemical potentials of the phases are initially equal (the two phases are in equilibrium). They remain equal when the conditions are changed to another point on the phase boundary, where the two phases continue to be in equilibrium (Fig. 4.15). Therefore, the changes in the chemical potentials of the two phases must be equal and we can write  $d\mu(\alpha) = d\mu(\beta)$ . Because, from eqn 3.52 ( $dG = Vdp - SdT$ ), we know that  $d\mu = -S_m dT + V_m dp$  for each phase, it follows that

$$-S_m(\alpha)dT + V_m(\alpha)dp = -S_m(\beta)dT + V_m(\beta)dp$$

where  $S_m(\alpha)$  and  $S_m(\beta)$  are the molar entropies of the phases and  $V_m(\alpha)$  and  $V_m(\beta)$  are their molar volumes. Hence

$$\{V_m(\beta) - V_m(\alpha)\}dp = \{S_m(\beta) - S_m(\alpha)\}dT$$

which rearranges into the **Clapeyron equation**:

$$\frac{dp}{dT} = \frac{\Delta_{\text{trs}}S}{\Delta_{\text{trs}}V} \quad \text{Clapeyron equation} \quad (4.6)$$

In this expression  $\Delta_{\text{trs}}S = S_m(\beta) - S_m(\alpha)$  and  $\Delta_{\text{trs}}V = V_m(\beta) - V_m(\alpha)$  are the entropy and volume of transition, respectively. The Clapeyron equation is an exact expression for the slope of the tangent to the boundary at any point and applies to any phase equilibrium of any pure substance. It implies that we can use thermodynamic data to predict the appearance of phase diagrams and to understand their form. A more practical application is to the prediction of the response of freezing and boiling points to the application of pressure.

### (b) The solid–liquid boundary

Melting (fusion) is accompanied by a molar enthalpy change  $\Delta_{\text{fus}}H$  and occurs at a temperature  $T$ . The molar entropy of melting at  $T$  is therefore  $\Delta_{\text{fus}}H/T$  (Section 3.3), and the Clapeyron equation becomes

$$\frac{dp}{dT} = \frac{\Delta_{\text{fus}}H}{T\Delta_{\text{fus}}V} \quad \text{Slope of solid–liquid boundary} \quad (4.7)$$

where  $\Delta_{\text{fus}}V$  is the change in molar volume that occurs on melting. The enthalpy of melting is positive (the only exception is helium-3) and the volume change is usually positive and always small. Consequently, the slope  $dp/dT$  is steep and usually positive (Fig. 4.16).

We can obtain the formula for the phase boundary by integrating  $dp/dT$ , assuming that  $\Delta_{\text{fus}}H$  and  $\Delta_{\text{fus}}V$  change so little with temperature and pressure that they can be treated as constant. If the melting temperature is  $T^*$  when the pressure is  $p^*$ , and  $T$  when the pressure is  $p$ , the integration required is

$$\int_{p^*}^p dp = \frac{\Delta_{\text{fus}}H}{\Delta_{\text{fus}}V} \int_{T^*}^T \frac{dT}{T}$$

Therefore, the approximate equation of the solid–liquid boundary is

$$p = p^* + \frac{\Delta_{\text{fus}}H}{\Delta_{\text{fus}}V} \ln \frac{T}{T^*} \quad (4.8)$$

This equation was originally obtained by yet another Thomson—James, the brother of William, Lord Kelvin. When  $T$  is close to  $T^*$ , the logarithm can be approximated by using

$$\ln \frac{T}{T^*} = \ln \left( 1 + \frac{T - T^*}{T^*} \right) \approx \frac{T - T^*}{T^*}$$

Therefore,

$$p = p^* + \frac{\Delta_{\text{fus}}H}{T^*\Delta_{\text{fus}}V} (T - T^*) \quad (4.9)$$

This expression is the equation of a steep straight line when  $p$  is plotted against  $T$  (as in Fig. 4.16).

**Fig. 4.16** A typical solid–liquid phase boundary slopes steeply upwards. This slope implies that, as the pressure is raised, the melting temperature rises. Most substances behave in this way.

#### A brief comment

Calculations involving natural logarithms often become simpler if we note that, provided  $-1 < x < 1$ ,  $\ln(1+x) = x - \frac{1}{2}x^2 + \frac{1}{3}x^3 \dots$ . If  $x \ll 1$ , a good approximation is  $\ln(1+x) \approx x$ .

**(c) The liquid–vapour boundary**

The entropy of vaporization at a temperature  $T$  is equal to  $\Delta_{\text{vap}}H/T$ ; the Clapeyron equation for the liquid–vapour boundary is therefore

$$\frac{dp}{dT} = \frac{\Delta_{\text{vap}}H}{T\Delta_{\text{vap}}V} \quad \text{Slope of liquid–vapour boundary} \quad (4.10)$$

The enthalpy of vaporization is positive;  $\Delta_{\text{vap}}V$  is large and positive. Therefore,  $dp/dT$  is positive, but it is much smaller than for the solid–liquid boundary. It follows that  $dT/dp$  is large, and hence that the boiling temperature is more responsive to pressure than the freezing temperature.

**Example 4.2** Estimating the effect of pressure on the boiling temperature

Estimate the typical size of the effect of increasing pressure on the boiling point of a liquid.

**Method** To use eqn 4.10 we need to estimate the right-hand side. At the boiling point, the term  $\Delta_{\text{vap}}H/T$  is Trouton's constant (Section 3.3b). Because the molar volume of a gas is so much greater than the molar volume of a liquid, we can write  $\Delta_{\text{vap}}V = V_{\text{m}}(\text{g}) - V_{\text{m}}(\text{l}) \approx V_{\text{m}}(\text{g})$  and take for  $V_{\text{m}}(\text{g})$  the molar volume of a perfect gas (at low pressures, at least).

**Answer** Trouton's constant has the value  $85 \text{ J K}^{-1} \text{ mol}^{-1}$ . The molar volume of a perfect gas is about  $25 \text{ dm}^3 \text{ mol}^{-1}$  at 1 atm and near but above room temperature. Therefore,

$$\frac{dp}{dT} \approx \frac{85 \text{ J K}^{-1} \text{ mol}^{-1}}{2.5 \times 10^{-2} \text{ m}^3 \text{ mol}^{-1}} = 3.4 \times 10^3 \text{ Pa K}^{-1}$$

We have used  $1 \text{ J} = 1 \text{ Pa m}^3$ . This value corresponds to  $0.034 \text{ atm K}^{-1}$  and hence to  $dT/dp = 29 \text{ K atm}^{-1}$ . Therefore, a change of pressure of  $+0.1 \text{ atm}$  can be expected to change a boiling temperature by about  $+3 \text{ K}$ .

**Self-test 4.3** Estimate  $dT/dp$  for water at its normal boiling point using the information in Table 3.2 and  $V_{\text{m}}(\text{g}) = RT/p$ . [28 K atm<sup>-1</sup>]

Because the molar volume of a gas is so much greater than the molar volume of a liquid, we can write  $\Delta_{\text{vap}}V \approx V_{\text{m}}(\text{g})$  (as in Example 4.2). Moreover, if the gas behaves perfectly,  $V_{\text{m}}(\text{g}) = RT/p$ . These two approximations turn the exact Clapeyron equation into

$$\frac{dp}{dT} = \frac{\Delta_{\text{vap}}H}{T(RT/p)}$$

which rearranges into the **Clausius–Clapeyron equation** for the variation of vapour pressure with temperature:

$$\frac{d \ln p}{dT} = \frac{\Delta_{\text{vap}}H}{RT^2} \quad \text{Clausius–Clapeyron equation} \quad (4.11)$$

(We have used  $dx/x = d \ln x$ .) Like the Clapeyron equation (which is exact), the Clausius–Clapeyron equation (which is an approximation) is important for understanding the appearance of phase diagrams, particularly the location and shape of the liquid–vapour and solid–vapour phase boundaries. It lets us predict how the vapour

pressure varies with temperature and how the boiling temperature varies with pressure. For instance, if we also assume that the enthalpy of vaporization is independent of temperature, this equation can be integrated as follows:

$$\int_{\ln p^*}^{\ln p} d \ln p = \frac{\Delta_{\text{vap}} H}{R} \int_{T^*}^T \frac{dT}{T^2} = -\frac{\Delta_{\text{vap}} H}{R} \left( \frac{1}{T} - \frac{1}{T^*} \right)$$

where  $p^*$  is the vapour pressure when the temperature is  $T^*$  and  $p$  the vapour pressure when the temperature is  $T$ . Therefore, because the integral on the left evaluates to  $\ln(p/p^*)$ , the two vapour pressures are related by

$$p = p^* e^{-\chi} \quad \chi = \frac{\Delta_{\text{vap}} H}{R} \left( \frac{1}{T} - \frac{1}{T^*} \right) \quad (4.12)$$

Equation 4.12 is plotted as the liquid–vapour boundary in Fig. 4.17. The line does not extend beyond the critical temperature  $T_c$ , because above this temperature the liquid does not exist.

#### • A brief illustration

Equation 4.12 can be used to estimate the vapour pressure of a liquid at any temperature from its normal boiling point, the temperature at which the vapour pressure is 1.00 atm (101 kPa). The normal boiling point of benzene is 80°C (353 K) and (from Table 2.3)  $\Delta_{\text{vap}} H^\circ = 30.8 \text{ kJ mol}^{-1}$ . Therefore, to calculate the vapour pressure at 20°C (293 K), we write

$$\chi = \frac{3.08 \times 10^4 \text{ J mol}^{-1}}{8.3145 \text{ J K}^{-1} \text{ mol}^{-1}} \left( \frac{1}{293 \text{ K}} - \frac{1}{353 \text{ K}} \right) = \frac{3.08 \times 10^4}{8.3145} \left( \frac{1}{293} - \frac{1}{353} \right)$$

and substitute this value into eqn 4.12 with  $p^* = 101 \text{ kPa}$ . The result is 12 kPa. The experimental value is 10 kPa. •

#### (d) The solid–vapour boundary

The only difference between this case and the last is the replacement of the enthalpy of vaporization by the enthalpy of sublimation,  $\Delta_{\text{sub}} H$ . Because the enthalpy of sublimation is greater than the enthalpy of vaporization (recall that  $\Delta_{\text{sub}} H = \Delta_{\text{fus}} H + \Delta_{\text{vap}} H$ ), the equation predicts a steeper slope for the sublimation curve than for the vaporization curve at similar temperatures, which is near where they meet at the triple point (Fig. 4.18).

### 4.6 The Ehrenfest classification of phase transitions

**Key points** (a) Different types of phase transition are identified by the behaviour of thermodynamic properties at the transition temperature. (b) The classification reveals the type of molecular process occurring at the phase transition.

There are many different types of phase transition, including the familiar examples of fusion and vaporization and the less familiar examples of solid–solid, conducting–superconducting, and fluid–superfluid transitions. We shall now see that it is possible to use thermodynamic properties of substances, and in particular the behaviour of the chemical potential, to classify phase transitions into different types. The classification scheme was originally proposed by Paul Ehrenfest, and is known as the **Ehrenfest classification**.

**Fig. 4.17** A typical liquid–vapour phase boundary. The boundary can be regarded as a plot of the vapour pressure against the temperature. Note that, in some depictions of phase diagrams in which a logarithmic pressure scale is used, the phase boundary has the opposite curvature (see Fig. 4.11). This phase boundary terminates at the critical point (not shown).

**A note on good practice** Because exponential functions are so sensitive, it is good practice to carry out numerical calculations like this without evaluating the intermediate steps and using rounded values.

**Fig. 4.18** Near the point where they coincide (at the triple point), the solid–gas boundary has a steeper slope than the liquid–gas boundary because the enthalpy of sublimation is greater than the enthalpy of vaporization and the temperatures that occur in the Clausius–Clapeyron equation for the slope have similar values.

Fig. 4.19 The changes in thermodynamic properties accompanying (a) first-order and (b) second-order phase transitions.

#### (a) The thermodynamic basis

Many familiar phase transitions, like fusion and vaporization, are accompanied by changes of enthalpy and volume. These changes have implications for the slopes of the chemical potentials of the phases at either side of the phase transition. Thus, at the transition from a phase  $\alpha$  to another phase  $\beta$ ,

$$\left(\frac{\partial \mu(\beta)}{\partial p}\right)_T - \left(\frac{\partial \mu(\alpha)}{\partial p}\right)_T = V_m(\beta) - V_m(\alpha) = \Delta_{\text{trs}} V$$

$$\left(\frac{\partial \mu(\beta)}{\partial T}\right)_p - \left(\frac{\partial \mu(\alpha)}{\partial T}\right)_p = -S_m(\beta) + S_m(\alpha) = -\Delta_{\text{trs}} S = -\frac{\Delta_{\text{trs}} H}{T_{\text{trs}}} \quad (4.13)$$

Because  $\Delta_{\text{trs}} V$  and  $\Delta_{\text{trs}} H$  are non-zero for melting and vaporization, it follows that for such transitions the slopes of the chemical potential plotted against either pressure or temperature are different on either side of the transition (Fig. 4.19a). In other words, the first derivatives of the chemical potentials with respect to pressure and temperature are discontinuous at the transition.

A transition for which the first derivative of the chemical potential with respect to temperature is discontinuous is classified as a **first-order phase transition**. The constant-pressure heat capacity,  $C_p$ , of a substance is the slope of a plot of the enthalpy with respect to temperature. At a first-order phase transition,  $H$  changes by a finite amount for an infinitesimal change of temperature. Therefore, at the transition the heat capacity is infinite. The physical reason is that heating drives the transition rather than raising the temperature. For example, boiling water stays at the same temperature even though heat is being supplied.

A **second-order phase transition** in the Ehrenfest sense is one in which the first derivative of  $\mu$  with respect to temperature is continuous but its second derivative is discontinuous. A continuous slope of  $\mu$  (a graph with the same slope on either side of the transition) implies that the volume and entropy (and hence the enthalpy) do

not change at the transition (Fig. 4.19b). The heat capacity is discontinuous at the transition but does not become infinite there. An example of a second-order transition is the conducting–superconducting transition in metals at low temperatures.<sup>2</sup>

The term  $\lambda$ -transition is applied to a phase transition that is not first-order yet the heat capacity becomes infinite at the transition temperature. Typically, the heat capacity of a system that shows such a transition begins to increase well before the transition (Fig. 4.20), and the shape of the heat capacity curve resembles the Greek letter lambda. This type of transition includes order–disorder transitions in alloys, the onset of ferromagnetism, and the fluid–superfluid transition of liquid helium.

### (b) Molecular interpretation

First-order transitions typically involve the relocation of atoms, molecules, or ions with a consequent change in the energies of their interactions. Thus, vaporization eliminates the attractions between molecules and a first-order phase transition from one ionic polymorph to another (as in the conversion of calcite to aragonite) involves the adjustment of the relative positions of ions.

One type of second-order transition is associated with a change in symmetry of the crystal structure of a solid. Thus, suppose the arrangement of atoms in a solid is like that represented in Fig. 4.21a, with one dimension (technically, of the unit cell) longer than the other two, which are equal. Such a crystal structure is classified as tetragonal (see Section 19.1). Moreover, suppose the two shorter dimensions increase more than the long dimension when the temperature is raised. There may come a stage when the three dimensions become equal. At that point the crystal has cubic symmetry (Fig. 4.21b), and at higher temperatures it will expand equally in all three directions (because there is no longer any distinction between them). The tetragonal  $\rightarrow$  cubic phase transition has occurred but, as it has not involved a discontinuity in the interaction energy between the atoms or the volume they occupy, the transition is not first-order.

The order–disorder transition in  $\beta$ -brass (CuZn) is an example of a  $\lambda$ -transition. The low-temperature phase is an orderly array of alternating Cu and Zn atoms. The high-temperature phase is a random array of the atoms (Fig. 4.22). At  $T = 0$  the order is perfect, but islands of disorder appear as the temperature is raised. The islands form because the transition is cooperative in the sense that, once two atoms have exchanged locations, it is easier for their neighbours to exchange their locations. The islands grow in extent and merge throughout the crystal at the transition temperature (742 K). The heat capacity increases as the transition temperature is approached because the cooperative nature of the transition means that it is increasingly easy for the heat supplied to drive the phase transition rather than to be stored as thermal motion.

**Fig. 4.20** The  $\lambda$ -curve for helium, where the heat capacity rises to infinity. The shape of this curve is the origin of the name  $\lambda$ -transition.

<sup>2</sup> A metallic conductor is a substance with an electrical conductivity that decreases as the temperature increases. A superconductor is a solid that conducts electricity without resistance. See Chapter 19 for more details.

**Fig. 4.21** (Left) One version of a second-order phase transition in which (a) a tetragonal phase expands more rapidly in two directions than a third, and hence becomes a cubic phase, which (b) expands uniformly in three directions as the temperature is raised. There is no rearrangement of atoms at the transition temperature, and hence no enthalpy of transition.

**Fig. 4.22** (Right) An order–disorder transition. (a) At  $T = 0$ , there is perfect order, with different kinds of atoms occupying alternate sites. (b) As the temperature is increased, atoms exchange locations and islands of each kind of atom form in regions of the solid. Some of the original order survives. (c) At and above the transition temperature, the islands occur at random throughout the sample.

## Checklist of key equations

| Property                                            | Equation                                                | Comment                                                               |
|-----------------------------------------------------|---------------------------------------------------------|-----------------------------------------------------------------------|
| Chemical potential                                  | $\mu = G_m$                                             | For a pure substance                                                  |
| Phase rule                                          | $F = C - P + 2$                                         |                                                                       |
| Variation of $\mu$ with temperature                 | $(\partial\mu/\partial T)_p = -S_m$                     |                                                                       |
| Variation of $\mu$ with pressure                    | $(\partial\mu/\partial p)_T = V_m$                      |                                                                       |
| Vapour pressure in the presence of applied pressure | $p = p^* e^{V_m \Delta P / RT}$                         | $\Delta P = P_{\text{applied}} - p^*$                                 |
| Clapeyron equation                                  | $dp/dT = \Delta_{\text{trs}} S / \Delta_{\text{trs}} V$ |                                                                       |
| Clausius–Clapeyron equation                         | $d \ln p / dT = \Delta_{\text{vap}} H / RT^2$           | Assumes $V_m(\text{g}) \gg V_m(\text{l})$ and vapour is a perfect gas |

## Discussion questions

**4.1** Describe how the concept of chemical potential unifies the discussion of phase equilibria.

**4.2** Why does the chemical potential change with pressure even if the system is incompressible (that is, remains at the same volume when pressure is applied)?

**4.3** How may DSC be used to identify phase transitions?

**4.4** Discuss what would be observed as a sample of water is taken along a path that encircles and is close to its critical point.

**4.5** Consult library and internet resources and prepare a discussion of the principles, advantages, disadvantages, and current uses of supercritical fluids.

**4.6** Distinguish between a first-order phase transition, a second-order phase transition, and a  $\lambda$ -transition at both molecular and macroscopic levels.

## Exercises

- 4.1(a)** How many phases are present at each of the points marked in Fig. 4.23a?
- 4.1(b)** How many phases are present at each of the points marked in Fig. 4.23b?
- 4.2(a)** The difference in chemical potential between two regions of a system is  $+7.1 \text{ kJ mol}^{-1}$ . By how much does the Gibbs energy change when  $0.10 \text{ mmol}$  of a substance is transferred from one region to the other?
- 4.2(b)** The difference in chemical potential between two regions of a system is  $-8.3 \text{ kJ mol}^{-1}$ . By how much does the Gibbs energy change when  $0.15 \text{ mmol}$  of a substance is transferred from one region to the other?
- 4.3(a)** Estimate the difference between the normal and standard melting points of ice.
- 4.3(b)** Estimate the difference between the normal and standard boiling points of water.
- 4.4(a)** What is the maximum number of phases that can be in mutual equilibrium in a two-component system?
- 4.4(b)** What is the maximum number of phases that can be in mutual equilibrium in a four-component system?
- 4.5(a)** Water is heated from  $25^\circ\text{C}$  to  $100^\circ\text{C}$ . By how much does its chemical potential change?
- 4.5(b)** Iron is heated from  $100^\circ\text{C}$  to  $1000^\circ\text{C}$ . By how much does its chemical potential change? Take  $S_m^\circ = 53 \text{ J K}^{-1} \text{ mol}^{-1}$  for the entire range (its average value).
- 4.6(a)** By how much does the chemical potential of copper change when the pressure exerted on a sample is increased from  $100 \text{ kPa}$  to  $10 \text{ MPa}$ ?
- 4.6(b)** By how much does the chemical potential of benzene change when the pressure exerted on a sample is increased from  $100 \text{ kPa}$  to  $10 \text{ MPa}$ ?
- 4.7(a)** Pressure was exerted with a piston on water at  $20^\circ\text{C}$ . The vapour pressure of water under  $1.0 \text{ bar}$  is  $2.34 \text{ kPa}$ . What is its vapour pressure when the pressure on the liquid is  $20 \text{ MPa}$ ?
- 4.7(b)** Pressure was exerted with a piston on molten naphthalene at  $95^\circ\text{C}$ . The vapour pressure of naphthalene under  $1.0 \text{ bar}$  is  $2.0 \text{ kPa}$  and its density is  $0.962 \text{ g cm}^{-3}$ . What is its vapour pressure when the pressure on the liquid is  $15 \text{ MPa}$ ?
- 4.8(a)** The molar volume of a certain solid is  $161.0 \text{ cm}^3 \text{ mol}^{-1}$  at  $1.00 \text{ atm}$  and  $350.75 \text{ K}$ , its melting temperature. The molar volume of the liquid at this temperature and pressure is  $163.3 \text{ cm}^3 \text{ mol}^{-1}$ . At  $100 \text{ atm}$  the melting temperature changes to  $351.26 \text{ K}$ . Calculate the enthalpy and entropy of fusion of the solid.
- 4.8(b)** The molar volume of a certain solid is  $142.0 \text{ cm}^3 \text{ mol}^{-1}$  at  $1.00 \text{ atm}$  and  $427.15 \text{ K}$ , its melting temperature. The molar volume of the liquid at this temperature and pressure is  $152.6 \text{ cm}^3 \text{ mol}^{-1}$ . At  $1.2 \text{ MPa}$  the melting temperature changes to  $429.26 \text{ K}$ . Calculate the enthalpy and entropy of fusion of the solid.
- 4.9(a)** The vapour pressure of dichloromethane at  $24.1^\circ\text{C}$  is  $53.3 \text{ kPa}$  and its enthalpy of vaporization is  $28.7 \text{ kJ mol}^{-1}$ . Estimate the temperature at which its vapour pressure is  $70.0 \text{ kPa}$ .
- 4.9(b)** The vapour pressure of a substance at  $20.0^\circ\text{C}$  is  $58.0 \text{ kPa}$  and its enthalpy of vaporization is  $32.7 \text{ kJ mol}^{-1}$ . Estimate the temperature at which its vapour pressure is  $66.0 \text{ kPa}$ .
- 4.10(a)** The vapour pressure of a liquid in the temperature range  $200 \text{ K}$  to  $260 \text{ K}$  was found to fit the expression  $\ln(p/\text{Torr}) = 16.255 - 2501.8/(T/\text{K})$ . What is the enthalpy of vaporization of the liquid?
- 4.10(b)** The vapour pressure of a liquid in the temperature range  $200 \text{ K}$  to  $260 \text{ K}$  was found to fit the expression  $\ln(p/\text{Torr}) = 18.361 - 3036.8/(T/\text{K})$ . What is the enthalpy of vaporization of the liquid?
- 4.11(a)** The vapour pressure of benzene between  $10^\circ\text{C}$  and  $30^\circ\text{C}$  fits the expression  $\log(p/\text{Torr}) = 7.960 - 1780/(T/\text{K})$ . Calculate (a) the enthalpy of vaporization and (b) the normal boiling point of benzene.
- 4.11(b)** The vapour pressure of a liquid between  $15^\circ\text{C}$  and  $35^\circ\text{C}$  fits the expression  $\log(p/\text{Torr}) = 8.750 - 1625/(T/\text{K})$ . Calculate (a) the enthalpy of vaporization and (b) the normal boiling point of the liquid.
- 4.12(a)** When benzene freezes at  $5.5^\circ\text{C}$  its density changes from  $0.879 \text{ g cm}^{-3}$  to  $0.891 \text{ g cm}^{-3}$ . Its enthalpy of fusion is  $10.59 \text{ kJ mol}^{-1}$ . Estimate the freezing point of benzene at  $1000 \text{ atm}$ .
- 4.12(b)** When a certain liquid of molar mass  $46.1 \text{ g mol}^{-1}$  freezes at  $-3.65^\circ\text{C}$  its density changes from  $0.789 \text{ g cm}^{-3}$  to  $0.801 \text{ g cm}^{-3}$ . Its enthalpy of fusion is  $8.68 \text{ kJ mol}^{-1}$ . Estimate the freezing point of the liquid at  $100 \text{ MPa}$ .
- 4.13(a)** In July in Los Angeles, the incident sunlight at ground level has a power density of  $1.2 \text{ kW m}^{-2}$  at noon. A swimming pool of area  $50 \text{ m}^2$  is directly exposed to the sun. What is the maximum rate of loss of water? Assume that all the radiant energy is absorbed.
- 4.13(b)** Suppose the incident sunlight at ground level has a power density of  $0.87 \text{ kW m}^{-2}$  at noon. What is the maximum rate of loss of water from a lake of area  $1.0 \text{ ha}$ ? ( $1 \text{ ha} = 10^4 \text{ m}^2$ .) Assume that all the radiant energy is absorbed.
- 4.14(a)** An open vessel containing (a) water, (b) benzene, (c) mercury stands in a laboratory measuring  $5.0 \text{ m} \times 5.0 \text{ m} \times 3.0 \text{ m}$  at  $25^\circ\text{C}$ . What mass of each substance will be found in the air if there is no ventilation? (The vapour pressures are (a)  $3.2 \text{ kPa}$ , (b)  $13.1 \text{ kPa}$ , (c)  $0.23 \text{ Pa}$ .)
- 4.14(b)** On a cold, dry morning after a frost, the temperature was  $-5^\circ\text{C}$  and the partial pressure of water in the atmosphere fell to  $0.30 \text{ kPa}$ . Will the frost sublime? What partial pressure of water would ensure that the frost remained?
- 4.15(a)** Naphthalene,  $\text{C}_{10}\text{H}_8$ , melts at  $80.2^\circ\text{C}$ . If the vapour pressure of the liquid is  $1.3 \text{ kPa}$  at  $85.8^\circ\text{C}$  and  $5.3 \text{ kPa}$  at  $119.3^\circ\text{C}$ , use the Clausius–Clapeyron

Fig. 4.23

equation to calculate (a) the enthalpy of vaporization, (b) the normal boiling point, and (c) the enthalpy of vaporization at the boiling point.

**4.15(b)** The normal boiling point of hexane is 69.0°C. Estimate (a) its enthalpy of vaporization and (b) its vapour pressure at 25°C and 60°C.

**4.16(a)** Calculate the melting point of ice under a pressure of 50 bar. Assume that the density of ice under these conditions is approximately 0.92 g cm<sup>-3</sup> and that of liquid water is 1.00 g cm<sup>-3</sup>.

**4.16(b)** Calculate the melting point of ice under a pressure of 10 MPa. Assume that the density of ice under these conditions is approximately 0.915 g cm<sup>-3</sup> and that of liquid water is 0.998 g cm<sup>-3</sup>.

**4.17(a)** What fraction of the enthalpy of vaporization of water is spent on expanding the water vapour?

**4.17(b)** What fraction of the enthalpy of vaporization of ethanol is spent on expanding its vapour?

## Problems\*

### Numerical problems

**4.1** The temperature dependence of the vapour pressure of solid sulfur dioxide can be approximately represented by the relation  $\log(p/\text{Torr}) = 10.5916 - 1871.2/(T/\text{K})$  and that of liquid sulfur dioxide by  $\log(p/\text{Torr}) = 8.3186 - 1425.7/(T/\text{K})$ . Estimate the temperature and pressure of the triple point of sulfur dioxide.

**4.2** Prior to the discovery that freon-12 (CF<sub>2</sub>Cl<sub>2</sub>) was harmful to the Earth's ozone layer, it was frequently used as the dispersing agent in spray cans for hair spray, etc. Its enthalpy of vaporization at its normal boiling point of -29.2°C is 20.25 kJ mol<sup>-1</sup>. Estimate the pressure that a can of hair spray using freon-12 had to withstand at 40°C, the temperature of a can that has been standing in sunlight. Assume that  $\Delta_{\text{vap}}H$  is a constant over the temperature range involved and equal to its value at -29.2°C.

**4.3** The enthalpy of vaporization of a certain liquid is found to be 14.4 kJ mol<sup>-1</sup> at 180 K, its normal boiling point. The molar volumes of the liquid and the vapour at the boiling point are 115 cm<sup>3</sup> mol<sup>-1</sup> and 14.5 dm<sup>3</sup> mol<sup>-1</sup>, respectively. (a) Estimate  $dp/dT$  from the Clapeyron equation and (b) the percentage error in its value if the Clausius–Clapeyron equation is used instead.

**4.4** Calculate the difference in slope of the chemical potential against temperature on either side of (a) the normal freezing point of water and (b) the normal boiling point of water. (c) By how much does the chemical potential of water supercooled to -5.0°C exceed that of ice at that temperature?

**4.5** Calculate the difference in slope of the chemical potential against pressure on either side of (a) the normal freezing point of water and (b) the normal boiling point of water. The densities of ice and water at 0°C are 0.917 g cm<sup>-3</sup> and 1.000 g cm<sup>-3</sup>, and those of water and water vapour at 100°C are 0.958 g cm<sup>-3</sup> and 0.598 g dm<sup>-3</sup>, respectively. By how much does the chemical potential of water vapour exceed that of liquid water at 1.2 atm and 100°C?

**4.6** The enthalpy of fusion of mercury is 2.292 kJ mol<sup>-1</sup>, and its normal freezing point is 234.3 K with a change in molar volume of +0.517 cm<sup>3</sup> mol<sup>-1</sup> on melting. At what temperature will the bottom of a column of mercury (density 13.6 g cm<sup>-3</sup>) of height 10.0 m be expected to freeze?

**4.7** 50.0 dm<sup>3</sup> of dry air was slowly bubbled through a thermally insulated beaker containing 250 g of water initially at 25°C. Calculate the final temperature. (The vapour pressure of water is approximately constant at 3.17 kPa throughout, and its heat capacity is 75.5 J K<sup>-1</sup> mol<sup>-1</sup>. Assume that the air is not heated or cooled and that water vapour is a perfect gas.)

**4.8** The vapour pressure,  $p$ , of nitric acid varies with temperature as follows:

| $\theta/^\circ\text{C}$ | 0    | 20   | 40   | 50   | 70   | 80   | 90    | 100   |
|-------------------------|------|------|------|------|------|------|-------|-------|
| $p/\text{kPa}$          | 1.92 | 6.38 | 17.7 | 27.7 | 62.3 | 89.3 | 124.9 | 170.9 |

What are (a) the normal boiling point and (b) the enthalpy of vaporization of nitric acid?

**4.9** The vapour pressure of the ketone carvone ( $M = 150.2$  g mol<sup>-1</sup>), a component of oil of spearmint, is as follows:

| $\theta/^\circ\text{C}$ | 57.4 | 100.4 | 133.0 | 157.3 | 203.5 | 227.5 |
|-------------------------|------|-------|-------|-------|-------|-------|
| $p/\text{Torr}$         | 1.00 | 10.0  | 40.0  | 100   | 400   | 760   |

What are (a) the normal boiling point and (b) the enthalpy of vaporization of carvone?

**4.10** Construct the phase diagram for benzene near its triple point at 36 Torr and 5.50°C using the following data:  $\Delta_{\text{fus}}H = 10.6$  kJ mol<sup>-1</sup>,  $\Delta_{\text{vap}}H = 30.8$  kJ mol<sup>-1</sup>,  $\rho(\text{s}) = 0.891$  g cm<sup>-3</sup>,  $\rho(\text{l}) = 0.879$  g cm<sup>-3</sup>.

**4.11‡** In an investigation of thermophysical properties of toluene, R.D. Goodwin (*J. Phys. Chem. Ref. Data* **18**, 1565 (1989)) presented expressions for two coexistence curves (phase boundaries). The solid–liquid coexistence curve is given by

$$p/\text{bar} = p_3/\text{bar} + 1000 \times (5.60 + 11.727x)x$$

where  $x = T/T_3 - 1$  and the triple point pressure and temperature are  $p_3 = 0.4362$  μbar and  $T_3 = 178.15$  K. The liquid–vapour curve is given by:

$$\ln(p/\text{bar}) = -10.418/y + 21.157 - 15.996y + 14.015y^2 - 5.0120y^3 + 4.7224(1-y)^{1.70}$$

where  $y = T/T_c = T/(593.95 \text{ K})$ . (a) Plot the solid–liquid and liquid–vapour phase boundaries. (b) Estimate the standard melting point of toluene. (c) Estimate the standard boiling point of toluene. (d) Compute the standard enthalpy of vaporization of toluene, given that the molar volumes of the liquid and vapour at the normal boiling point are 0.12 dm<sup>3</sup> mol<sup>-1</sup> and 30.3 dm<sup>3</sup> mol<sup>-1</sup>, respectively.

**4.12‡** In a study of the vapour pressure of chloromethane, A. Bah and N. Dupont-Pavlovsky (*J. Chem. Eng. Data* **40**, 869 (1995)) presented data for the vapour pressure over solid chloromethane at low temperatures. Some of that data is shown below:

| $T/\text{K}$  | 145.94 | 147.96 | 149.93 | 151.94 | 153.97 | 154.94 |
|---------------|--------|--------|--------|--------|--------|--------|
| $p/\text{Pa}$ | 13.07  | 18.49  | 25.99  | 36.76  | 50.86  | 59.56  |

Estimate the standard enthalpy of sublimation of chloromethane at 150 K. (Take the molar volume of the vapour to be that of a perfect gas, and that of the solid to be negligible.)

### Theoretical problems

**4.13** Show that, for a transition between two incompressible solid phases,  $\Delta G$  is independent of the pressure.

\* Problems denoted by the symbol ‡ were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

**4.14** The change in enthalpy is given by  $dH = C_p dT + V dp$ . The Clapeyron equation relates  $dp$  and  $dT$  at equilibrium, and so in combination the two equations can be used to find how the enthalpy changes along a phase boundary as the temperature changes and the two phases remain in equilibrium. Show that  $d(\Delta H/T) = \Delta C_p d \ln T$ .

**4.15** In the 'gas saturation method' for the measurement of vapour pressure, a volume  $V$  of gas (as measured at a temperature  $T$  and a pressure  $P$ ) is bubbled slowly through the liquid that is maintained at the temperature  $T$ , and a mass loss  $m$  is measured. Show that the vapour pressure,  $p$ , of the liquid is related to its molar mass,  $M$ , by  $p = AmP/(1 + Am)$ , where  $A = RT/MPV$ . The vapour pressure of geraniol ( $M = 154.2 \text{ g mol}^{-1}$ ), which is a component of oil of roses, was measured at  $110^\circ\text{C}$ . It was found that, when  $5.00 \text{ dm}^3$  of nitrogen at 760 Torr was passed slowly through the heated liquid, the loss of mass was 0.32 g. Calculate the vapour pressure of geraniol.

**4.16** The vapour pressure of a liquid in a gravitational field varies with the depth below the surface on account of the hydrostatic pressure exerted by the overlying liquid. Adapt eqn. 4.4 to predict how the vapour pressure of a liquid of molar mass  $M$  varies with depth. Estimate the effect on the vapour pressure of water at  $25^\circ\text{C}$  in a column 10 m high.

**4.17** Combine the barometric formula (stated in *Impact II.1*) for the dependence of the pressure on altitude with the Clausius–Clapeyron equation, and predict how the boiling temperature of a liquid depends on the altitude and the ambient temperature. Take the mean ambient temperature as  $20^\circ\text{C}$  and predict the boiling temperature of water at 3000 m.

**4.18** Figure 4.12 gives a schematic representation of how the chemical potentials of the solid, liquid, and gaseous phases of a substance vary with temperature. All have a negative slope, but it is unlikely that they are truly straight lines as indicated in the illustration. Derive an expression for the curvatures (specifically, the second derivatives with respect to temperature) of these lines. Is there a restriction on the curvature of these lines? Which state of matter shows the greatest curvature?

**4.19** The Clapeyron equation does not apply to second-order phase transitions, but there are two analogous equations, the *Ehrenfest equations*, that do. They are:

$$\frac{dp}{dT} = \frac{\alpha_2 - \alpha_1}{\kappa_{T,2} - \kappa_{T,1}} \quad \frac{dp}{dT} = \frac{C_{p,m2} - C_{p,m1}}{TV_m(\alpha_2 - \alpha_1)}$$

where  $\alpha$  is the expansion coefficient,  $\kappa_T$  the isothermal compressibility, and the subscripts 1 and 2 refer to two different phases. Derive these two equations. Why does the Clapeyron equation not apply to second-order transitions?

**4.20** For a first-order phase transition, to which the Clapeyron equation does apply, prove the relation

$$C_S = C_p - \frac{\alpha V \Delta_{\text{trs}} H}{\Delta_{\text{trs}} V}$$

where  $C_S = (\partial q / \partial T)_S$  is the heat capacity along the coexistence curve of two phases.

### Applications: to biology and engineering

**4.21** Proteins are polypeptides, polymers of amino acids, that can exist in ordered structures stabilized by a variety of molecular interactions. However, when certain conditions are changed, the compact structure of a polypeptide chain may collapse into a random coil. This structural change may be regarded as a phase transition occurring at a characteristic transition temperature, the *melting temperature*,  $T_m$ , which increases with the strength and number of intermolecular interactions in the chain. A thermodynamic treatment allows predictions to be made of the temperature  $T_m$  for the unfolding of a helical polypeptide held together by hydrogen bonds into a random coil. If a polypeptide has  $n$  amino acids,  $n - 4$  hydrogen bonds are

formed to form an  $\alpha$ -helix, the most common type of helix in naturally occurring proteins (see Chapter 18). Because the first and last residues in the chain are free to move,  $n - 2$  residues form the compact helix and have restricted motion. Based on these ideas, the molar Gibbs energy of unfolding of a polypeptide with  $n \geq 5$  may be written as

$$\Delta G_m = (n - 4)\Delta_{\text{hb}} H_m - (n - 2)\Delta_{\text{hb}} S_m$$

where  $\Delta_{\text{hb}} H_m$  and  $\Delta_{\text{hb}} S_m$  are, respectively, the molar enthalpy and entropy of dissociation of hydrogen bonds in the polypeptide. (a) Justify the form of the equation for the Gibbs energy of unfolding. That is, why are the enthalpy and entropy terms written as  $(n - 4)\Delta_{\text{hb}} H_m$  and  $(n - 2)\Delta_{\text{hb}} S_m$ , respectively? (b) Show that  $T_m$  may be written as

$$T_m = \frac{(n - 4)\Delta_{\text{hb}} H_m}{(n - 2)\Delta_{\text{hb}} S_m}$$

(c) Plot  $T_m/(\Delta_{\text{hb}} H_m/\Delta_{\text{hb}} S_m)$  for  $5 \leq n \leq 20$ . At what value of  $n$  does  $T_m$  change by less than 1 per cent when  $n$  increases by one?

**4.22†** The use of supercritical fluids as mobile phases in SFC depends on their properties as nonpolar solvents. The solubility parameter,  $\delta$ , is defined as  $(\Delta U_{\text{cohesive}}/V_m)^{1/2}$ , where  $\Delta U_{\text{cohesive}}$  is the cohesive energy of the solvent, the energy per mole needed to increase the volume isothermally to an infinite value. Diethyl ether, carbon tetrachloride, and dioxane have solubility parameter ranges of 7–8, 8–9, and 10–11, respectively. (a) Derive a practical equation for the computation of the isotherms for the reduced internal energy change,  $\Delta U_r(T_r, V_r)$  defined as

$$\Delta U_r(T_r, V_r) = \frac{U_r(T_r, V_r) - U_r(T_r, \infty)}{p_c V_c}$$

(b) Draw a graph of  $\Delta U_r$  against  $p_r$  for the isotherms  $T_r = 1, 1.2$ , and  $1.5$  in the reduced pressure range for which  $0.7 \leq V_r \leq 2$ . (c) Draw a graph of  $\delta$  against  $p_r$  for the carbon dioxide isotherms  $T_r = 1$  and  $1.5$  in the reduced pressure range for which  $1 \leq V_r \leq 3$ . In what pressure range at  $T_r = 1$  will carbon dioxide have solvent properties similar to those of liquid carbon tetrachloride? *Hint.* Use mathematical software or a spreadsheet.

**4.23†** A substance as well known as methane still receives research attention because it is an important component of natural gas, a commonly used fossil fuel. Friend *et al.* have published a review of thermophysical properties of methane (D.G. Friend, J.F. Ely, and H. Ingham, *J. Phys. Chem. Ref. Data* **18**, 583 (1989)), which included the following data describing the liquid–vapour phase boundary.

|                |       |       |       |       |       |       |       |       |       |       |       |       |
|----------------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|
| $T/\text{K}$   | 100   | 108   | 110   | 112   | 114   | 120   | 130   | 140   | 150   | 160   | 170   | 190   |
| $p/\text{MPa}$ | 0.034 | 0.074 | 0.088 | 0.104 | 0.122 | 0.192 | 0.368 | 0.642 | 1.041 | 1.593 | 2.329 | 4.521 |

(a) Plot the liquid–vapour phase boundary. (b) Estimate the standard boiling point of methane. (c) Compute the standard enthalpy of vaporization of methane, given that the molar volumes of the liquid and vapour at the standard boiling point are  $3.80 \times 10^{-2}$  and  $8.89 \text{ dm}^3 \text{ mol}^{-1}$ , respectively.

**4.24†** Diamond is the hardest substance and the best conductor of heat yet characterized. For these reasons, it is used widely in industrial applications that require a strong abrasive. Unfortunately, it is difficult to synthesize diamond from the more readily available allotropes of carbon, such as graphite. To illustrate this point, calculate the pressure required to convert graphite into diamond at  $25^\circ\text{C}$ . The following data apply to  $25^\circ\text{C}$  and 100 kPa. Assume the specific volume,  $V_s$ , and  $\kappa_T$  are constant with respect to pressure changes.

|                                         | Graphite              | Diamond                |
|-----------------------------------------|-----------------------|------------------------|
| $\Delta_f G^\circ/(\text{kJ mol}^{-1})$ | 0                     | +2.8678                |
| $V_s/(\text{cm}^3 \text{ g}^{-1})$      | 0.444                 | 0.284                  |
| $\kappa_T/\text{kPa}$                   | $3.04 \times 10^{-8}$ | $0.187 \times 10^{-8}$ |

### Problems

This chapter begins by developing the concept of chemical potential to show that it is a particular case of a class of properties called partial molar quantities. Then it explores how to use the chemical potential of a substance to describe the physical properties of mixtures. The underlying principle to keep in mind is that at equilibrium the chemical potential of a species is the same in every phase. We see, by making use of the experimental observations known as Raoult's and Henry's laws, how to express the chemical potential of a substance in terms of its mole fraction in a mixture. With this result established, we can calculate the effect of a solute on certain thermodynamic properties of a solution. These properties include the lowering of vapour pressure of the solvent, the elevation of its boiling point, the depression of its freezing point, and the origin of osmotic pressure. We then see how to construct and interpret phase diagrams that summarize the properties of binary mixtures over a wide range of compositions. The chapter introduces systems of gradually increasing complexity. In each case we shall see how the phase diagram for the system summarizes empirical observations on the conditions under which the various phases of the system are stable. Finally, we see how to express the chemical potential of a substance in a real mixture in terms of a property known as the activity. We see how the activity may be measured and conclude with a discussion of how the standard states of solutes and solvents are defined and ion–ion interactions are taken into account in electrolyte solutions.

Chemistry deals with mixtures, including mixtures of substances that can react together. Therefore, we need to generalize the concepts introduced so far to deal with substances that are mingled together. As a first step towards dealing with chemical reactions (which are treated in the next chapter), here we consider mixtures of substances that do not react together. At this stage we deal mainly with **binary mixtures**, which are mixtures of two components, A and B. We shall therefore often be able to simplify equations by making use of the relation  $x_A + x_B = 1$ .

## The thermodynamic description of mixtures

We have already seen that the partial pressure, which is the contribution of one component to the total pressure, is used to discuss the properties of mixtures of gases. For a more general description of the thermodynamics of mixtures we need to introduce other analogous 'partial' properties.

## 5.1 Partial molar quantities

**Key points** (a) The partial molar volume of a substance is the contribution to the volume that a substance makes when it is part of a mixture. (b) The chemical potential is the partial molar Gibbs energy and enables us to express the dependence of the Gibbs energy on the composition of a mixture. (c) The chemical potential also shows how, under a variety of different conditions, the thermodynamic functions vary with composition. (d) The Gibbs–Duhem equation shows how the changes in chemical potential of the components of a mixture are related.

The easiest partial molar property to visualize is the ‘partial molar volume’, the contribution that a component of a mixture makes to the total volume of a sample.

### (a) Partial molar volume

Imagine a huge volume of pure water at 25°C. When a further 1 mol H<sub>2</sub>O is added, the volume increases by 18 cm<sup>3</sup> and we can report that 18 cm<sup>3</sup> mol<sup>−1</sup> is the molar volume of pure water. However, when we add 1 mol H<sub>2</sub>O to a huge volume of pure ethanol, the volume increases by only 14 cm<sup>3</sup>. The reason for the different increase in volume is that the volume occupied by a given number of water molecules depends on the identity of the molecules that surround them. In the latter case there is so much ethanol present that each H<sub>2</sub>O molecule is surrounded by ethanol molecules. The network of hydrogen bonds that normally hold H<sub>2</sub>O molecules at certain distances from each other in pure water does not form. The packing of the molecules in the mixture results in the H<sub>2</sub>O molecules increasing the volume by only 14 cm<sup>3</sup>. The quantity 14 cm<sup>3</sup> mol<sup>−1</sup> is the partial molar volume of water in pure ethanol. In general, the **partial molar volume** of a substance A in a mixture is the change in volume per mole of A added to a large volume of the mixture.

The partial molar volumes of the components of a mixture vary with composition because the environment of each type of molecule changes as the composition changes from pure A to pure B. It is this changing molecular environment, and the consequential modification of the forces acting between molecules, that results in the variation of the thermodynamic properties of a mixture as its composition is changed. The partial molar volumes of water and ethanol across the full composition range at 25°C are shown in Fig. 5.1.

The partial molar volume,  $V_J$ , of a substance J at some general composition is defined formally as follows:

$$V_J = \left( \frac{\partial V}{\partial n_J} \right)_{p, T, n'} \quad \text{Definition of partial molar volume} \quad (5.1)$$

where the subscript  $n'$  signifies that the amounts of all other substances present are constant. The partial molar volume is the slope of the plot of the total volume as the amount of J is changed, the pressure, temperature, and amount of the other components being constant (Fig. 5.2). Its value depends on the composition, as we saw for water and ethanol.

The definition in eqn 5.1 implies that, when the composition of the mixture is changed by the addition of  $dn_A$  of A and  $dn_B$  of B, then the total volume of the mixture changes by

$$dV = \left( \frac{\partial V}{\partial n_A} \right)_{p, T, n_B} dn_A + \left( \frac{\partial V}{\partial n_B} \right)_{p, T, n_A} dn_B = V_A dn_A + V_B dn_B \quad (5.2)$$

Provided the relative composition is held constant as the amounts of A and B are increased, we can obtain the final volume by integration:

**Fig. 5.1** The partial molar volumes of water and ethanol at 25°C. Note the different scales (water on the left, ethanol on the right).

#### A note on good practice

The IUPAC recommendation is to denote a partial molar quantity by  $\bar{X}$ , but only when there is the possibility of confusion with the quantity  $X$ . For instance, the partial molar volume of NaCl in water could be written  $V(\text{NaCl}, \text{aq})$  to distinguish it from the volume of the solution,  $V$ .

**Fig. 5.2** The partial molar volume of a substance is the slope of the variation of the total volume of the sample plotted against the composition. In general, partial molar quantities vary with the composition, as shown by the different slopes at the compositions  $a$  and  $b$ . Note that the partial molar volume at  $b$  is negative: the overall volume of the sample decreases as  $A$  is added.

**Fig. 5.3** The partial molar volume of ethanol as expressed by the polynomial in the *brief illustration*.

 **interActivity** Using the data from the *brief illustration*, determine the value of  $b$  at which  $V_E$  has a minimum value.

$$V = \int_0^{n_A} V_A dn_A + \int_0^{n_B} V_B dn_B = V_A \int_0^{n_A} dn_A + V_B \int_0^{n_B} dn_B \\ = V_A n_A + V_B n_B \quad (5.3)$$

Although we have envisaged the two integrations as being linked (in order to preserve constant relative composition), because  $V$  is a state function the final result in eqn 5.3 is valid however the solution is in fact prepared.

Partial molar volumes can be measured in several ways. One method is to measure the dependence of the volume on the composition and to fit the observed volume to a function of the amount of the substance. Once the function has been found, its slope can be determined at any composition of interest by differentiation.

#### • A brief illustration

A polynomial fit to measurements of the total volume of a water/ethanol mixture at 25°C that contains 1.000 kg of water is

$$v = 1002.93 + 54.6664x - 0.363\,94x^2 + 0.028\,256x^3$$

where  $v = V/\text{cm}^3$ ,  $x = n_E/\text{mol}$ , and  $n_E$  is the amount of  $\text{CH}_3\text{CH}_2\text{OH}$  present. The partial molar volume of ethanol,  $V_E$ , is therefore

$$V_E = \left( \frac{\partial V}{\partial n_E} \right)_{p,T,n_W} = \left( \frac{\partial (V/\text{cm}^3)}{\partial (n_E/\text{mol})} \right)_{p,T,n_W} \frac{\text{cm}^3}{\text{mol}} = \left( \frac{\partial v}{\partial x} \right)_{p,T,n_W} \text{cm}^3 \text{mol}^{-1}$$

Then, because

$$\frac{dv}{dx} = 54.6664 - 2(0.363\,94)x + 3(0.028\,256)x^2$$

we can conclude that

$$V_E/(\text{cm}^3 \text{mol}^{-1}) = 54.6664 - 0.72788x + 0.084768x^2$$

Figure 5.3 is a graph of this function. •

**Self-test 5.1** At 25°C, the density of a 50 per cent by mass ethanol/water solution is  $0.914 \text{ g cm}^{-3}$ . Given that the partial molar volume of water in the solution is  $17.4 \text{ cm}^3 \text{mol}^{-1}$ , what is the partial molar volume of the ethanol? [ $56.4 \text{ cm}^3 \text{mol}^{-1}$ ]

Molar volumes are always positive, but partial molar quantities need not be. For example, the limiting partial molar volume of  $\text{MgSO}_4$  in water (its partial molar volume in the limit of zero concentration) is  $-1.4 \text{ cm}^3 \text{mol}^{-1}$ , which means that the addition of 1 mol  $\text{MgSO}_4$  to a large volume of water results in a decrease in volume of  $1.4 \text{ cm}^3$ . The mixture contracts because the salt breaks up the open structure of water as the  $\text{Mg}^{2+}$  and  $\text{SO}_4^{2-}$  ions become hydrated, and it collapses slightly.

#### (b) Partial molar Gibbs energies

The concept of a partial molar quantity can be extended to any extensive state function. For a substance in a mixture, the chemical potential is *defined* as the partial molar Gibbs energy:

$$\mu_j = \left( \frac{\partial G}{\partial n_j} \right)_{p,T,n'} \quad \text{Definition of chemical potential} \quad [5.4]$$

That is, the chemical potential is the slope of a plot of Gibbs energy against the amount of the component J, with the pressure and temperature (and the amounts of the other substances) held constant (Fig. 5.4). For a pure substance we can write  $G = n_J G_{J,m}$ , and from eqn 5.4 obtain  $\mu_J = G_{J,m}$ ; in this case, the chemical potential is simply the molar Gibbs energy of the substance, as we saw in Chapter 4.

By the same argument that led to eqn 5.3, it follows that the total Gibbs energy of a binary mixture is

$$G = n_A \mu_A + n_B \mu_B \quad (5.5)$$

where  $\mu_A$  and  $\mu_B$  are the chemical potentials at the composition of the mixture. That is, the chemical potential of a substance in a mixture is the contribution of that substance to the total Gibbs energy of the mixture. Because the chemical potentials depend on composition (and the pressure and temperature), the Gibbs energy of a mixture may change when these variables change, and, for a system of components A, B, etc., the equation  $dG = Vdp - SdT$  becomes

$$dG = Vdp - SdT + \mu_A dn_A + \mu_B dn_B + \dots \quad (5.6)$$

Fundamental equation of chemical thermodynamics

This expression is the **fundamental equation of chemical thermodynamics**. Its implications and consequences are explored and developed in this and the next two chapters.

At constant pressure and temperature, eqn 5.6 simplifies to

$$dG = \mu_A dn_A + \mu_B dn_B + \dots \quad (5.7)$$

We saw in Section 3.5e that under the same conditions  $dG = dw_{\text{add,max}}$ . Therefore, at constant temperature and pressure,

$$dw_{\text{add,max}} = \mu_A dn_A + \mu_B dn_B + \dots \quad (5.8)$$

That is, additional (non-expansion) work can arise from the changing composition of a system. For instance, in an electrochemical cell, the chemical reaction is arranged to take place in two distinct sites (at the two electrodes). The electrical work the cell performs can be traced to its changing composition as products are formed from reactants.

### (c) The wider significance of the chemical potential

The chemical potential does more than show how  $G$  varies with composition. Because  $G = U + pV - TS$ , and therefore  $U = -pV + TS + G$ , we can write a general infinitesimal change in  $U$  for a system of variable composition as

$$\begin{aligned} dU &= -pdV - Vdp + SdT + TdS + dG \\ &= -pdV - Vdp + SdT + TdS + (Vdp - SdT + \mu_A dn_A + \mu_B dn_B + \dots) \\ &= -pdV + TdS + \mu_A dn_A + \mu_B dn_B + \dots \end{aligned}$$

This expression is the generalization of eqn 3.46 (that  $dU = TdS - pdV$ ) to systems in which the composition may change. It follows that, at constant volume and entropy,

$$dU = \mu_A dn_A + \mu_B dn_B + \dots \quad (5.9)$$

and hence that

$$\mu_J = \left( \frac{\partial U}{\partial n_J} \right)_{S, V, n'} \quad (5.10)$$

**Fig. 5.4** The chemical potential of a substance is the slope of the total Gibbs energy of a mixture with respect to the amount of substance of interest. In general, the chemical potential varies with composition, as shown for the two values at  $a$  and  $b$ . In this case, both chemical potentials are positive.

Therefore, not only does the chemical potential show how  $G$  changes when the composition changes, it also shows how the internal energy changes too (but under a different set of conditions). In the same way it is easy to deduce that

$$(a) \mu_j = \left( \frac{\partial H}{\partial n_j} \right)_{S,p,n'} \quad (b) \mu_j = \left( \frac{\partial A}{\partial n_j} \right)_{T,V,n'} \quad (5.11)$$

Thus we see that the  $\mu_j$  shows how all the extensive thermodynamic properties  $U$ ,  $H$ ,  $A$ , and  $G$  depend on the composition. This is why the chemical potential is so central to chemistry.

#### (d) The Gibbs–Duhem equation

Because the total Gibbs energy of a binary mixture is given by eqn 5.5 and the chemical potentials depend on the composition, when the compositions are changed infinitesimally we might expect  $G$  of a binary system to change by

$$dG = \mu_A dn_A + \mu_B dn_B + n_A d\mu_A + n_B d\mu_B$$

However, we have seen that at constant pressure and temperature a change in Gibbs energy is given by eqn 5.7. Because  $G$  is a state function, these two equations must be equal, which implies that at constant temperature and pressure

$$n_A d\mu_A + n_B d\mu_B = 0 \quad (5.12a)$$

This equation is a special case of the **Gibbs–Duhem equation**:

$$\sum_j n_j d\mu_j = 0 \quad \text{Gibbs–Duhem equation} \quad (5.12b)$$

The significance of the Gibbs–Duhem equation is that the chemical potential of one component of a mixture cannot change independently of the chemical potentials of the other components. In a binary mixture, if one partial molar quantity increases, then the other must decrease, with the two changes related by

$$d\mu_B = -\frac{n_A}{n_B} d\mu_A \quad (5.13)$$

The same line of reasoning applies to all partial molar quantities. We can see in Fig. 5.1, for example, that where the partial molar volume of water increases, that of ethanol decreases. Moreover, as eqn 5.13 shows, and as we can see from Fig. 5.1, a small change in the partial molar volume of A corresponds to a large change in the partial molar volume of B if  $n_A/n_B$  is large, but the opposite is true when this ratio is small. In practice, the Gibbs–Duhem equation is used to determine the partial molar volume of one component of a binary mixture from measurements of the partial molar volume of the second component.

#### A brief comment

The *molar concentration* (colloquially, the ‘molarity’,  $[J]$  or  $c_j$ ) is the amount of solute divided by the volume of the solution and is usually expressed in moles per cubic decimetre ( $\text{mol dm}^{-3}$ ). We write  $c^\ominus = 1 \text{ mol dm}^{-3}$ . The term *molality*,  $b$ , is the amount of solute divided by the mass of solvent and is usually expressed in moles per kilogram of solvent ( $\text{mol kg}^{-1}$ ). We write  $b^\ominus = 1 \text{ mol kg}^{-1}$ .

#### Example 5.1 Using the Gibbs–Duhem equation

The experimental values of the partial molar volume of  $\text{K}_2\text{SO}_4(\text{aq})$  at 298 K are found to fit the expression

$$v_B = 32.280 + 18.216x^{1/2}$$

where  $v_B = V_{\text{K}_2\text{SO}_4}/(\text{cm}^3 \text{ mol}^{-1})$  and  $x$  is the numerical value of the molality of  $\text{K}_2\text{SO}_4$  ( $x = b/b^\ominus$ ; see the *brief comment* in the margin). Use the Gibbs–Duhem equation to derive an equation for the molar volume of water in the solution. The molar volume of pure water at 298 K is  $18.079 \text{ cm}^3 \text{ mol}^{-1}$ .

**Method** Let A denote  $\text{H}_2\text{O}$ , the solvent, and B denote  $\text{K}_2\text{SO}_4$ , the solute. The Gibbs–Duhem equation for the partial molar volumes of two components is  $n_A dV_A + n_B dV_B = 0$ . This relation implies that  $dv_A = -(n_B/n_A)dv_B$ , and therefore that  $v_A$  can be found by integration:

$$v_A = v_A^* - \int_0^{v_B} \frac{n_B}{n_A} dv_B$$

where  $v_A^* = V_A/(\text{cm}^3 \text{ mol}^{-1})$  is the numerical value of the molar volume of pure A. The first step is to change the variable  $v_B$  to  $x = b/b^\ominus$  and then to integrate the right-hand side between  $x = 0$  (pure B) and the molality of interest.

**Answer** It follows from the information in the question that, with  $B = \text{K}_2\text{SO}_4$ ,  $dv_B/dx = 9.108x^{-1/2}$ . Therefore, the integration required is

$$v_A = v_A^* - 9.108 \int_0^{b/b^\ominus} \frac{n_B}{n_A} x^{-1/2} dx$$

However, the ratio of amounts of A ( $\text{H}_2\text{O}$ ) and B ( $\text{K}_2\text{SO}_4$ ) is related to the molality of B,  $b = n_B/(1 \text{ kg water})$  and  $n_A = (1 \text{ kg water})/M_A$  where  $M_A$  is the molar mass of water, by

$$\frac{n_B}{n_A} = \frac{n_B}{(1 \text{ kg})/M_A} = \frac{n_B M_A}{1 \text{ kg}} = b M_A = x b^\ominus M_A$$

and hence

$$v_A = v_A^* - 9.108 M_A b^\ominus \int_0^{b/b^\ominus} x^{1/2} dx = v_A^* - \frac{2}{3} (9.108 M_A b^\ominus) (b/b^\ominus)^{3/2}$$

It then follows, by substituting the data (including  $M_A = 1.802 \times 10^{-2} \text{ kg mol}^{-1}$ , the molar mass of water), that

$$V_A/(\text{cm}^3 \text{ mol}^{-1}) = 18.079 - 0.1094(b/b^\ominus)^{3/2}$$

The partial molar volumes are plotted in Fig. 5.5.

**Self-test 5.2** Repeat the calculation for a salt B for which  $V_B/(\text{cm}^3 \text{ mol}^{-1}) = 6.218 + 5.146b - 7.147b^2$ .  $[V_A/(\text{cm}^3 \text{ mol}^{-1}) = 18.079 - 0.0464b^2 + 0.0859b^3]$

**Fig. 5.5** The partial molar volumes of the components of an aqueous solution of potassium sulfate. The blue curve corresponds to water and the purple curve to potassium sulfate.

## 5.2 The thermodynamics of mixing

**Key points** (a) The Gibbs energy of mixing is calculated by forming the difference of the Gibbs energies before and after mixing; the quantity is negative for perfect gases at the same pressure. (b) The entropy of mixing of perfect gases initially at the same pressure is positive and the enthalpy of mixing is zero.

The dependence of the Gibbs energy of a mixture on its composition is given by eqn 5.5, and we know that at constant temperature and pressure systems tend towards lower Gibbs energy. This is the link we need in order to apply thermodynamics to the discussion of spontaneous changes of composition, as in the mixing of two substances. One simple example of a spontaneous mixing process is that of two gases introduced into the same container. The mixing is spontaneous, so it must correspond to a decrease in  $G$ . We shall now see how to express this idea quantitatively.

**Fig. 5.6** The arrangement for calculating the thermodynamic functions of mixing of two perfect gases.

**Fig. 5.7** The Gibbs energy of mixing of two perfect gases and (as discussed later) of two liquids that form an ideal solution. The Gibbs energy of mixing is negative for all compositions and temperatures, so perfect gases mix spontaneously in all proportions.

**InterActivity** Draw graphs of  $\Delta_{\text{mix}} G$  against  $x_A$  at different temperatures in the range 298 K to 500 K. For what value of  $x_A$  does  $\Delta_{\text{mix}} G$  depend on temperature most strongly?

### (a) The Gibbs energy of mixing of perfect gases

Let the amounts of two perfect gases in the two containers be  $n_A$  and  $n_B$ ; both are at a temperature  $T$  and a pressure  $p$  (Fig. 5.6). At this stage, the chemical potentials of the two gases have their 'pure' values, which are obtained by applying the definition  $\mu = G_m$  to eqn 3.60:

$$\mu = \mu^\circ + RT \ln \frac{p}{p^\circ} \quad \text{Variation of chemical potential of a perfect gas with pressure} \quad (5.14a)^\circ$$

where  $\mu^\circ$  is the **standard chemical potential**, the chemical potential of the pure gas at 1 bar. It will be much simpler notationally if we agree to let  $p$  denote the pressure relative to  $p^\circ$ ; that is, to replace  $p/p^\circ$  by  $p$ , for then we can write

$$\mu = \mu^\circ + RT \ln p \quad (5.14b)^\circ$$

Equations for which this convention is used will be labelled {1}, {2}, ...; to use the equations, we have to remember to replace  $p$  by  $p/p^\circ$  again. In practice, that simply means using the numerical value of  $p$  in bars. The Gibbs energy of the total system is then given by eqn 5.5 as

$$G_i = n_A \mu_A + n_B \mu_B = n_A (\mu_A^\circ + RT \ln p) + n_B (\mu_B^\circ + RT \ln p) \quad (5.15a)^\circ$$

After mixing, the partial pressures of the gases are  $p_A$  and  $p_B$ , with  $p_A + p_B = p$ . The total Gibbs energy changes to

$$G_f = n_A (\mu_A^\circ + RT \ln p_A) + n_B (\mu_B^\circ + RT \ln p_B) \quad (5.15b)^\circ$$

The difference  $G_f - G_i$ , the **Gibbs energy of mixing**,  $\Delta_{\text{mix}} G$ , is therefore

$$\Delta_{\text{mix}} G = n_A RT \ln \frac{p_A}{p} + n_B RT \ln \frac{p_B}{p} \quad (5.15c)^\circ$$

At this point we may replace  $n_i$  by  $x_i n$ , where  $n$  is the total amount of A and B, and use the relation between partial pressure and mole fraction (Section 1.2c) to write  $p_i/p = x_i$  for each component, which gives

$$\Delta_{\text{mix}} G = nRT(x_A \ln x_A + x_B \ln x_B) \quad \text{Gibbs energy of mixing of perfect gases} \quad (5.16)^\circ$$

Because mole fractions are never greater than 1, the logarithms in this equation are negative, and  $\Delta_{\text{mix}} G < 0$  (Fig. 5.7). The conclusion that  $\Delta_{\text{mix}} G$  is negative for all compositions confirms that perfect gases mix spontaneously in all proportions. However, the equation extends common sense by allowing us to discuss the process quantitatively.

### Example 5.2 Calculating a Gibbs energy of mixing

A container is divided into two equal compartments (Fig. 5.8). One contains 3.0 mol  $\text{H}_2(\text{g})$  at 25°C; the other contains 1.0 mol  $\text{N}_2(\text{g})$  at 25°C. Calculate the Gibbs energy of mixing when the partition is removed. Assume perfect behaviour.

**Method** Equation 5.16 cannot be used directly because the two gases are initially at different pressures. We proceed by calculating the initial Gibbs energy from the chemical potentials. To do so, we need the pressure of each gas. Write the pressure of nitrogen as  $p$ ; then the pressure of hydrogen as a multiple of  $p$  can be found from the gas laws. Next, calculate the Gibbs energy for the system when the partition is removed. The volume occupied by each gas doubles, so its initial partial pressure is halved.

**Answer** Given that the pressure of nitrogen is  $p$ , the pressure of hydrogen is  $3p$ ; therefore, the initial Gibbs energy is

$$G_i = (3.0 \text{ mol})\{\mu^\circ(\text{H}_2) + RT \ln 3p\} + (1.0 \text{ mol})\{\mu^\circ(\text{N}_2) + RT \ln p\}$$

When the partition is removed and each gas occupies twice the original volume, the partial pressure of nitrogen falls to  $\frac{1}{2}p$  and that of hydrogen falls to  $\frac{3}{2}p$ . Therefore, the Gibbs energy changes to

$$G_f = (3.0 \text{ mol})\{\mu^\circ(\text{H}_2) + RT \ln \frac{3}{2}p\} + (1.0 \text{ mol})\{\mu^\circ(\text{N}_2) + RT \ln \frac{1}{2}p\}$$

The Gibbs energy of mixing is the difference of these two quantities:

$$\begin{aligned}\Delta_{\text{mix}}G &= (3.0 \text{ mol})RT \ln \left(\frac{\frac{3}{2}p}{3p}\right) + (1.0 \text{ mol})RT \ln \left(\frac{\frac{1}{2}p}{p}\right) \\ &= -(3.0 \text{ mol})RT \ln 2 - (1.0 \text{ mol})RT \ln 2 \\ &= -(4.0 \text{ mol})RT \ln 2 = -6.9 \text{ kJ}\end{aligned}$$

In this example, the value of  $\Delta_{\text{mix}}G$  is the sum of two contributions: the mixing itself, and the changes in pressure of the two gases to their final total pressure,  $2p$ . When 3.0 mol  $\text{H}_2$  mixes with 1.0 mol  $\text{N}_2$  at the same pressure, with the volumes of the vessels adjusted accordingly, the change of Gibbs energy is  $-5.6 \text{ kJ}$ . However, do not be misled into interpreting this negative change in Gibbs energy as a sign of spontaneity: in this case, the pressure changes, and  $\Delta G < 0$  is a signpost of spontaneous change only at constant temperature and pressure.

**Self-test 5.3** Suppose that 2.0 mol  $\text{H}_2$  at 2.0 atm and  $25^\circ\text{C}$  and 4.0 mol  $\text{N}_2$  at 3.0 atm and  $25^\circ\text{C}$  are mixed at constant volume. Calculate  $\Delta_{\text{mix}}G$ . What would be the value of  $\Delta_{\text{mix}}G$  had the pressures been identical initially? [ $-9.7 \text{ kJ}$ ,  $-9.5 \text{ kJ}$ ]

### (b) Other thermodynamic mixing functions

Because  $(\partial G/\partial T)_{p,n} = -S$ , it follows immediately from eqn 5.16 that, for a mixture of perfect gases initially at the same pressure, the entropy of mixing,  $\Delta_{\text{mix}}S$ , is

$$\Delta_{\text{mix}}S = \left( \frac{\partial \Delta_{\text{mix}}G}{\partial T} \right)_{p,n_A,n_B} = -nR(x_A \ln x_A + x_B \ln x_B) \quad \text{Entropy of mixing of perfect gases} \quad (5.17)^\circ$$

Because  $\ln x < 0$ , it follows that  $\Delta_{\text{mix}}S > 0$  for all compositions (Fig. 5.9). For equal amounts of gas, for instance, we set  $x_A = x_B = \frac{1}{2}$  and obtain  $\Delta_{\text{mix}}S = nR \ln 2$ , with  $n$  the total amount of gas molecules. This increase in entropy is what we expect when one gas disperses into the other and the disorder increases.

We can calculate the isothermal, isobaric (constant pressure) **enthalpy of mixing**,  $\Delta_{\text{mix}}H$ , the enthalpy change accompanying mixing, of two perfect gases from  $\Delta G = \Delta H - T\Delta S$ . It follows from eqns 5.16 and 5.17 that

$$\Delta_{\text{mix}}H = 0 \quad \text{Enthalpy of mixing of perfect gases} \quad (5.18)^\circ$$

The enthalpy of mixing is zero, as we should expect for a system in which there are no interactions between the molecules forming the gaseous mixture. It follows that the whole of the driving force for mixing comes from the increase in entropy of the system because the entropy of the surroundings is unchanged.

**Fig. 5.8** The initial and final states considered in the calculation of the Gibbs energy of mixing of gases at different initial pressures.

**Fig. 5.9** The entropy of mixing of two perfect gases and (as discussed later) of two liquids that form an ideal solution. The entropy increases for all compositions and temperatures, so perfect gases mix spontaneously in all proportions. Because there is no transfer of heat to the surroundings when perfect gases mix, the entropy of the surroundings is unchanged. Hence, the graph also shows the total entropy of the system plus the surroundings when perfect gases mix.

**Fig. 5.10** At equilibrium, the chemical potential of the gaseous form of a substance A is equal to the chemical potential of its condensed phase. The equality is preserved if a solute is also present. Because the chemical potential of A in the vapour depends on its partial vapour pressure, it follows that the chemical potential of liquid A can be related to its partial vapour pressure.

**Fig. 5.11** The total vapour pressure and the two partial vapour pressures of an ideal binary mixture are proportional to the mole fractions of the components.

### 5.3 The chemical potentials of liquids

**Key points** (a) Raoult's law provides a relation between the vapour pressure of a substance and its mole fraction in a mixture; it is the basis of the definition of an ideal solution. (b) Henry's law provides a relation between the vapour pressure of a solute and its mole fraction in a mixture; it is the basis of the definition of an ideal-dilute solution.

To discuss the equilibrium properties of liquid mixtures we need to know how the Gibbs energy of a liquid varies with composition. To calculate its value, we use the fact that, at equilibrium, the chemical potential of a substance present as a vapour must be equal to its chemical potential in the liquid.

#### (a) Ideal solutions

We shall denote quantities relating to pure substances by a superscript \*, so the chemical potential of pure A is written  $\mu_A^*$  and as  $\mu_A^*(l)$  when we need to emphasize that A is a liquid. Because the vapour pressure of the pure liquid is  $p_A^*$  it follows from eqn 5.14 that the chemical potential of A in the vapour (treated as a perfect gas) is  $\mu_A^\ominus + RT \ln p_A^*$  (with  $p_A$  to be interpreted as the relative pressure  $p_A/p^\ominus$ ). These two chemical potentials are equal at equilibrium (Fig. 5.10), so we can write

$$\mu_A^* = \mu_A^\ominus + RT \ln p_A^* \quad \{5.19a\}^\ominus$$

If another substance, a solute, is also present in the liquid, the chemical potential of A in the liquid is changed to  $\mu_A$  and its vapour pressure is changed to  $p_A$ . The vapour and solvent are still in equilibrium, so we can write

$$\mu_A = \mu_A^\ominus + RT \ln p_A \quad \{5.19b\}^\ominus$$

Next, we combine these two equations to eliminate the standard chemical potential of the gas. To do so, we write eqn 5.19a as  $\mu_A^\ominus = \mu_A^* - RT \ln p_A^*$  and substitute this expression into eqn 5.19b to obtain

$$\mu_A = \mu_A^* - RT \ln p_A^* + RT \ln p_A = \mu_A^* + RT \ln \frac{p_A}{p_A^*} \quad (5.20)^\ominus$$

In the final step we draw on additional experimental information about the relation between the ratio of vapour pressures and the composition of the liquid. In a series of experiments on mixtures of closely related liquids (such as benzene and methylbenzene), the French chemist François Raoult found that the ratio of the partial vapour pressure of each component to its vapour pressure as a pure liquid,  $p_A/p_A^*$ , is approximately equal to the mole fraction of A in the liquid mixture. That is, he established what we now call **Raoult's law**:

$$p_A = x_A p_A^* \quad \text{Raoult's law} \quad (5.21)^\ominus$$

This law is illustrated in Fig. 5.11. Some mixtures obey Raoult's law very well, especially when the components are structurally similar (Fig. 5.12). Mixtures that obey the law throughout the composition range from pure A to pure B are called **ideal solutions**. When we write equations that are valid only for ideal solutions, we shall label them with a superscript  $^\ominus$ , as in eqn 5.21.

For an ideal solution, it follows from eqns 5.20 and 5.21 that

$$\mu_A = \mu_A^* + RT \ln x_A \quad \text{Chemical potential of component of an ideal solution} \quad (5.22)^\ominus$$

**Fig. 5.12** Two similar liquids, in this case benzene and methylbenzene (toluene), behave almost ideally, and the variation of their vapour pressures with composition resembles that for an ideal solution.

**Fig. 5.13** Strong deviations from ideality are shown by dissimilar liquids (in this case carbon disulfide and acetone, propanone).

**Fig. 5.14** When a component (the solvent) is nearly pure, it has a vapour pressure that is proportional to its mole fraction with a slope  $p_B^*$  (Raoult's law). When it is the minor component (the solute) its vapour pressure is still proportional to the mole fraction, but the constant of proportionality is now  $K_B$  (Henry's law).

This important equation can be used as the *definition* of an ideal solution (so that it implies Raoult's law rather than stemming from it). It is in fact a better definition than eqn 5.21 because it does not assume that the vapour is a perfect gas.

The molecular origin of Raoult's law is the effect of the solute on the entropy of the solution. In the pure solvent, the molecules have a certain disorder and a corresponding entropy; the vapour pressure then represents the tendency of the system and its surroundings to reach a higher entropy. When a solute is present, the solution has a greater disorder than the pure solvent because we cannot be sure that a molecule chosen at random will be a solvent molecule. Because the entropy of the solution is higher than that of the pure solvent, the solution has a lower tendency to acquire an even higher entropy by the solvent vaporizing. In other words, the vapour pressure of the solvent in the solution is lower than that of the pure solvent.

Some solutions depart significantly from Raoult's law (Fig. 5.13). Nevertheless, even in these cases the law is obeyed increasingly closely for the component in excess (the solvent) as it approaches purity. The law is therefore a good approximation for the properties of the solvent if the solution is dilute.

### (b) Ideal-dilute solutions

In ideal solutions the solute, as well as the solvent, obeys Raoult's law. However, the English chemist William Henry found experimentally that, for real solutions at low concentrations, although the vapour pressure of the solute is proportional to its mole fraction, the constant of proportionality is not the vapour pressure of the pure substance (Fig. 5.14). **Henry's law** is:

$$p_B = x_B K_B \quad \text{Henry's law} \quad (5.23)^\circ$$

In this expression  $x_B$  is the mole fraction of the solute and  $K_B$  is an empirical constant (with the dimensions of pressure) chosen so that the plot of the vapour pressure of B against its mole fraction is tangent to the experimental curve at  $x_B = 0$ .

**Fig. 5.15** In a dilute solution, the solvent molecules (the blue spheres) are in an environment that differs only slightly from that of the pure solvent. The solute particles, however, are in an environment totally unlike that of the pure solute.

**Fig. 5.16** The experimental partial vapour pressures of a mixture of chloroform (trichloromethane) and acetone (propanone) based on the data in Example 5.3. The values of  $K$  are obtained by extrapolating the dilute solution vapour pressures as explained in the Example.

**Table 5.1\*** Henry's law constants for gases in water at 298 K

|               | $K/(\text{kPa kg mol}^{-1})$ |
|---------------|------------------------------|
| $\text{CO}_2$ | $3.01 \times 10^3$           |
| $\text{H}_2$  | $1.28 \times 10^5$           |
| $\text{N}_2$  | $1.56 \times 10^5$           |
| $\text{O}_2$  | $7.92 \times 10^4$           |

\* More values are given in the Data section.

Mixtures for which the solute obeys Henry's law and the solvent obeys Raoult's law are called **ideal-dilute solutions**. We shall also label equations with a superscript  $^\circ$  when they have been derived from Henry's law. The difference in behaviour of the solute and solvent at low concentrations (as expressed by Henry's and Raoult's laws, respectively) arises from the fact that in a dilute solution the solvent molecules are in an environment very much like the one they have in the pure liquid (Fig. 5.15). In contrast, the solute molecules are surrounded by solvent molecules, which is entirely different from their environment when pure. Thus, the solvent behaves like a slightly modified pure liquid, but the solute behaves entirely differently from its pure state unless the solvent and solute molecules happen to be very similar. In the latter case, the solute also obeys Raoult's law.

### Example 5.3 Investigating the validity of Raoult's and Henry's laws

The vapour pressures of each component in a mixture of propanone (acetone, A) and trichloromethane (chloroform, C) were measured at 35°C with the following results:

|                  |      |      |      |      |      |      |
|------------------|------|------|------|------|------|------|
| $x_C$            | 0    | 0.20 | 0.40 | 0.60 | 0.80 | 1    |
| $p_C/\text{kPa}$ | 0    | 4.7  | 11   | 18.9 | 26.7 | 36.4 |
| $p_A/\text{kPa}$ | 46.3 | 33.3 | 23.3 | 12.3 | 4.9  | 0    |

Confirm that the mixture conforms to Raoult's law for the component in large excess and to Henry's law for the minor component. Find the Henry's law constants.

**Method** Both Raoult's and Henry's laws are statements about the form of the graph of partial vapour pressure against mole fraction. Therefore, plot the partial vapour pressures against mole fraction. Raoult's law is tested by comparing the data with the straight line  $p_j = x_j p_j^*$  for each component in the region in which it is in excess (and acting as the solvent). Henry's law is tested by finding a straight line  $p_j = x_j K_j^*$  that is tangent to each partial vapour pressure at low  $x$ , where the component can be treated as the solute.

**Answer** The data are plotted in Fig. 5.16 together with the Raoult's law lines. Henry's law requires  $K = 23.3$  kPa for propanone and  $K = 22.0$  kPa for trichloromethane. Notice how the system deviates from both Raoult's and Henry's laws even for quite small departures from  $x=1$  and  $x=0$ , respectively. We deal with these deviations in Sections 5.10 and 5.11.

**Self-test 5.4** The vapour pressure of chloromethane at various mole fractions in a mixture at 25°C was found to be as follows:

|                |       |       |       |       |
|----------------|-------|-------|-------|-------|
| $x$            | 0.005 | 0.009 | 0.019 | 0.024 |
| $p/\text{kPa}$ | 27.3  | 48.4  | 101   | 126   |

Estimate Henry's law constant.

[5 MPa]

For practical applications, Henry's law is expressed in terms of the molality,  $b$ , of the solute,  $p_B = b_B K_B$ . Some Henry's law data for this convention are listed in Table 5.1. As well as providing a link between the mole fraction of solute and its partial pressure, the data in the table may also be used to calculate gas solubilities. A knowledge of Henry's law constants for gases in blood and fats is important for the discussion of respiration, especially when the partial pressure of oxygen is abnormal, as in diving and mountaineering, and for the discussion of the action of gaseous anaesthetics.

• **A brief illustration**

To estimate the molar solubility of oxygen in water at 25°C and a partial pressure of 21 kPa, its partial pressure in the atmosphere at sea level, we write

$$b_{\text{O}_2} = \frac{p_{\text{O}_2}}{K_{\text{O}_2}} = \frac{21 \text{ kPa}}{7.9 \times 10^4 \text{ kPa mol}^{-1}} = 2.7 \times 10^{-4} \text{ mol kg}^{-1}$$

The molality of the saturated solution is therefore 0.27 mmol kg<sup>-1</sup>. To convert this quantity to a molar concentration, we assume that the mass density of this dilute solution is essentially that of pure water at 25°C, or  $\rho_{\text{H}_2\text{O}} = 0.99709 \text{ kg dm}^{-3}$ . It follows that the molar concentration of oxygen is

$$[\text{O}_2] = b_{\text{O}_2} \times \rho_{\text{H}_2\text{O}} = 0.27 \text{ mmol kg}^{-1} \times 0.99709 \text{ kg dm}^{-3} = 0.27 \text{ mmol dm}^{-3} \quad \bullet$$

**Self-test 5.5** Calculate the molar solubility of nitrogen in water exposed to air at 25°C; partial pressures were calculated in *Example 1.3*. [0.51 mmol dm<sup>-3</sup>]

## The properties of solutions

In this section we consider the thermodynamics of mixing of liquids. First, we consider the simple case of mixtures of liquids that mix to form an ideal solution. In this way, we identify the thermodynamic consequences of molecules of one species mingling randomly with molecules of the second species. The calculation provides a background for discussing the deviations from ideal behaviour exhibited by real solutions.

### 5.4 Liquid mixtures

**Key points** (a) The Gibbs energy of mixing of two liquids to form an ideal solution is calculated in the same way as for two perfect gases. The enthalpy of mixing is zero and the Gibbs energy is due entirely to the entropy of mixing. (b) A regular solution is one in which the entropy of mixing is the same as for an ideal solution but the enthalpy of mixing is non-zero.

Thermodynamics can provide insight into the properties of liquid mixtures, and a few simple ideas can bring the whole field of study together.

#### (a) Ideal solutions

The Gibbs energy of mixing of two liquids to form an ideal solution is calculated in exactly the same way as for two gases (Section 5.2). The total Gibbs energy before liquids are mixed is

$$G_i = n_A \mu_A^* + n_B \mu_B^* \quad (5.24a)$$

When they are mixed, the individual chemical potentials are given by eqn 5.22 and the total Gibbs energy is

$$G_f = n_A \{\mu_A^* + RT \ln x_A\} + n_B \{\mu_B^* + RT \ln x_B\} \quad (5.24b)^\circ$$

Consequently, the Gibbs energy of mixing, the difference of these two quantities, is

$$\Delta_{\text{mix}} G = nRT \{x_A \ln x_A + x_B \ln x_B\}$$

Gibbs energy of mixing  
to form an ideal solution

$$(5.25)^\circ$$

**A note on good practice** It is on the basis of this distinction (in the second paragraph) that the term ‘perfect gas’ is preferable to the more common ‘ideal gas’. In an ideal solution there are interactions, but they are effectively the same between the various species. In a perfect gas, not only are the interactions the same, but they are also zero. Few people, however, trouble to make this valuable distinction.

**Fig. 5.17** Experimental excess functions at 25°C. (a)  $H^E$  for benzene/cyclohexane; this graph shows that the mixing is endothermic (because  $\Delta_{\text{mix}}H = 0$  for an ideal solution). (b) The excess volume,  $V^E$ , for tetrachloroethene/cyclopentane; this graph shows that there is a contraction at low tetrachloroethene mole fractions, but an expansion at high mole fractions (because  $\Delta_{\text{mix}}V = 0$  for an ideal mixture).

where  $n = n_A + n_B$ . As for gases, it follows that the ideal entropy of mixing of two liquids is

$$\Delta_{\text{mix}}S = -nR\{x_A \ln x_A + x_B \ln x_B\} \quad \text{Entropy of mixing to form an ideal solution} \quad (5.26)^{\circ}$$

Because  $\Delta_{\text{mix}}H = \Delta_{\text{mix}}G + T\Delta_{\text{mix}}S = 0$ , the ideal enthalpy of mixing is zero. The ideal volume of mixing, the change in volume on mixing, is also zero because it follows from eqn 3.53 ( $(\partial G/\partial p)_T = V$ ) that  $\Delta_{\text{mix}}V = (\partial \Delta_{\text{mix}}G/\partial p)_T$ , but  $\Delta_{\text{mix}}G$  in eqn 5.25 is independent of pressure, so the derivative with respect to pressure is zero.

Equation 5.26 is the same as that for two perfect gases and all the conclusions drawn there are valid here: the driving force for mixing is the increasing entropy of the system as the molecules mingle and the enthalpy of mixing is zero. It should be noted, however, that solution ideality means something different from gas perfection. In a perfect gas there are no forces acting between molecules. In ideal solutions there are interactions, but the average energy of A–B interactions in the mixture is the same as the average energy of A–A and B–B interactions in the pure liquids. The variation of the Gibbs energy of mixing with composition is the same as that already depicted for gases in Fig. 5.7; the same is true of the entropy of mixing, Fig. 5.9.

Real solutions are composed of particles for which A–A, A–B, and B–B interactions are all different. Not only may there be enthalpy and volume changes when liquids mix, but there may also be an additional contribution to the entropy arising from the way in which the molecules of one type might cluster together instead of mingling freely with the others. If the enthalpy change is large and positive or if the entropy change is adverse (because of a reorganization of the molecules that results in an orderly mixture), then the Gibbs energy might be positive for mixing. In that case, separation is spontaneous and the liquids may be immiscible. Alternatively, the liquids might be **partially miscible**, which means that they are miscible only over a certain range of compositions.

### (b) Excess functions and regular solutions

The thermodynamic properties of real solutions are expressed in terms of the **excess functions**,  $X^E$ , the difference between the observed thermodynamic function of mixing and the function for an ideal solution. The **excess entropy**,  $S^E$ , for example, is defined as

$$S^E = \Delta_{\text{mix}}S - \Delta_{\text{mix}}S^{\text{ideal}} \quad \text{Definition of excess entropy} \quad [5.27]$$

where  $\Delta_{\text{mix}}S^{\text{ideal}}$  is given by eqn 5.26. The excess enthalpy and volume are both equal to the observed enthalpy and volume of mixing, because the ideal values are zero in each case. Figure 5.17 shows two examples of the composition dependence of molar excess functions. In Fig. 5.17(a), the positive values of  $H^E$  indicate that the A–B interactions in the mixture are weaker than the A–A and B–B interactions in the pure liquids (which are benzene and pure cyclohexane). The symmetrical shape of the curve reflects the similar strengths of the A–A and B–B interactions. Figure 5.17(b) shows the composition dependence of the excess volume,  $V^E$ , of a mixture of tetrachloroethene and cyclopentane. At high mole fractions of cyclopentane, the solution contracts as tetrachloroethene is added because the ring structure of cyclopentane results in inefficient packing of the molecules but, as tetrachloroethene is added, the molecules in the mixture pack together more tightly. Similarly, at high mole fractions of tetrachloroethene, the solution expands as cyclopentane is added because tetrachloroethene molecules are nearly flat and pack efficiently in the pure liquid but become disrupted as bulky ring cyclopentane is added.

Deviations of the excess energies from zero indicate the extent to which the solutions are nonideal. In this connection a useful model system is the **regular solution**, a solution for which  $H^E \neq 0$  but  $S^E = 0$ . We can think of a regular solution as one in which the two kinds of molecules are distributed randomly (as in an ideal solution) but have different energies of interactions with each other. To express this concept more quantitatively we can suppose that the excess enthalpy depends on composition as

$$H^E = n\xi RTx_Ax_B \quad (5.28)$$

where  $\xi$  (xi) is a dimensionless parameter that is a measure of the energy of AB interactions relative to that of the AA and BB interactions. The function given by eqn 5.28 is plotted in Fig. 5.18, and we see it resembles the experimental curve in Fig. 5.17. If  $\xi < 0$ , mixing is exothermic and the solute–solvent interactions are more favourable than the solvent–solvent and solute–solute interactions. If  $\xi > 0$ , then the mixing is endothermic. Because the entropy of mixing has its ideal value for a regular solution, the excess Gibbs energy is equal to the excess enthalpy, and the Gibbs energy of mixing is

$$\Delta_{\text{mix}}G = nRT\{x_A \ln x_A + x_B \ln x_B + \xi x_Ax_B\} \quad (5.29)$$

Figure 5.19 shows how  $\Delta_{\text{mix}}G$  varies with composition for different values of  $\xi$ . The important feature is that for  $\xi > 2$  the graph shows two minima separated by a maximum. The implication of this observation is that, provided  $\xi > 2$ , the system will separate spontaneously into two phases with compositions corresponding to the two minima, for that separation corresponds to a reduction in Gibbs energy. We develop this point in Sections 5.6 and 5.10.

## 5.5 Colligative properties

**Key points** A colligative property depends only on the number of solute particles present, not their identity. (a) All the colligative properties stem from the reduction of the chemical potential of the liquid solvent as a result of the presence of solute. (b) The elevation of boiling point is proportional to the molality of the solute. (c) The depression of freezing point is also proportional to the molality of the solute. (d) Solutes with high melting points and large enthalpies of melting have low solubilities at normal temperatures. (e) The relation of the osmotic pressure to the molar concentration of the solute is given by the van't Hoff equation and is a sensitive way of determining molar mass.

The properties we now consider are the lowering of vapour pressure, the elevation of boiling point, the depression of freezing point, and the osmotic pressure arising from the presence of a solute. In dilute solutions these properties depend only on the number of solute particles present, not their identity. For this reason, they are called **colligative properties** (denoting ‘depending on the collection’).

We assume throughout the following that the solute is not volatile, so it does not contribute to the vapour. We also assume that the solute does not dissolve in the solid solvent: that is, the pure solid solvent separates when the solution is frozen. The latter assumption is quite drastic, although it is true of many mixtures; it can be avoided at the expense of more algebra, but that introduces no new principles.

### (a) The common features of colligative properties

All the colligative properties stem from the reduction of the chemical potential of the liquid solvent as a result of the presence of solute. For an ideal-dilute solution, the reduction is from  $\mu_A^*$  for the pure solvent to  $\mu_A^* + RT \ln x_A$  when a solute is present ( $\ln x_A$  is negative because  $x_A < 1$ ). There is no direct influence of the solute on the

**Fig. 5.18** The excess enthalpy according to a model in which it is proportional to  $\xi x_Ax_B$ , for different values of the parameter  $\xi$ .

**InterActivity** Using the graph above, fix  $\xi$  and vary the temperature. For what value of  $x_A$  does the excess enthalpy depend on temperature most strongly?

**Fig. 5.19** The Gibbs energy of mixing for different values of the parameter  $\xi$ .

**Fig. 5.20** The chemical potential of a solvent in the presence of a solute. The lowering of the liquid's chemical potential has a greater effect on the freezing point than on the boiling point because of the angles at which the lines intersect.

**Fig. 5.21** The vapour pressure of a pure liquid represents a balance between the increase in disorder arising from vaporization and the decrease in disorder of the surroundings. (a) Here the structure of the liquid is represented highly schematically by the grid of squares. (b) When solute (the dark squares) is present, the disorder of the condensed phase is higher than that of the pure liquid, and there is a decreased tendency to acquire the disorder characteristic of the vapour.

chemical potential of the solvent vapour and the solid solvent because the solute appears in neither the vapour nor the solid. As can be seen from Fig. 5.20, the reduction in chemical potential of the solvent implies that the liquid–vapour equilibrium occurs at a higher temperature (the boiling point is raised) and the solid–liquid equilibrium occurs at a lower temperature (the freezing point is lowered).

The molecular origin of the lowering of the chemical potential is not the energy of interaction of the solute and solvent particles, because the lowering occurs even in an ideal solution (for which the enthalpy of mixing is zero). If it is not an enthalpy effect, it must be an entropy effect. The vapour pressure of the pure liquid reflects the tendency of the solution towards greater entropy, which can be achieved if the liquid vaporizes to form a gas. When a solute is present, there is an additional contribution to the entropy of the liquid, even in an ideal solution. Because the entropy of the liquid is already higher than that of the pure liquid, there is a weaker tendency to form the gas (Fig. 5.21). The effect of the solute appears as a lowered vapour pressure, and hence a higher boiling point. Similarly, the enhanced molecular randomness of the solution opposes the tendency to freeze. Consequently, a lower temperature must be reached before equilibrium between solid and solution is achieved. Hence, the freezing point is lowered.

The strategy for the quantitative discussion of the elevation of boiling point and the depression of freezing point is to look for the temperature at which, at 1 atm, one phase (the pure solvent vapour or the pure solid solvent) has the same chemical potential as the solvent in the solution. This is the new equilibrium temperature for the phase transition at 1 atm, and hence corresponds to the new boiling point or the new freezing point of the solvent.

### (b) The elevation of boiling point

The heterogeneous equilibrium of interest when considering boiling is between the solvent vapour and the solvent in solution at 1 atm (Fig. 5.22). We denote the solvent by A and the solute by B. The equilibrium is established at a temperature for which

$$\mu_A^*(g) = \mu_A^*(l) + RT \ln x_A \quad (5.30)^\circ$$

(The pressure of 1 atm is the same throughout, and will not be written explicitly.) We show in the following *Justification* that this equation implies that the presence of a solute at a mole fraction  $x_B$  causes an increase in normal boiling point from  $T^*$  to  $T^* + \Delta T$ , where

$$\Delta T = Kx_B \quad K = \frac{RT^{*2}}{\Delta_{\text{vap}}H} \quad (5.31)^\circ$$

#### Justification 5.1 The elevation of the boiling point of a solvent

Equation 5.30 can be rearranged into

$$\ln x_A = \frac{\mu_A^*(g) - \mu_A^*(l)}{RT} = \frac{\Delta_{\text{vap}}G}{RT}$$

where  $\Delta_{\text{vap}}G$  is the Gibbs energy of vaporization of the pure solvent (A). First, to find the relation between a change in composition and the resulting change in boiling temperature, we differentiate both sides with respect to temperature and use the Gibbs–Helmholtz equation (eqn 3.55,  $(\partial(G/T)/\partial T)_p = -H/T^2$ ) to express the term on the right:

$$\frac{d \ln x_A}{dT} = \frac{1}{R} \frac{d(\Delta_{\text{vap}}G/T)}{dT} = -\frac{\Delta_{\text{vap}}H}{RT^2}$$

Now multiply both sides by  $dT$  and integrate from  $x_A = 1$ , corresponding to  $\ln x_A = 0$  (and when  $T = T^*$ , the boiling point of pure A) to  $x_A$  (when the boiling point is  $T$ ):

$$\int_0^{\ln x_A} d \ln x_A = -\frac{1}{R} \int_{T^*}^T \frac{\Delta_{\text{vap}} H}{T^2} dT$$

The left-hand side integrates to  $\ln x_A$ , which is equal to  $\ln(1 - x_B)$ . The right-hand side can be integrated if we assume that the enthalpy of vaporization is a constant over the small range of temperatures involved and can be taken outside the integral. Thus, we obtain

$$\ln(1 - x_B) = -\frac{\Delta_{\text{vap}} H}{R} \int_{T^*}^T \frac{1}{T^2} dT$$

and therefore

$$\ln(1 - x_B) = \frac{\Delta_{\text{vap}} H}{R} \left( \frac{1}{T} - \frac{1}{T^*} \right)$$

We now suppose that the amount of solute present is so small that  $x_B \ll 1$ . We can then write  $\ln(1 - x_B) = -x_B$  and hence obtain

$$x_B = \frac{\Delta_{\text{vap}} H}{R} \left( \frac{1}{T^*} - \frac{1}{T} \right)$$

Finally, because  $T \approx T^*$ , it also follows that

$$\frac{1}{T^*} - \frac{1}{T} = \frac{T - T^*}{TT^*} \approx \frac{\Delta T}{T^{*2}}$$

with  $\Delta T = T - T^*$ . The previous equation then rearranges into eqn 5.31.

Because eqn 5.31 makes no reference to the identity of the solute, only to its mole fraction, we conclude that the elevation of boiling point is a colligative property. The value of  $\Delta T$  does depend on the properties of the solvent, and the biggest changes occur for solvents with high boiling points.<sup>1</sup> For practical applications of eqn 5.31, we note that the mole fraction of B is proportional to its molality,  $b$ , in the solution, and write

$$\Delta T = K_b b$$

Boiling point  
elevation

(5.32)

where  $K_b$  is the empirical **boiling-point constant** of the solvent (Table 5.2).

**Fig. 5.22** The heterogeneous equilibrium involved in the calculation of the elevation of boiling point is between A in the pure vapour and A in the mixture, A being the solvent and B an involatile solute.

#### A brief comment

The series expansion of a natural logarithm is

$$\ln(1 - x) = -x - \frac{1}{2}x^2 - \frac{1}{3}x^3 \dots$$

provided that  $-1 < x < 1$ . If  $x \ll 1$ , then the terms involving  $x$  raised to a power greater than 1 are much smaller than  $x$ , so  $\ln(1 - x) \approx -x$ .

**Table 5.2\*** Freezing-point and boiling-point constants

|         | $K_f/(\text{K kg mol}^{-1})$ | $K_b/(\text{K kg mol}^{-1})$ |
|---------|------------------------------|------------------------------|
| Benzene | 5.12                         | 2.53                         |
| Camphor | 40                           |                              |
| Phenol  | 7.27                         | 3.04                         |
| Water   | 1.86                         | 0.51                         |

\* More values are given in the *Data section*.

<sup>1</sup> By Trouton's rule (Section 3.3b),  $\Delta_{\text{vap}} H/T^*$  is a constant; therefore eqn 5.31 has the form  $\Delta T \propto T^*$  and is independent of  $\Delta_{\text{vap}} H$  itself.

**Fig. 5.23** The heterogeneous equilibrium involved in the calculation of the lowering of freezing point is between A in the pure solid and A in the mixture, A being the solvent and B a solute that is insoluble in solid A.

**Fig. 5.24** The heterogeneous equilibrium involved in the calculation of the solubility is between pure solid B and B in the mixture.

### (c) The depression of freezing point

The heterogeneous equilibrium now of interest is between pure solid solvent A and the solution with solute present at a mole fraction  $x_B$  (Fig. 5.23). At the freezing point, the chemical potentials of A in the two phases are equal:

$$\mu_A^*(s) = \mu_A^*(l) + RT \ln x_A \quad (5.33)^\circ$$

The only difference between this calculation and the last is the appearance of the solid's chemical potential in place of the vapour's. Therefore we can write the result directly from eqn 5.31:

$$\Delta T = K' x_B \quad K' = \frac{RT^{*2}}{\Delta_{\text{fus}} H} \quad (5.34)^\circ$$

where  $\Delta T$  is the freezing point depression,  $T^* - T$ , and  $\Delta_{\text{fus}} H$  is the enthalpy of fusion of the solvent. Larger depressions are observed in solvents with low enthalpies of fusion and high melting points. When the solution is dilute, the mole fraction is proportional to the molality of the solute,  $b$ , and it is common to write the last equation as

$$\Delta T = K_f b \quad \text{Freezing point depression} \quad (5.35)$$

where  $K_f$  is the empirical **freezing-point constant** (Table 5.2). Once the freezing-point constant of a solvent is known, the depression of freezing point may be used to measure the molar mass of a solute in the method known as **cryoscopy**; however, the technique is of little more than historical interest.

### (d) Solubility

Although solubility is not a colligative property (because solubility varies with the identity of the solute), it may be estimated by the same techniques as we have been using. When a solid solute is left in contact with a solvent, it dissolves until the solution is saturated. Saturation is a state of equilibrium, with the undissolved solute in equilibrium with the dissolved solute. Therefore, in a saturated solution the chemical potential of the pure solid solute,  $\mu_B^*(s)$ , and the chemical potential of B in solution,  $\mu_B$ , are equal (Fig. 5.24). Because the latter is  $\mu_B = \mu_B^*(l) + RT \ln x_B$ , we can write

$$\mu_B^*(s) = \mu_B^*(l) + RT \ln x_B \quad (5.36)^\circ$$

This expression is the same as the starting equation of the last section, except that the quantities refer to the solute B, not the solvent A. We now show in the following *Justification* that

$$\ln x_B = \frac{\Delta_{\text{fus}} H}{R} \left( \frac{1}{T_f} - \frac{1}{T} \right) \quad \text{Ideal solubility} \quad (5.37)^\circ$$

#### Justification 5.2 The solubility of an ideal solute

The starting point is the same as in *Justification 5.1* but the aim is different. In the present case, we want to find the mole fraction of B in solution at equilibrium when the temperature is  $T$ . Therefore, we start by rearranging eqn 5.36 into

$$\ln x_B = \frac{\mu_B^*(s) - \mu_B^*(l)}{RT} = -\frac{\Delta_{\text{fus}} G}{RT}$$

As in *Justification 5.1*, we relate the change in composition  $d \ln x_B$  to the change in temperature by differentiation and use of the Gibbs–Helmholtz equation. Then we

integrate from the melting temperature of B (when  $x_B = 1$  and  $\ln x_B = 0$ ) to the *lower* temperature of interest (when  $x_B$  has a value between 0 and 1):

$$\int_0^{\ln x_B} d \ln x_B = \frac{1}{R} \int_{T_f}^T \frac{\Delta_{\text{fus}} H}{T^2} dT$$

If we suppose that the enthalpy of fusion of B is constant over the range of temperatures of interest, it can be taken outside the integral, and we obtain eqn 5.37.

Equation 5.37 is plotted in Fig. 5.25. It shows that the solubility of B decreases exponentially as the temperature is lowered from its melting point. The illustration also shows that solutes with low melting points and large enthalpies of melting have low solubilities at normal temperatures. However, the detailed content of eqn 5.37 should not be treated too seriously because it is based on highly questionable approximations, such as the ideality of the solution. One aspect of its approximate character is that it fails to predict that solutes will have different solubilities in different solvents, for no solvent properties appear in the expression.

### (e) Osmosis

The phenomenon of **osmosis** (from the Greek word for ‘push’) is the spontaneous passage of a pure solvent into a solution separated from it by a **semipermeable membrane**, a membrane permeable to the solvent but not to the solute (Fig. 5.26). The **osmotic pressure**,  $\Pi$ , is the pressure that must be applied to the solution to stop the influx of solvent. Important examples of osmosis include transport of fluids through cell membranes, dialysis, and **osmometry**, the determination of molar mass by the measurement of osmotic pressure. Osmometry is widely used to determine the molar masses of macromolecules.

In the simple arrangement shown in Fig. 5.27, the opposing pressure arises from the head of solution that the osmosis itself produces. Equilibrium is reached when the hydrostatic pressure of the column of solution matches the osmotic pressure. The complicating feature of this arrangement is that the entry of solvent into the solution results in its dilution, and so it is more difficult to treat than the arrangement in Fig. 5.26, in which there is no flow and the concentrations remain unchanged.

The thermodynamic treatment of osmosis depends on noting that, at equilibrium, the chemical potential of the solvent must be the same on each side of the membrane. The chemical potential of the solvent is lowered by the solute, but is restored to its ‘pure’ value by the application of pressure. As shown in the following *Justification*, this equality implies that for dilute solutions the osmotic pressure is given by the **van’t Hoff equation**:

$$\Pi = [B]RT \quad \text{van't Hoff equation} \quad (5.38)^\circ$$

where  $[B] = n_B/V$  is the molar concentration of the solute.

#### Justification 5.3 The van’t Hoff equation

On the pure solvent side the chemical potential of the solvent, which is at a pressure  $p$ , is  $\mu_A^*(p)$ . On the solution side, the chemical potential is lowered by the presence of the solute, which reduces the mole fraction of the solvent from 1 to  $x_A$ . However, the chemical potential of A is raised on account of the greater pressure,  $p + \Pi$ , that the solution experiences. At equilibrium the chemical potential of A is the same in both compartments, and we can write

$$\mu_A^*(p) = \mu_A(x_A, p + \Pi)$$

**Fig. 5.25** The variation of solubility (the mole fraction of solute in a saturated solution) with temperature ( $T^*$  is the freezing temperature of the solute). Individual curves are labelled with the value of  $\Delta_{\text{fus}} H/RT^*$ .

**InterActivity** Derive an expression for the temperature coefficient of the solubility,  $dx_B/dT$ , and plot it as a function of temperature for several values of the enthalpy of fusion.

**Fig. 5.26** The equilibrium involved in the calculation of osmotic pressure,  $\Pi$ , is between pure solvent A at a pressure  $p$  on one side of the semipermeable membrane and A as a component of the mixture on the other side of the membrane, where the pressure is  $p + \Pi$ .

**Fig. 5.27** In a simple version of the osmotic pressure experiment, A is at equilibrium on each side of the membrane when enough has passed into the solution to cause a hydrostatic pressure difference.

The presence of solute is taken into account in the normal way:

$$\mu_A(x_A, p + \Pi) = \mu_A^*(p + \Pi) + RT \ln x_A$$

We saw in Section 3.9 (eqn 3.57) how to take the effect of pressure into account:

$$\mu_A^*(p + \Pi) = \mu_A^*(p) + \int_p^{p+\Pi} V_m dp$$

where  $V_m$  is the molar volume of the pure solvent A. When these three equations are combined we get

$$-RT \ln x_A = \int_p^{p+\Pi} V_m dp \quad (5.39)^\circ$$

This expression enables us to calculate the additional pressure  $\Pi$  that must be applied to the solution to restore the chemical potential of the solvent to its 'pure' value and thus to restore equilibrium across the semipermeable membrane. For dilute solutions,  $\ln x_A$  may be replaced by  $\ln(1 - x_B) \approx -x_B$ . We may also assume that the pressure range in the integration is so small that the molar volume of the solvent is a constant. That being so,  $V_m$  may be taken outside the integral, giving

$$RTx_B = \Pi V_m$$

When the solution is dilute,  $x_B \approx n_B/n_A$ . Moreover, because  $n_A V_m = V$ , the total volume of the solvent, the equation simplifies to eqn 5.38.

Because the effect of osmotic pressure is so readily measurable and large, one of the most common applications of osmometry is to the measurement of molar masses of macromolecules, such as proteins and synthetic polymers. As these huge molecules dissolve to produce solutions that are far from ideal, it is assumed that the van't Hoff equation is only the first term of a virial-like expansion:

$$\Pi = [J]RT\{1 + B[J] + \dots\} \quad (5.40)$$

(We have denoted the solute J to avoid too many different Bs in this expression). The additional terms take the nonideality into account; the empirical constant  $B$  is called the **osmotic virial coefficient**.

**Example 5.4** Using osmometry to determine the molar mass of a macromolecule

The osmotic pressures of solutions of poly(vinyl chloride), PVC, in cyclohexanone at 298 K are given below. The pressures are expressed in terms of the heights of solution (of mass density  $\rho = 0.980 \text{ g cm}^{-3}$ ) in balance with the osmotic pressure. Determine the molar mass of the polymer.

|                        |      |      |      |      |      |
|------------------------|------|------|------|------|------|
| $c/(\text{g dm}^{-3})$ | 1.00 | 2.00 | 4.00 | 7.00 | 9.00 |
| $h/\text{cm}$          | 0.28 | 0.71 | 2.01 | 5.10 | 8.00 |

**Method** The osmotic pressure is measured at a series of mass concentrations,  $c$ , and a plot of  $\Pi/c$  against  $c$  is used to determine the molar mass of the polymer. We use eqn 5.40 with  $[J] = c/M$  where  $c$  is the mass concentration of the polymer and  $M$  is its molar mass. The osmotic pressure is related to the hydrostatic pressure by  $\Pi = \rho gh$  (Example 1.1) with  $g = 9.81 \text{ m s}^{-2}$ . With these substitutions, eqn 5.40 becomes

$$\frac{h}{c} = \frac{RT}{\rho g M} \left( 1 + \frac{Bc}{M} + \dots \right) = \frac{RT}{\rho g M} + \left( \frac{RTB}{\rho g M^2} \right) c + \dots$$

Therefore, to find  $M$ , plot  $h/c$  against  $c$ , and expect a straight line with intercept  $RT/\rho gM$  at  $c = 0$ .

**Answer** The data give the following values for the quantities to plot:

|                                         |      |      |       |       |       |
|-----------------------------------------|------|------|-------|-------|-------|
| $c/(\text{g dm}^{-3})$                  | 1.00 | 2.00 | 4.00  | 7.00  | 9.00  |
| $(h/c)/(\text{cm g}^{-1} \text{ dm}^3)$ | 0.28 | 0.36 | 0.503 | 0.729 | 0.889 |

The points are plotted in Fig. 5.28. The intercept is at 0.21. Therefore,

$$\begin{aligned}
 M &= \frac{RT}{\rho g} \times \frac{1}{0.21 \text{ cm g}^{-1} \text{ dm}^3} \\
 &= \frac{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})}{(980 \text{ kg m}^{-1}) \times (9.81 \text{ m s}^{-2})} \times \frac{1}{2.1 \times 10^{-3} \text{ m}^4 \text{ kg}^{-1}} \\
 &= 1.2 \times 10^2 \text{ kg mol}^{-1}
 \end{aligned}$$

where we have used  $1 \text{ kg m}^2 \text{ s}^{-2} = 1 \text{ J}$ . Molecular masses of macromolecules are often reported in daltons (Da), with  $1 \text{ Da} = m_u$ . The macromolecule in this example has a molecular mass of about 120 kDa. Modern osmometers give readings of osmotic pressure in pascals, so the analysis of the data is more straightforward and eqn 5.40 can be used directly. As we shall see in Chapter 19, the value obtained from osmometry is the ‘number average molar mass’.

**Self-test 5.6** Estimate the depression of freezing point of the most concentrated of these solutions, taking  $K_f$  as about  $10 \text{ K}/(\text{mol kg}^{-1})$ . [0.8 mK]

**Fig. 5.28** The plot involved in the determination of molar mass by osmometry. The molar mass is calculated from the intercept at  $c = 0$ .

 **InterActivity** Calculate the osmotic virial coefficient  $B$  from these data.

## IMPACT ON BIOLOGY

### 15.1 Osmosis in physiology and biochemistry

Osmosis helps biological cells maintain their structure. Cell membranes are semipermeable and allow water, small molecules, and hydrated ions to pass, while blocking the passage of biopolymers synthesized inside the cell. The difference in concentrations of solutes inside and outside the cell gives rise to an osmotic pressure, and water passes into the more concentrated solution in the interior of the cell, carrying small nutrient molecules. The influx of water also keeps the cell swollen, whereas dehydration causes the cell to shrink. These effects are important in everyday medical practice. To maintain the integrity of blood cells, solutions that are injected into the bloodstream for blood transfusions and intravenous feeding must be *isotonic* with the blood, meaning that they must have the same osmotic pressure as blood. If the injected solution is too dilute, or *hypotonic*, the flow of solvent into the cells, required to equalize the osmotic pressure, causes the cells to burst and die by a process called *haemolysis*. If the solution is too concentrated, or *hypertonic*, equalization of the osmotic pressure requires flow of solvent out of the cells, which shrink and die.

Osmosis also forms the basis of *dialysis*, a common technique for the removal of impurities from solutions of biological macromolecules and for the study of binding of small molecules to macromolecules, such as an inhibitor to an enzyme, an antibiotic to DNA, and any other instance of cooperation or inhibition by small molecules attaching to large ones. In a purification experiment, a solution of macromolecules containing impurities, such as ions or small molecules (including small proteins or nucleic acids), is placed in a bag made of a material that acts as a semipermeable membrane and the filled bag is immersed in a solvent. The membrane permits the passage of the small ions and molecules but not the larger macromolecules, so the former

**Fig. 5.29** The variation of the total vapour pressure of a binary mixture with the mole fraction of A in the liquid when Raoult's law is obeyed.

migrate through the membrane, leaving the macromolecules behind. In practice, purification of the sample requires several changes of solvent to coax most of the impurities out of the dialysis bag.

## Phase diagrams of binary systems

We encountered one-component phase diagrams in Chapter 4. The phase equilibria of binary systems are more complex because composition is an additional variable. However, they provide very useful summaries of phase equilibria for both ideal and empirically established real systems.

### 5.6 Vapour pressure diagrams

**Key points** Raoult's law is used to calculate the total vapour pressure of a binary system of two volatile liquids. (a) The composition of the vapour in equilibrium with a binary mixture is calculated by using Dalton's law. (b) The compositions of the vapour and the liquid phase in equilibrium are located at each end of a tie line. (c) The lever rule is used to deduce the relative abundances of each phase in equilibrium.

The partial vapour pressures of the components of an ideal solution of two volatile liquids are related to the composition of the liquid mixture by Raoult's law (Section 5.3)

$$p_A = x_A p_A^* \quad p_B = x_B p_B^* \quad (5.41)^\circ$$

where  $p_A^*$  is the vapour pressure of pure A and  $p_B^*$  that of pure B. The total vapour pressure  $p$  of the mixture is therefore

$$p = p_A + p_B = x_A p_A^* + x_B p_B^* = p_B^* + (p_A^* - p_B^*)x_A \quad (5.42)^\circ$$

This expression shows that the total vapour pressure (at some fixed temperature) changes linearly with the composition from  $p_B^*$  to  $p_A^*$  as  $x_A$  changes from 0 to 1 (Fig. 5.29).

#### (a) The composition of the vapour

The compositions of the liquid and vapour that are in mutual equilibrium are not necessarily the same. Common sense suggests that the vapour should be richer in the more volatile component. This expectation can be confirmed as follows. The partial pressures of the components are given by eqn 1.13. It follows from Dalton's law that the mole fractions in the gas,  $y_A$  and  $y_B$ , are

$$y_A = \frac{p_A}{p} \quad y_B = \frac{p_B}{p} \quad (5.43)$$

Provided the mixture is ideal, the partial pressures and the total pressure may be expressed in terms of the mole fractions in the liquid by using eqn 5.41 for  $p_i$  and eqn 5.42 for the total vapour pressure  $p$ , which gives

$$y_A = \frac{x_A p_A^*}{p_B^* + (p_A^* - p_B^*)x_A} \quad y_B = 1 - y_A \quad (5.44)^\circ$$

Figure 5.30 shows the composition of the vapour plotted against the composition of the liquid for various values of  $p_A^*/p_B^* > 1$ . We see that in all cases  $y_A > x_A$ , that is, the vapour is richer than the liquid in the more volatile component. Note that if B is non-volatile, so that  $p_B^* = 0$  at the temperature of interest, then it makes no contribution to the vapour ( $y_B = 0$ ).

**Fig. 5.30** The mole fraction of A in the vapour of a binary ideal solution expressed in terms of its mole fraction in the liquid, calculated using eqn 5.44 for various values of  $p_A^*/p_B^*$  (the label on each curve) with A more volatile than B. In all cases the vapour is richer than the liquid in A.

**InterActivity** To reproduce the results of Fig. 5.30, first rearrange eqn 5.44 so that  $y_A$  is expressed as a function of  $x_A$  and the ratio  $p_A^*/p_B^*$ . Then plot  $y_A$  against  $x_A$  for several values of  $p_A^*/p_B^* > 1$ .

**Fig. 5.31** The dependence of the vapour pressure of the same system as in Fig. 5.30, but expressed in terms of the mole fraction of A in the vapour by using eqn 5.45. Individual curves are labelled with the value of  $p_A^*/p_B^*$ .

**InterActivity** To reproduce the results of Fig. 5.31, first rearrange eqn 5.45 so that the ratio  $p_A/p_A^*$  is expressed as a function of  $y_A$  and the ratio  $p_A^*/p_B^*$ . Then plot  $p_A/p_A^*$  against  $y_A$  for several values of  $p_A^*/p_B^* > 1$ .

**Fig. 5.32** The dependence of the total vapour pressure of an ideal solution on the mole fraction of A in the entire system. A point between the two lines corresponds to both liquid and vapour being present; outside that region there is only one phase present. The mole fraction of A is denoted  $z_A$ , as explained below.

Equation 5.42 shows how the total vapour pressure of the mixture varies with the composition of the liquid. Because we can relate the composition of the liquid to the composition of the vapour through eqn 5.44, we can now also relate the total vapour pressure to the composition of the vapour:

$$p = \frac{p_A^* p_B^*}{p_A^* + (p_B^* - p_A^*) y_A} \quad (5.45)^\circ$$

This expression is plotted in Fig. 5.31.

### (b) The interpretation of the diagrams

If we are interested in distillation, both the vapour and the liquid compositions are of equal interest. It is therefore sensible to combine Figs. 5.29 and 5.31 into one (Fig. 5.32). The point *a* indicates the vapour pressure of a mixture of composition  $x_A$ , and the point *b* indicates the composition of the vapour that is in equilibrium with the liquid at that pressure. A richer interpretation of the phase diagram is obtained, however, if we interpret the horizontal axis as showing the *overall* composition,  $z_A$ , of the system. If the horizontal axis of the vapour pressure diagram is labelled with  $z_A$ , then all the points down to the solid diagonal line in the graph correspond to a system that is under such high pressure that it contains only a liquid phase (the applied pressure is higher than the vapour pressure), so  $z_A = x_A$ , the composition of the liquid. On the other hand, all points below the lower curve correspond to a system that is

**Fig. 5.33** The points of the pressure–composition diagram discussed in the text. The vertical line through  $a$  is an *isopleth*, a line of constant composition of the entire system.

**Fig. 5.34** (a) A liquid in a container exists in equilibrium with its vapour. The superimposed fragment of the phase diagram shows the compositions of the two phases and their abundances (by the lever rule). (b) When the pressure is changed by drawing out a piston, the compositions of the phases adjust as shown by the tie line in the phase diagram. (c) When the piston is pulled so far out that all the liquid has vaporized and only the vapour is present, the pressure falls as the piston is withdrawn and the point on the phase diagram moves into the one-phase region.

under such low pressure that it contains only a vapour phase (the applied pressure is lower than the vapour pressure), so  $z_A = y_A$ .

Points that lie between the two lines correspond to a system in which there are two phases present, one a liquid and the other a vapour. To see this interpretation, consider the effect of lowering the pressure on a liquid mixture of overall composition  $a$  in Fig. 5.33. The lowering of pressure can be achieved by drawing out a piston (Fig. 5.34). The changes to the system do not affect the overall composition, so the state of the system moves down the vertical line that passes through  $a$ . This vertical line is called an *isopleth*, from the Greek words for ‘equal abundance’. Until the point  $a_1$  is reached (when the pressure has been reduced to  $p_1$ ), the sample consists of a single liquid phase. At  $a_1$  the liquid can exist in equilibrium with its vapour. As we have seen, the composition of the vapour phase is given by point  $a'_1$ . A line joining two points representing phases in equilibrium is called a *tie line*. The composition of the liquid is the same as initially ( $a_1$  lies on the isopleth through  $a$ ), so we have to conclude that at this pressure there is virtually no vapour present; however, the tiny amount of vapour that is present has the composition  $a'_1$ .

Now consider the effect of lowering the pressure to  $p_2$ , so taking the system to a pressure and overall composition represented by the point  $a''_2$ . This new pressure is below the vapour pressure of the original liquid, so it vaporizes until the vapour pressure of the remaining liquid falls to  $p_2$ . Now we know that the composition of such a liquid must be  $a_2$ . Moreover, the composition of the vapour in equilibrium with that liquid must be given by the point  $a'_2$  at the other end of the tie line. If the pressure is reduced to  $p_3$ , a similar readjustment in composition takes place, and now the compositions of the liquid and vapour are represented by the points  $a_3$  and  $a'_3$ , respectively. The latter point corresponds to a system in which the composition of the vapour is the same as the overall composition, so we have to conclude that the amount of liquid present is now virtually zero, but the tiny amount of liquid present has the composition  $a_3$ . A further decrease in pressure takes the system to the point  $a_4$ ; at this stage, only vapour is present and its composition is the same as the initial overall composition of the system (the composition of the original liquid).

### (c) The lever rule

A point in the two-phase region of a phase diagram indicates not only qualitatively that both liquid and vapour are present, but represents quantitatively the relative amounts of each. To find the relative amounts of two phases  $\alpha$  and  $\beta$  that are in equilibrium, we measure the distances  $l_\alpha$  and  $l_\beta$  along the horizontal tie line, and then use the *lever rule* (Fig. 5.35):

$$n_\alpha l_\alpha = n_\beta l_\beta \quad \text{Lever rule} \quad (5.46)$$

Here  $n_\alpha$  is the amount of phase  $\alpha$  and  $n_\beta$  the amount of phase  $\beta$ . In the case illustrated in Fig. 5.35, because  $l_\beta \approx 2l_\alpha$ , the amount of phase  $\alpha$  is about twice the amount of phase  $\beta$ .

#### Justification 5.4 The lever rule

To prove the lever rule we write  $n = n_\alpha + n_\beta$  and the overall amount of A as  $nz_A$ . The overall amount of A is also the sum of its amounts in the two phases:

$$nz_A = n_\alpha x_A + n_\beta y_A$$

Since also

$$nz_A = n_\alpha z_A + n_\beta z_A$$

by equating these two expressions it follows that

$$n_{\alpha}(x_A - z_A) = n_{\beta}(z_A - y_A)$$

which corresponds to eqn 5.46.

### • A brief illustration

At  $p_1$  in Fig. 5.33, the ratio  $l_{\text{vap}}/l_{\text{liq}}$  is almost infinite for this tie line, so  $n_{\text{liq}}/n_{\text{vap}}$  is also almost infinite, and there is only a trace of vapour present. When the pressure is reduced to  $p_2$ , the value of  $l_{\text{vap}}/l_{\text{liq}}$  is about 0.5, so  $n_{\text{liq}}/n_{\text{vap}} \approx 0.5$  and the amount of liquid is about 0.5 times the amount of vapour. When the pressure has been reduced to  $p_3$ , the sample is almost completely gaseous and because  $l_{\text{vap}}/l_{\text{liq}} \approx 0$  we conclude that there is only a trace of liquid present. •

## 5.7 Temperature-composition diagrams

**Key points** (a) A phase diagram can be used to discuss the process of fractional distillation. (b) Depending on the relative strengths of the intermolecular forces, high- or low-boiling azeotropes may be formed. (c) The vapour pressure of a system composed of immiscible liquids is the sum of the vapour pressures of the pure liquids. (d) A phase diagram may be used to discuss the distillation of partially miscible liquids.

To discuss distillation we need a **temperature-composition diagram**, a phase diagram in which the boundaries show the composition of the phases that are in equilibrium at various temperatures (and a given pressure, typically 1 atm). An example is shown in Fig. 5.36. Note that the liquid phase now lies in the lower part of the diagram.

### (a) The distillation of mixtures

Consider what happens when a liquid of composition  $a_1$  in Fig. 5.36 is heated. It boils when the temperature reaches  $T_2$ . Then the liquid has composition  $a_2$  (the same as  $a_1$ ) and the vapour (which is present only as a trace) has composition  $a'_2$ . The vapour is richer in the more volatile component A (the component with the lower boiling point). From the location of  $a_2$ , we can state the vapour's composition at the boiling point, and from the location of the tie line joining  $a_2$  and  $a'_2$  we can read off the boiling temperature ( $T_2$ ) of the original liquid mixture.

In a **simple distillation**, the vapour is withdrawn and condensed. This technique is used to separate a volatile liquid from a non-volatile solute or solid. In **fractional distillation**, the boiling and condensation cycle is repeated successively. This technique is used to separate volatile liquids. We can follow the changes that occur by seeing what happens when the first condensate of composition  $a_3$  is reheated. The phase diagram shows that this mixture boils at  $T_3$  and yields a vapour of composition  $a'_3$ , which is even richer in the more volatile component. That vapour is drawn off, and the first drop condenses to a liquid of composition  $a_4$ . The cycle can then be repeated until in due course almost pure A is obtained in the vapour and pure B remains in the liquid.

The efficiency of a fractionating column is expressed in terms of the number of **theoretical plates**, the number of effective vaporization and condensation steps that are required to achieve a condensate of given composition from a given distillate. Thus, to achieve the degree of separation shown in Fig. 5.37a, the fractionating column must correspond to three theoretical plates. To achieve the same separation for the system shown in Fig. 5.37b, in which the components have more similar partial pressures, the fractionating column must be designed to correspond to five theoretical plates.

**Fig. 5.35** The lever rule. The distances  $l_{\alpha}$  and  $l_{\beta}$  are used to find the proportions of the amounts of phases  $\alpha$  (such as liquid) and  $\beta$  (for example, vapour) present at equilibrium. The lever rule is so called because a similar rule relates the masses at two ends of a lever to their distances from a pivot ( $m_{\alpha}l_{\alpha} = m_{\beta}l_{\beta}$  for balance).

**Fig. 5.36** The temperature-composition diagram corresponding to an ideal mixture with the component A more volatile than component B. Successive boilings and condensations of a liquid originally of composition  $a_1$  lead to a condensate that is pure A. The separation technique is called fractional distillation.

**Fig. 5.37** The number of theoretical plates is the number of steps needed to bring about a specified degree of separation of two components in a mixture. The two systems shown correspond to (a) 3, (b) 5 theoretical plates.

**Fig. 5.38** A high-boiling azeotrope. When the liquid of composition  $a$  is distilled, the composition of the remaining liquid changes towards  $b$  but no further.

### (b) Azeotropes

Although many liquids have temperature–composition phase diagrams resembling the ideal version in Fig. 5.36, in a number of important cases there are marked deviations. A maximum in the phase diagram (Fig. 5.38) may occur when the favourable interactions between A and B molecules reduce the vapour pressure of the mixture below the ideal value: in effect, the A–B interactions stabilize the liquid. In such cases the excess Gibbs energy,  $G^E$  (Section 5.4), is negative (more favourable to mixing than ideal). Examples of this behaviour include trichloromethane/propanone and nitric acid/water mixtures. Phase diagrams showing a minimum (Fig. 5.39) indicate that the mixture is destabilized relative to the ideal solution, the A–B interactions then being unfavourable. For such mixtures  $G^E$  is positive (less favourable to mixing than ideal), and there may be contributions from both enthalpy and entropy effects. Examples include dioxane/water and ethanol/water mixtures.

Deviations from ideality are not always so strong as to lead to a maximum or minimum in the phase diagram, but when they do there are important consequences for distillation. Consider a liquid of composition  $a$  on the right of the maximum in Fig. 5.38. The vapour (at  $a'_2$ ) of the boiling mixture (at  $a_2$ ) is richer in A. If that vapour is removed (and condensed elsewhere), then the remaining liquid will move to a composition that is richer in B, such as that represented by  $a_3$ , and the vapour in equilibrium with this mixture will have composition  $a'_3$ . As that vapour is removed, the composition of the boiling liquid shifts to a point such as  $a_4$ , and the composition of the vapour shifts to  $a'_4$ . Hence, as evaporation proceeds, the composition of the remaining liquid shifts towards B as A is drawn off. The boiling point of the liquid rises, and the vapour becomes richer in B. When so much A has been evaporated that the liquid has reached the composition  $b$ , the vapour has the same composition as the liquid. Evaporation then occurs without change of composition. The mixture is said to form an **azeotrope**.<sup>2</sup> When the azeotropic composition has been reached, distillation cannot separate the two liquids because the condensate has the same composition as the azeotropic liquid. One example of azeotrope formation is hydrochloric acid/water, which is azeotropic at 80 per cent by mass of water and boils unchanged at 108.6°C.

The system shown in Fig. 5.39 is also azeotropic, but shows its azeotropy in a different way. Suppose we start with a mixture of composition  $a_1$ , and follow the changes in the composition of the vapour that rises through a fractionating column (essentially a vertical glass tube packed with glass rings to give a large surface area). The mixture boils at  $a_2$  to give a vapour of composition  $a'_2$ . This vapour condenses in the column to a liquid of the same composition (now marked  $a_3$ ). That liquid reaches equilibrium with its vapour at  $a'_3$ , which condenses higher up the tube to give a liquid of the same composition, which we now call  $a_4$ . The fractionation therefore shifts the vapour towards the azeotropic composition at  $b$ , but not beyond, and the azeotropic vapour emerges from the top of the column. An example is ethanol/water, which boils unchanged when the water content is 4 per cent by mass and the temperature is 78°C.

### (c) Immiscible liquids

Finally we consider the distillation of two immiscible liquids, such as octane and water. At equilibrium, there is a tiny amount of A dissolved in B, and similarly a tiny amount of B dissolved in A: both liquids are saturated with the other component

<sup>2</sup> The name comes from the Greek words for 'boiling without changing'.

**Fig. 5.39** A low-boiling azeotrope. When the mixture at  $a$  is fractionally distilled, the vapour in equilibrium in the fractionating column moves towards  $b$  and then remains unchanged.

**Fig. 5.40** The distillation of (a) two immiscible liquids can be regarded as (b) the joint distillation of the separated components, and boiling occurs when the sum of the partial pressures equals the external pressure.

(Fig. 5.40a). As a result, the total vapour pressure of the mixture is close to  $p = p_A^* + p_B^*$ . If the temperature is raised to the value at which this total vapour pressure is equal to the atmospheric pressure, boiling commences and the dissolved substances are purged from their solution. However, this boiling results in a vigorous agitation of the mixture, so each component is kept saturated in the other component, and the purging continues as the very dilute solutions are replenished. This intimate contact is essential: two immiscible liquids heated in a container like that shown in Fig. 5.40b would not boil at the same temperature. The presence of the saturated solutions means that the ‘mixture’ boils at a lower temperature than either component would alone because boiling begins when the total vapour pressure reaches 1 atm, not when either vapour pressure reaches 1 atm. This distinction is the basis of **steam distillation**, which enables some heat-sensitive, water-insoluble organic compounds to be distilled at a lower temperature than their normal boiling point. The only snag is that the composition of the condensate is in proportion to the vapour pressures of the components, so oils of low volatility distil in low abundance.

## 5.8 Liquid–liquid phase diagrams

**Key points** (a) Phase separation of partially miscible liquids may occur when the temperature is below the upper critical solution temperature or above the lower critical solution temperature; the process may be discussed in terms of the model of a regular solution. (b) The upper critical solution temperature is the highest temperature at which phase separation occurs. The lower critical solution temperature is the temperature below which components mix in all proportions and above which they form two phases. (c) The outcome of a distillation of a low-boiling azeotrope depends on whether the liquids become fully miscible before they boil or boiling occurs before mixing is complete.

Now we consider temperature–composition diagrams for systems that consist of pairs of **partially miscible** liquids, which are liquids that do not mix in all proportions at all temperatures. An example is hexane and nitrobenzene. The same principles of interpretation apply as to liquid–vapour diagrams.

**Fig. 5.41** The temperature–composition diagram for hexane and nitrobenzene at 1 atm. The region below the curve corresponds to the compositions and temperatures at which the liquids are partially miscible. The upper critical temperature,  $T_{uc}$ , is the temperature above which the two liquids are miscible in all proportions.

**Fig. 5.42** The temperature–composition diagram for hexane and nitrobenzene at 1 atm again, with the points and lengths discussed in the text.

### (a) Phase separation

Suppose a small amount of a liquid B is added to a sample of another liquid A at a temperature  $T'$ . Liquid B dissolves completely, and the binary system remains a single phase. As more B is added, a stage comes at which no more dissolves. The sample now consists of two phases in equilibrium with each other, the most abundant one consisting of A saturated with B, the minor one a trace of B saturated with A. In the temperature–composition diagram drawn in Fig. 5.41, the composition of the former is represented by the point  $a'$  and that of the latter by the point  $a''$ . The relative abundances of the two phases are given by the lever rule. When more B is added, A dissolves in it slightly. The compositions of the two phases in equilibrium remain  $a'$  and  $a''$ . A stage is reached when so much B is present that it can dissolve all the A, and the system reverts to a single phase. The addition of more B now simply dilutes the solution, and from then on a single phase remains.

The composition of the two phases at equilibrium varies with the temperature. For hexane and nitrobenzene, raising the temperature increases their miscibility. The two-phase region therefore covers a narrower range of composition because each phase in equilibrium is richer in its minor component: the A-rich phase is richer in B and the B-rich phase is richer in A. We can construct the entire phase diagram by repeating the observations at different temperatures and drawing the envelope of the two-phase region.

#### Example 5.5 Interpreting a liquid–liquid phase diagram

A mixture of 50 g of hexane (0.58 mol  $C_6H_{14}$ ) and 50 g of nitrobenzene (0.41 mol  $C_6H_5NO_2$ ) was prepared at 290 K. What are the compositions of the phases, and in what proportions do they occur? To what temperature must the sample be heated in order to obtain a single phase?

**Method** The compositions of phases in equilibrium are given by the points where the tie line representing the temperature intersects the phase boundary. Their proportions are given by the lever rule (eqn 5.46). The temperature at which the components are completely miscible is found by following the isopleth upwards and noting the temperature at which it enters the one-phase region of the phase diagram.

**Answer** We denote hexane by H and nitrobenzene by N; refer to Fig. 5.42, which is a simplified version of Fig. 5.41. The point  $x_N = 0.41$ ,  $T = 290$  K occurs in the two-phase region of the phase diagram. The horizontal tie line cuts the phase boundary at  $x_N = 0.35$  and  $x_N = 0.83$ , so those are the compositions of the two phases. According to the lever rule, the ratio of amounts of each phase is equal to the ratio of the distances  $l_\alpha$  and  $l_\beta$ :

$$\frac{n_\alpha}{n_\beta} = \frac{l_\beta}{l_\alpha} = \frac{0.83 - 0.41}{0.41 - 0.35} = \frac{0.42}{0.06} = 7$$

That is, there is about 7 times more hexane-rich phase than nitrobenzene-rich phase. Heating the sample to 292 K takes it into the single-phase region. Because the phase diagram has been constructed experimentally, these conclusions are not based on any assumptions about ideality. They would be modified if the system were subjected to a different pressure.

**Self-test 5.7** Repeat the problem for 50 g of hexane and 100 g of nitrobenzene at 273 K.  
[ $x_N = 0.09$  and 0.95 in ratio 1:1.3; 294 K]

### (b) Critical solution temperatures

The **upper critical solution temperature**,  $T_{uc}$  (or *upper consolute temperature*), is the highest temperature at which phase separation occurs. Above the upper critical temperature the two components are fully miscible. This temperature exists because the greater thermal motion overcomes any potential energy advantage in molecules of one type being close together. One example is the nitrobenzene/hexane system shown in Fig. 5.41. An example of a solid solution is the palladium/hydrogen system, which shows two phases, one a solid solution of hydrogen in palladium and the other a palladium hydride, up to 300°C but forms a single phase at higher temperatures (Fig. 5.43).

The thermodynamic interpretation of the upper critical solution temperature focuses on the Gibbs energy of mixing and its variation with temperature. We saw in Section 5.4 that a simple model of a real solution results in a Gibbs energy of mixing that behaves as shown in Fig. 5.44. Provided the parameter  $\xi$  that was introduced in eqn 5.28 is greater than 2, the Gibbs energy of mixing has a double minimum. As a result, for  $\xi > 2$  we can expect phase separation to occur. The same model shows that the compositions corresponding to the minima are obtained by looking for the conditions at which  $\partial\Delta_{\text{mix}}G/\partial x = 0$ , and a simple manipulation of eqn 5.29 shows that we have to solve

$$\ln \frac{x}{1-x} + \xi(1-2x) = 0 \quad (5.47)$$

The solutions are plotted in Fig. 5.45. We see that, as  $\xi$  decreases, which can be interpreted as an increase in temperature provided the intermolecular forces remain constant, the two minima move together and merge when  $\xi = 2$ .

Some systems show a **lower critical solution temperature**,  $T_{lc}$  (or *lower consolute temperature*), below which they mix in all proportions and above which they form two phases. An example is water and triethylamine (Fig. 5.46). In this case, at low temperatures the two components are more miscible because they form a weak complex; at higher temperatures the complexes break up and the two components are less miscible.

Some systems have both upper and lower critical solution temperatures. They occur because, after the weak complexes have been disrupted, leading to partial miscibility, the thermal motion at higher temperatures homogenizes the mixture again, just as in the case of ordinary partially miscible liquids. The most famous example is nicotine and water, which are partially miscible between 61°C and 210°C (Fig. 5.47).

### (c) The distillation of partially miscible liquids

Consider a pair of liquids that are partially miscible and form a low-boiling azeotrope. This combination is quite common because both properties reflect the tendency of the two kinds of molecule to avoid each other. There are two possibilities: one in which the liquids become fully miscible before they boil; the other in which boiling occurs before mixing is complete.

Figure 5.48 shows the phase diagram for two components that become fully miscible before they boil. Distillation of a mixture of composition  $a_1$  leads to a vapour of composition  $b_1$ , which condenses to the completely miscible single-phase solution at  $b_2$ . Phase separation occurs only when this distillate is cooled to a point in the two-phase liquid region, such as  $b_3$ . This description applies only to the first drop of distillate. If distillation continues, the composition of the remaining liquid changes. In the end, when the whole sample has evaporated and condensed, the composition is back to  $a_1$ .

**Fig. 5.43** The phase diagram for palladium and palladium hydride, which has an upper critical temperature at 300°C.

#### A brief comment

Equation 5.47 is an example of a *transcendental equation*, an equation that does not have a solution that can be expressed in a closed form. The solutions can be found numerically by using mathematical software or by plotting the first term against the second and identifying the points of intersection as  $\xi$  is changed.

**Fig. 5.44** The temperature variation of the Gibbs energy of mixing of a system that is partially miscible at low temperatures. A system of composition in the region  $P = 2$  forms two phases with compositions corresponding to the two local minima of the curve. This illustration is a duplicate of Fig. 5.19.

**interActivity** Working from eqn 5.29, write an expression for  $T_{\min}$ , the temperature at which  $\Delta_{\text{mix}}G$  has a minimum, as a function of  $\xi$  and  $x_A$ . Then, plot  $T_{\min}$  against  $x_A$  for several values of  $\xi$ . Provide a physical interpretation for any maxima or minima that you observe in these plots.

**Fig. 5.45** The location of the phase boundary as computed on the basis of the  $\xi$ -parameter model introduced in Section 5.4a.

**interActivity** Using mathematical software or an electronic spreadsheet, generate the plot of  $\xi$  against  $x_A$  by one of two methods: (a) solve the transcendental equation  $\ln\{x/(1-x)\} + \xi(1-2x) = 0$  numerically, or (b) plot the first term of the transcendental equation against the second and identify the points of intersection as  $\xi$  is changed.

**Fig. 5.46** The temperature–composition diagram for water and triethylamine. This system shows a lower critical temperature at 292 K. The labels indicate the interpretation of the boundaries.

**Fig. 5.47** The temperature–composition diagram for water and nicotine, which has both upper and lower critical temperatures. Note the high temperatures for the liquid (especially the water): the diagram corresponds to a sample under pressure.

**Fig. 5.48** The temperature–composition diagram for a binary system in which the upper critical temperature is less than the boiling point at all compositions. The mixture forms a low-boiling azeotrope.

Figure 5.49 shows the second possibility, in which there is no upper critical solution temperature. The distillate obtained from a liquid initially of composition  $a_1$  has composition  $b_3$  and is a two-phase mixture. One phase has composition  $b'_3$  and the other has composition  $b''_3$ .

The behaviour of a system of composition represented by the isopleth  $e$  in Fig. 5.49 is interesting. A system at  $e_1$  forms two phases, which persist (but with changing proportions) up to the boiling point at  $e_2$ . The vapour of this mixture has the same composition as the liquid (the liquid is an azeotrope). Similarly, condensing a vapour of composition  $e_3$  gives a two-phase liquid of the same overall composition. At a fixed temperature, the mixture vaporizes and condenses like a single substance.

#### Example 5.6 Interpreting a phase diagram

State the changes that occur when a mixture of composition  $x_B = 0.95$  ( $a_1$ ) in Fig. 5.50 is boiled and the vapour condensed.

**Method** The area in which the point lies gives the number of phases; the compositions of the phases are given by the points at the intersections of the horizontal tie line with the phase boundaries; the relative abundances are given by the lever rule.

**Answer** The initial point is in the one-phase region. When heated it boils at 350 K ( $a_2$ ) giving a vapour of composition  $x_B = 0.56$  ( $b_1$ ). The liquid gets richer in B, and the last drop (of pure B) evaporates at 390 K. The boiling range of the liquid is therefore 350 to 390 K. If the initial vapour is drawn off, it has a composition  $x_B = 0.56$ . This composition would be maintained if the sample were very large, but for a finite sample it shifts to higher values and ultimately to  $x_B = 0.95$ . Cooling the distillate corresponds to moving down the  $x_B = 0.56$  isopleth. At 330 K, for instance, the liquid phase has composition  $x_B = 0.87$ , the vapour  $x_B = 0.49$ ; their relative proportions are 1:4:4. At 320 K the sample consists of three phases: the vapour and two liquids. One liquid phase has composition  $x_B = 0.30$ ; the other has composition  $x_B = 0.80$  in the ratio 0.92:1. Further cooling moves the system into the two-phase region, and at 298 K the compositions are 0.20 and 0.90 in the ratio 0.94:1. As further distillate boils over, the overall composition of the distillate becomes richer in B. When the last drop has been condensed the phase composition is the same as at the beginning.

**Self-test 5.8** Repeat the discussion, beginning at the point  $x_B = 0.4$ ,  $T = 298$  K.

Fig. 5.49 The temperature–composition diagram for a binary system in which boiling occurs before the two liquids are fully miscible.

Fig. 5.50 The points of the phase diagram in Fig. 5.49 that are discussed in Example 5.6.

## 5.9 Liquid–solid phase diagrams

**Key points** (a) A phase diagram summarizes the temperature–composition properties of a binary system with solid and liquid phases; at the eutectic composition the liquid phase solidifies without change of composition. (b) The phase equilibria of binary systems in which the components react may also be summarized by a phase diagram. (c) In some cases, a solid compound does not survive melting.

Knowledge of the temperature–composition diagrams for solid mixtures guides the design of important industrial processes, such as the manufacture of liquid crystal displays and semiconductors. In this section, we shall consider systems where solid and liquid phases may both be present at temperatures below the boiling point.

**Fig. 5.51** The temperature–composition phase diagram for two almost immiscible solids and their completely miscible liquids. Note the similarity to Fig. 5.49. The isopleth through  $e$  corresponds to the eutectic composition, the mixture with lowest melting point.

**Fig. 5.52** The cooling curves for the system shown in Fig. 5.51. For isopleth  $a$ , the rate of cooling slows at  $a_2$  because solid B deposits from solution. There is a complete halt at  $a_4$  while the eutectic solidifies. This halt is longest for the eutectic isopleth,  $e$ . The eutectic halt shortens again for compositions beyond  $e$  (richer in A). Cooling curves are used to construct the phase diagram.

### (a) Eutectics

Consider the two-component liquid of composition  $a_1$  in Fig. 5.51. The changes that occur as the system is cooled may be expressed as follows.

1.  $a_1 \rightarrow a_2$ . The system enters the two-phase region labelled ‘Liquid + B’. Pure solid B begins to come out of solution and the remaining liquid becomes richer in A.
2.  $a_2 \rightarrow a_3$ . More of the solid B forms, and the relative amounts of the solid and liquid (which are in equilibrium) are given by the lever rule. At this stage there are roughly equal amounts of each. The liquid phase is richer in A than before (its composition is given by  $b_3$ ) because some B has been deposited.
3.  $a_3 \rightarrow a_4$ . At the end of this step, there is less liquid than at  $a_3$ , and its composition is given by  $e_2$ . This liquid now freezes to give a two-phase system of pure B and pure A.

The isopleth at  $e_2$  in Fig. 5.51 corresponds to the **eutectic** composition, the mixture with the lowest melting point.<sup>3</sup> A liquid with the eutectic composition freezes at a single temperature, without previously depositing solid A or B. A solid with the eutectic composition melts, without change of composition, at the lowest temperature of any mixture. Solutions of composition to the right of  $e_2$  deposit B as they cool, and solutions to the left deposit A: only the eutectic mixture (apart from pure A or pure B) solidifies at a single definite temperature without gradually unloading one or other of the components from the liquid.

One technologically important eutectic is solder, which in one form has mass composition of about 67 per cent tin and 33 per cent lead and melts at 183°C. The eutectic formed by 23 per cent NaCl and 77 per cent H<sub>2</sub>O by mass melts at –21.1°C. When salt is added to ice under isothermal conditions (for example, when spread on an icy road) the mixture melts if the temperature is above –21.1°C (and the eutectic composition has been achieved). When salt is added to ice under adiabatic conditions (for example, when added to ice in a vacuum flask) the ice melts, but in doing so it absorbs heat from the rest of the mixture. The temperature of the system falls and, if enough salt is added, cooling continues down to the eutectic temperature. Eutectic formation occurs in the great majority of binary alloy systems, and is of great importance for the microstructure of solid materials. Although a eutectic solid is a two-phase system, it crystallizes out in a nearly homogeneous mixture of microcrystals. The two microcrystalline phases can be distinguished by microscopy and structural techniques such as X-ray diffraction (Chapter 19).

Thermal analysis is a very useful practical way of detecting eutectics. We can see how it is used by considering the rate of cooling down the isopleth through  $a_1$  in Fig. 5.51. The liquid cools steadily until it reaches  $a_2$ , when B begins to be deposited (Fig. 5.52). Cooling is now slower because the solidification of B is exothermic and retards the cooling. When the remaining liquid reaches the eutectic composition, the temperature remains constant until the whole sample has solidified: this region of constant temperature is the **eutectic halt**. If the liquid has the eutectic composition  $e$  initially, the liquid cools steadily down to the freezing temperature of the eutectic, when there is a long **eutectic halt** as the entire sample solidifies (like the freezing of a pure liquid).

Monitoring the cooling curves at different overall compositions gives a clear indication of the structure of the phase diagram. The solid–liquid boundary is given by the points at which the rate of cooling changes. The longest eutectic halt gives the location of the eutectic composition and its melting temperature.

<sup>3</sup> The name comes from the Greek words for ‘easily melted’.

**(b) Reacting systems**

Many binary mixtures react to produce compounds, and technologically important examples of this behaviour include the Group 13/15 (III/V) semiconductors, such as the gallium arsenide system, which forms the compound GaAs. Although three constituents are present, there are only two components because GaAs is formed from the reaction  $\text{Ga} + \text{As} \rightleftharpoons \text{GaAs}$ . We shall illustrate some of the principles involved with a system that forms a compound C that also forms eutectic mixtures with the species A and B (Fig. 5.53).

A system prepared by mixing an excess of B with A consists of C and unreacted B. This is a binary B, C system, which we suppose forms a eutectic. The principal change from the eutectic phase diagram in Fig. 5.51 is that the whole of the phase diagram is squeezed into the range of compositions lying between equal amounts of A and B ( $x_B = 0.5$ , marked C in Fig. 5.53) and pure B. The interpretation of the information in the diagram is obtained in the same way as for Fig. 5.51. The solid deposited on cooling along the isopleth  $a$  is the compound C. At temperatures below  $a_4$  there are two solid phases, one consisting of C and the other of B. The pure compound C melts **congruently**, that is, the composition of the liquid it forms is the same as that of the solid compound.

**(c) Incongruent melting**

In some cases the compound C is not stable as a liquid. An example is the alloy  $\text{Na}_2\text{K}$ , which survives only as a solid (Fig. 5.54). Consider what happens as a liquid at  $a_1$  is cooled:

1.  $a_1 \rightarrow a_2$ . A solid solution rich in Na is deposited, and the remaining liquid is richer in K.
2.  $a_2 \rightarrow$  just below  $a_3$ . The sample is now entirely solid and consists of a solid solution rich in Na and solid  $\text{Na}_2\text{K}$ .

Now consider the isopleth through  $b_1$ :

1.  $b_1 \rightarrow b_2$ . No obvious change occurs until the phase boundary is reached at  $b_2$  when a solid solution rich in Na begins to deposit.
2.  $b_2 \rightarrow b_3$ . A solid solution rich in Na deposits, but at  $b_3$  a reaction occurs to form  $\text{Na}_2\text{K}$ : this compound is formed by the K atoms diffusing into the solid Na.
3.  $b_3$ . At  $b_3$ , three phases are in mutual equilibrium: the liquid, the compound  $\text{Na}_2\text{K}$ , and a solid solution rich in Na. The horizontal line representing this three-phase equilibrium is called a **peritectic line**.

**Fig. 5.53** The phase diagram for a system in which A and B react to form a compound  $C = AB$ . This resembles two versions of Fig. 5.51 in each half of the diagram. The constituent C is a true compound, not just an equimolar mixture.

**Fig. 5.54** The phase diagram for an actual system (sodium and potassium) like that shown in Fig. 5.53, but with two differences. One is that the compound is  $\text{Na}_2\text{K}$ , corresponding to  $\text{A}_2\text{B}$  and not AB as in that illustration. The second is that the compound exists only as the solid, not as the liquid. The transformation of the compound at its melting point is an example of incongruent melting.

At this stage the liquid Na/K mixture is in equilibrium with a little solid  $\text{Na}_2\text{K}$ , but there is still no liquid compound.

4.  $b_3 \rightarrow b_4$ . As cooling continues, the amount of solid compound increases until at  $b_4$  the liquid reaches its eutectic composition. It then solidifies to give a two-phase solid consisting of a solid solution rich in K and solid  $\text{Na}_2\text{K}$ .

If the solid is reheated, the sequence of events is reversed. No liquid  $\text{Na}_2\text{K}$  forms at any stage because it is too unstable to exist as a liquid. This behaviour is an example of **incongruent melting**, in which a compound melts into its components and does not itself form a liquid phase.

#### IMPACT ON MATERIALS SCIENCE

##### 15.2 Liquid crystals

A *mesophase* is a phase intermediate between solid and liquid. Mesophases are of great importance in biology, for they occur as lipid bilayers and in vesicular systems. A mesophase may arise when molecules have highly non-spherical shapes, such as being long and thin (1), or disc-like (2). When the solid melts, some aspects of the long-range order characteristic of the solid may be retained, and the new phase may be a *liquid crystal*, a substance having liquid-like imperfect long-range order in at least one direction in space but positional or orientational order in at least one other direction. *Calamitic liquid crystals* (from the Greek word for reed) are made from long and thin molecules, whereas *discotic liquid crystals* are made from disc-like molecules. A *thermotropic* liquid crystal displays a transition to the liquid crystalline phase as the temperature is changed. A *lyotropic* liquid crystal is a solution that undergoes a transition to the liquid crystalline phase as the composition is changed.

One type of retained long-range order gives rise to a *smectic phase* (from the Greek word for soapy), in which the molecules align themselves in layers (Fig. 5.55). Other materials, and some smectic liquid crystals at higher temperatures, lack the layered structure but retain a parallel alignment; this mesophase is called a *nematic phase* (from the Greek for thread, which refers to the observed defect structure of the phase). In the *cholesteric phase* (from the Greek for bile solid) the molecules lie in sheets at angles that change slightly between each sheet. That is, they form helical structures

**Fig. 5.55** The arrangement of molecules in (a) the nematic phase, (b) the smectic phase, and (c) the cholesteric phase of liquid crystals. In the cholesteric phase, the stacking of layers continues to give a helical arrangement of molecules.

**Fig. 5.56** The pressure–temperature diagram of octylcyanobiphenyl (8CB). (Based on R. Shashidhar and G. Venkatesh, *J. de Physique Colloque*, **40**, C3 (1979).)

with a pitch that depends on the temperature. As a result, cholesteric liquid crystals diffract light and have colours that depend on the temperature. Disc-like molecules such as (2) can form nematic and *columnar* mesophases. In the latter, the aromatic rings stack one on top of the other and are separated by very small distances (less than 0.5 nm). Figure 5.56 shows the pressure–temperature phase diagram of octylcyanobiphenyl, which is widely used in liquid crystal displays.

The optical properties of nematic liquid crystals are anisotropic, meaning that they depend on the relative orientation of the molecular assemblies with respect to the polarization of the incident beam of light. Nematic liquid crystals also respond in special ways to electric fields. Together, these unique optical and electrical properties form the basis of operation of liquid crystal displays (LCDs). In a ‘twisted nematic’ LCD, the liquid crystal is held between two flat plates about 10 mm apart. The inner surface of each plate is coated with a transparent conducting material, such as indium–tin oxide. The plates also have a surface that causes the liquid crystal to adopt a particular orientation at its interface and are typically set at 90° to each other but 270° in a ‘supertwist’ arrangement. The entire assembly is set between two polarizers, optical filters that allow light of only one specific plane of polarization to pass. The incident light passes through the outer polarizer, then its plane of polarization is rotated as it passes through the twisted nematic, and, depending on the setting of the second polarizer, will pass through (if that is how the second polarizer is arranged). When a potential difference is applied across the cell, the helical arrangement is lost and the plane of the light is no longer rotated and will be blocked by the second polarizer.

Although there are many liquid crystalline materials, some difficulty is often experienced in achieving a technologically useful temperature range for the existence of the mesophase. To overcome this difficulty, mixtures can be used. An example of the type of phase diagram that is then obtained is shown in Fig. 5.57. As can be seen, the mesophase exists over a wider range of temperatures than either liquid crystalline material alone.

**Fig. 5.57** The phase diagram at 1 atm for a binary system of two liquid crystalline materials, octylcyanobiphenyl (8CB) and octyloxycyanobiphenyl (8OCB). (Based on P. Rushikesh, A. Matkar, and T. Kyua, *J. Chem. Phys.*, 124, 224902 (2006).)

## Activities

Now we see how to adjust the expressions developed earlier in the chapter to take into account deviations from ideal behavior that we have encountered during the discussion of phase diagrams. In Chapter 3 (specifically, *Further information 3.2*) we remarked that a quantity called ‘fugacity’ takes into account the effects of gas imperfections in a manner that resulted in the least upset of the form of equations. Here we see how the expressions encountered in the treatment of ideal solutions can also be preserved almost intact by introducing the concept of ‘activity’. It is important to be aware of the different definitions of standard states and activities, and they are summarized in Table 5.3. We shall put them to work in the next few chapters, when we shall see that using them is much easier than defining them.

### 5.10 The solvent activity

**Key point** The activity is an effective concentration that preserves the form of the expression for the chemical potential.

The general form of the chemical potential of a real or ideal solvent is given by a straightforward modification of eqn 5.20 (that  $\mu_A = \mu_A^* + RT \ln(p_A/p_A^*)$ , where  $p_A^*$  is the vapour pressure of pure A and  $p_A$  is the vapour pressure of A when it is a

**Table 5.3** Standard states

| Component       | Basis  | Standard state                                                 | Activity                  | Limits                                                     |
|-----------------|--------|----------------------------------------------------------------|---------------------------|------------------------------------------------------------|
| Solid or liquid |        | Pure                                                           | $a = 1$                   |                                                            |
| Solvent         | Raoult | Pure solvent                                                   | $a = p/p^*, a = \gamma x$ | $\gamma \rightarrow 1$ as $x \rightarrow 1$ (pure solvent) |
| Solute          | Henry  | (1) A hypothetical state of the pure solute                    | $a = p/K, a = \gamma x$   | $\gamma \rightarrow 1$ as $x \rightarrow 0$                |
|                 |        | (2) A hypothetical state of the solute at molality $b^\ominus$ | $a = \gamma b/b^\ominus$  | $\gamma \rightarrow 1$ as $b \rightarrow 0$                |

In each case,  $\mu = \mu^\ominus + RT \ln a$ .

component of a solution. For an ideal solution, as we have seen, the solvent obeys Raoult's law at all concentrations and we can express this relation as eqn 5.22 (that is, as  $\mu_A = \mu_A^* + RT \ln x_A$ ). The form of this relation can be preserved when the solution does not obey Raoult's law by writing

$$\mu_A = \mu_A^* + RT \ln a_A \quad \text{Definition of activity of solvent} \quad (5.48)$$

The quantity  $a_A$  is the **activity** of A, a kind of 'effective' mole fraction, just as the fugacity is an effective pressure.

Because eqn 5.20 is true for both real and ideal solutions (the only approximation being the use of pressures rather than fugacities), we can conclude by comparing it with eqn 5.48 that

$$a_A = \frac{p_A}{p_A^*} \quad \text{Procedure for determining activity of solvent} \quad (5.49)$$

We see that there is nothing mysterious about the activity of a solvent: it can be determined experimentally simply by measuring the vapour pressure and then using eqn 5.49.

#### • A brief illustration

The vapour pressure of 0.500 M  $\text{KNO}_3(\text{aq})$  at  $100^\circ\text{C}$  is 99.95 kPa, so the activity of water in the solution at this temperature is

$$a_A = \frac{99.95 \text{ kPa}}{101.325 \text{ kPa}} = 0.9864 \quad \bullet$$

Because all solvents obey Raoult's law (that  $p_A/p_A^* = x_A$ ) more closely as the concentration of solute approaches zero, the activity of the solvent approaches the mole fraction as  $x_A \rightarrow 1$ :

$$a_A \rightarrow x_A \quad \text{as} \quad x_A \rightarrow 1 \quad (5.50)$$

A convenient way of expressing this convergence is to introduce the **activity coefficient**,  $\gamma$  (gamma), by the definition

$$a_A = \gamma_A x_A \quad \gamma_A \rightarrow 1 \quad \text{as} \quad x_A \rightarrow 1 \quad \text{Definition of activity coefficient of solvent} \quad [5.51]$$

at all temperatures and pressures. The chemical potential of the solvent is then

$$\mu_A = \mu_A^* + RT \ln x_A + RT \ln \gamma_A \quad (5.52)$$

The standard state of the solvent, the pure liquid solvent at 1 bar, is established when  $x_A = 1$ .

## 5.11 The solute activity

**Key points** (a) The chemical potential of a solute in an ideal-dilute solution is defined on the basis of Henry's law. (b) The activity of a solute takes into account departures from Henry's law behavior. (c) An alternative approach to the definition of the solute activity is based on the molality of the solute. (d) The biological standard state of a species in solution is defined as  $\text{pH} = 7$  (and 1 bar).

The problem with defining activity coefficients and standard states for solutes is that they approach ideal-dilute (Henry's law) behaviour as  $x_B \rightarrow 0$ , not as  $x_B \rightarrow 1$  (corresponding to pure solute). We shall show how to set up the definitions for a solute that obeys Henry's law exactly, and then show how to allow for deviations.

**(a) Ideal-dilute solutions**

A solute B that satisfies Henry's law has a vapour pressure given by  $p_B = K_B x_B$ , where  $K_B$  is an empirical constant. In this case, the chemical potential of B is

$$\mu_B = \mu_B^* + RT \ln \frac{p_B}{p_B^*} = \mu_B^* + RT \ln \frac{K_B}{p_B^*} + RT \ln x_B \quad (5.53)^\circ$$

Both  $K_B$  and  $p_B^*$  are characteristics of the solute, so the second term may be combined with the first to give a new standard chemical potential:

$$\mu_B^\ominus = \mu_B^* + RT \ln \frac{K_B}{p_B^*} \quad [5.54]^\circ$$

It then follows that the chemical potential of a solute in an ideal-dilute solution is related to its mole fraction by

$$\mu_B = \mu_B^\ominus + RT \ln x_B \quad (5.55)^\circ$$

If the solution is ideal,  $K_B = p_B^*$  and eqn 5.54 reduces to  $\mu_B^\ominus = \mu_B^*$ , as we should expect.

**(b) Real solutes**

We now permit deviations from ideal-dilute, Henry's law behaviour. For the solute, we introduce  $a_B$  in place of  $x_B$  in eqn 5.55, and obtain

$$\mu_B = \mu_B^\ominus + RT \ln a_B \quad \text{Definition of activity of solute} \quad [5.56]$$

The standard state remains unchanged in this last stage, and all the deviations from ideality are captured in the activity  $a_B$ . The value of the activity at any concentration can be obtained in the same way as for the solvent, but in place of eqn 5.49 we use

$$a_B = \frac{p_B}{K_B} \quad \text{Procedure for determining activity of solute} \quad (5.57)$$

As we did for the solvent, it is sensible to introduce an activity coefficient through

$$a_B = \gamma_B x_B \quad \text{Definition of activity coefficient of solute} \quad [5.58]$$

Now all the deviations from ideality are captured in the activity coefficient  $\gamma_B$ . Because the solute obeys Henry's law as its concentration goes to zero, it follows that

$$a_B \rightarrow x_B \quad \text{and} \quad \gamma_B \rightarrow 1 \quad \text{as} \quad x_B \rightarrow 0 \quad (5.59)$$

at all temperatures and pressures. Deviations of the solute from ideality disappear as zero concentration is approached.

**Example 5.7** *Measuring activity*

Use the information in Example 5.3 to calculate the activity and activity coefficient of chloroform in acetone at 25°C, treating it first as a solvent and then as a solute. For convenience, the data are repeated here:

|                  |      |      |      |      |      |      |
|------------------|------|------|------|------|------|------|
| $x_C$            | 0    | 0.20 | 0.40 | 0.60 | 0.80 | 1    |
| $p_C/\text{kPa}$ | 0    | 4.7  | 11   | 18.9 | 26.7 | 36.4 |
| $p_A/\text{kPa}$ | 46.3 | 33.3 | 23.3 | 12.3 | 4.9  | 0    |

**Method** For the activity of chloroform as a solvent (the Raoult's law activity), form  $a_C = p_C/p_C^*$  and  $\gamma_C = a_C/x_C$ . For its activity as a solute (the Henry's law activity), form  $a_C = p_C/K_C$  and  $\gamma_C = a_C/x_C$ .

**Answer** Because  $p_C^* = 36.4$  kPa and  $K_C = 22.0$  kPa, we can construct the following tables. For instance, at  $x_C = 0.20$ , in the Raoult's law case we find  $a_C = (4.7 \text{ kPa})/(36.4 \text{ kPa}) = 0.13$  and  $\gamma_C = 0.13/0.20 = 0.65$ ; likewise, in the Henry's law case,  $a_C = (4.7 \text{ kPa})/(22.0 \text{ kPa}) = 0.21$  and  $\gamma_C = 0.21/0.20 = 1.05$ .

From Raoult's law (chloroform regarded as the solvent):

|            |   |      |      |      |      |      |
|------------|---|------|------|------|------|------|
| $a_C$      | 0 | 0.13 | 0.30 | 0.52 | 0.73 | 1.00 |
| $\gamma_C$ |   | 0.65 | 0.75 | 0.87 | 0.91 | 1.00 |

From Henry's law (chloroform regarded as the solute):

|            |   |      |      |      |      |      |
|------------|---|------|------|------|------|------|
| $a_C$      | 0 | 0.21 | 0.50 | 0.86 | 1.21 | 1.65 |
| $\gamma_C$ | 1 | 1.05 | 1.25 | 1.43 | 1.51 | 1.65 |

These values are plotted in Fig. 5.58. Notice that  $\gamma_C \rightarrow 1$  as  $x_C \rightarrow 1$  in the Raoult's law case, but that  $\gamma_C \rightarrow 1$  as  $x_C \rightarrow 0$  in the Henry's law case.

**Self-test 5.9** Calculate the activities and activity coefficients for acetone according to the two conventions.

[At  $x_A = 0.60$ , for instance  $a_R = 0.50$ ;  $\gamma_R = 0.83$ ;  $a_H = 1.00$ ,  $\gamma_H = 1.67$ ]

### (c) Activities in terms of molalities

The selection of a standard state is entirely arbitrary, so we are free to choose one that best suits our purpose and the description of the composition of the system. In chemistry, compositions are often expressed as molalities,  $b$ , in place of mole fractions. It therefore proves convenient to write

$$\mu_B = \mu_B^\ominus + RT \ln b_B \quad \{5.60\}$$

Where  $\mu^\ominus$  has a different value from the standard values introduced earlier. According to this definition, the chemical potential of the solute has its standard value  $\mu^\ominus$  when the molality of B is equal to  $b^\ominus$  (that is, at  $1 \text{ mol kg}^{-1}$ ). Note that as  $b_B \rightarrow 0$ ,  $\mu_B \rightarrow \infty$ ; that is, as the solution becomes diluted, so the solute becomes increasingly stabilized. The practical consequence of this result is that it is very difficult to remove the last traces of a solute from a solution.

Now, as before, we incorporate deviations from ideality by introducing a dimensionless activity  $a_B$ , a dimensionless activity coefficient  $\gamma_B$ , and writing

$$a_B = \gamma_B \frac{b_B}{b^\ominus} \quad \text{where} \quad \gamma_B \rightarrow 1 \quad \text{as} \quad b_B \rightarrow 0 \quad [5.61]$$

at all temperatures and pressures. The standard state remains unchanged in this last stage and, as before, all the deviations from ideality are captured in the activity coefficient  $\gamma_B$ . We then arrive at the following succinct expression for the chemical potential of a real solute at any molality:

$$\mu = \mu^\ominus + RT \ln a \quad (5.62)$$

### (d) The biological standard state

One important illustration of the ability to choose a standard state to suit the circumstances arises in biological applications. The conventional standard state of hydrogen

**Fig. 5.58** The variation of activity and activity coefficient of chloroform (trichloromethane) with composition according to (a) Raoult's law, (b) Henry's law.

ions (unit activity, corresponding to  $\text{pH} = 0$ )<sup>4</sup> is not appropriate to normal biological conditions. Therefore, in biochemistry it is common to adopt the **biological standard state**, in which  $\text{pH} = 7$  (an activity of  $10^{-7}$ , neutral solution) and to label the corresponding standard thermodynamic functions as  $G^\oplus$ ,  $H^\oplus$ ,  $\mu^\oplus$ , and  $S^\oplus$  (some texts use  $X^\circ$ ).

To find the relation between the thermodynamic and biological standard values of the chemical potential of hydrogen ions we need to note from eqn 5.62 that

$$\mu(\text{H}^+) = \mu^\circ(\text{H}^+) + RT \ln a(\text{H}^+) = \mu^\circ(\text{H}^+) - (RT \ln 10) \times \text{pH}$$

It follows that

$$\mu^\oplus(\text{H}^+) = \mu^\circ(\text{H}^+) - 7RT \ln 10 \quad \text{Relation between standard state and biological standard state} \quad (5.63)$$

At 298 K,  $7RT \ln 10 = 39.96 \text{ kJ mol}^{-1}$ , so the two standard values differ by about 40  $\text{kJ mol}^{-1}$ .

## 5.12 The activities of regular solutions

**Key point** The Margules equations relate the activities of the components of a model regular solution to its composition. They lead to expressions for the vapour pressures of the components of a regular solution.

The material on regular solutions presented in Section 5.4 gives further insight into the origin of deviations from Raoult's law and its relation to activity coefficients. The starting point is the expression for the Gibbs energy of mixing for a regular solution (eqn 5.29). We show in the following *Justification* that eqn 5.29 implies that the activity coefficients are given by expressions of the form

$$\ln \gamma_A = \xi x_B^2 \quad \ln \gamma_B = \xi x_A^2 \quad \text{Margules equations} \quad (5.64)$$

These relations are called the **Margules equations**.

### Justification 5.5 The Margules equations

The Gibbs energy of mixing to form a nonideal solution is

$$\Delta_{\text{mix}} G = nRT \{x_A \ln a_A + x_B \ln a_B\}$$

This relation follows from the derivation of eqn 5.16 with activities in place of mole fractions. If each activity is replaced by  $\gamma x$ , this expression becomes

$$\Delta_{\text{mix}} G = nRT \{x_A \ln x_A + x_B \ln x_B + x_A \ln \gamma_A + x_B \ln \gamma_B\}$$

Now we introduce the two expressions in eqn 5.64, and use  $x_A + x_B = 1$ , which gives

$$\begin{aligned} \Delta_{\text{mix}} G &= nRT \{x_A \ln x_A + x_B \ln x_B + \xi x_A x_B^2 + \xi x_B x_A^2\} \\ &= nRT \{x_A \ln x_A + x_B \ln x_B + \xi x_A x_B (x_A + x_B)\} \\ &= nRT \{x_A \ln x_A + x_B \ln x_B + \xi x_A x_B\} \end{aligned}$$

as required by eqn 5.29. Note, moreover, that the activity coefficients behave correctly for dilute solutions:  $\gamma_A \rightarrow 1$  as  $x_B \rightarrow 0$  and  $\gamma_B \rightarrow 1$  as  $x_A \rightarrow 0$ .

At this point we can use the Margules equations to write the activity of A as

$$a_A = \gamma_A x_A = x_A e^{\xi x_B^2} = x_A e^{\xi(1-x_A)^2} \quad (5.65)$$

<sup>4</sup> Recall from introductory chemistry courses that  $\text{pH} = -\log a(\text{H}_3\text{O}^+)$ .

with a similar expression for  $a_B$ . The activity of A, though, is just the ratio of the vapour pressure of A in the solution to the vapour pressure of pure A (eqn 5.49), so we can write

$$p_A = \{x_A e^{\xi(1-x_A)^2}\} p_A^* \quad (5.66)$$

This function is plotted in Fig. 5.59. We see that  $\xi = 0$ , corresponding to an ideal solution, gives a straight line, in accord with Raoult's law (indeed, when  $\xi = 0$ , eqn 5.66 becomes  $p_A = x_A p_A^*$ , which is Raoult's law). Positive values of  $\xi$  (endothermic mixing, unfavourable solute–solvent interactions) give vapour pressures higher than ideal. Negative values of  $\xi$  (exothermic mixing, favourable solute–solvent interactions) give a lower vapour pressure. All the curves approach linearity and coincide with the Raoult's law line as  $x_A \rightarrow 1$  and the exponential function in eqn 5.66 approaches 1. When  $x_A \ll 1$ , eqn 5.66 approaches

$$p_A = x_A e^{\xi} p_A^* \quad (5.67)$$

This expression has the form of Henry's law once we identify  $K$  with  $e^{\xi} p_A^*$ , which is different for each solute–solvent system.

### 5.13 The activities of ions in solution

**Key points** (a) Mean activity coefficients apportion deviations from ideality equally to the cations and anions in an ionic solution. (b) The Debye–Hückel theory ascribes deviations from ideality to the Coulombic interaction of an ion with the ionic atmosphere that assembles around it. (c) The Debye–Hückel limiting law is extended by including two further empirical constants.

Interactions between ions are so strong that the approximation of replacing activities by molalities is valid only in very dilute solutions (less than 1 mmol kg<sup>−1</sup> in total ion concentration) and in precise work activities themselves must be used. We need, therefore, to pay special attention to the activities of ions in solution, especially in preparation for the discussion of electrochemical phenomena.

#### (a) Mean activity coefficients

If the chemical potential of the cation M<sup>+</sup> is denoted  $\mu_+$  and that of the anion X<sup>−</sup> is denoted  $\mu_-$ , the total molar Gibbs energy of the ions in the electrically neutral solution is the sum of these partial molar quantities. The molar Gibbs energy of an *ideal* solution of such ions is

$$G_m^{\text{ideal}} = \mu_+^{\text{ideal}} + \mu_-^{\text{ideal}} \quad (5.68)^{\circ}$$

However, for a *real* solution of M<sup>+</sup> and X<sup>−</sup> of the same molality,

$$G_m = \mu_+ + \mu_- = \mu_+^{\text{ideal}} + \mu_-^{\text{ideal}} + RT \ln \gamma_+ + RT \ln \gamma_- = G_m^{\text{ideal}} + RT \ln \gamma_+ \gamma_- \quad (5.69)$$

All the deviations from ideality are contained in the last term.

There is no experimental way of separating the product  $\gamma_+ \gamma_-$  into contributions from the cations and the anions. The best we can do experimentally is to assign responsibility for the nonideality equally to both kinds of ion. Therefore, for a 1,1-electrolyte, we introduce the **mean activity coefficient** as the geometric mean of the individual coefficients:

$$\gamma_{\pm} = (\gamma_+ \gamma_-)^{1/2} \quad (5.70)$$

and express the individual chemical potentials of the ions as

$$\mu_+ = \mu_+^{\text{ideal}} + RT \ln \gamma_{\pm} \quad \mu_- = \mu_-^{\text{ideal}} + RT \ln \gamma_{\pm} \quad (5.71)$$

**Fig. 5.59** The vapour pressure of a mixture based on a model in which the excess enthalpy is proportional to  $\xi RT x_A x_B$ . An ideal solution corresponds to  $\xi = 0$  and gives a straight line, in accord with Raoult's law. Positive values of  $\xi$  give vapour pressures higher than ideal. Negative values of  $\xi$  give a lower vapour pressure.

**InterActivity** Plot  $p_A/p_A^*$  against  $x_A$  with  $\xi = 2.5$  by using eqn 5.66 and then eqn 5.67. Above what value of  $x_A$  do the values of  $p_A/p_A^*$  given by these equations differ by more than 10 per cent?

**A brief comment**

The geometric mean of  $x^p$  and  $y^q$  is  $(x^p y^q)^{1/(p+q)}$ . For example, the geometric mean of  $x^2$  and  $y^{-3}$  is  $(x^2 y^{-3})^{-1}$ .

The sum of these two chemical potentials is the same as before, eqn 5.69, but now the nonideality is shared equally.

We can generalize this approach to the case of a compound  $M_p X_q$  that dissolves to give a solution of  $p$  cations and  $q$  anions from each formula unit. The molar Gibbs energy of the ions is the sum of their partial molar Gibbs energies:

$$G_m = p\mu_+ + q\mu_- = G_m^{\text{ideal}} + pRT \ln \gamma_+ + qRT \ln \gamma_- \quad (5.72)$$

If we introduce the mean activity coefficient now defined in a more general way as

$$\gamma_{\pm} = (\gamma_+^p \gamma_-^q)^{1/s} \quad s = p + q \quad \text{Mean activity coefficient} \quad [5.73]$$

and write the chemical potential of each ion as

$$\mu_i = \mu_i^{\text{ideal}} + RT \ln \gamma_{\pm} \quad (5.74)$$

we get the same expression as in eqn 5.72 for  $G_m$  when we write  $G = p\mu_+ + q\mu_-$ . However, both types of ion now share equal responsibility for the nonideality.

**(b) The Debye–Hückel limiting law**

The long range and strength of the Coulombic interaction between ions means that it is likely to be primarily responsible for the departures from ideality in ionic solutions and to dominate all the other contributions to nonideality. This domination is the basis of the **Debye–Hückel theory** of ionic solutions, which was devised by Peter Debye and Erich Hückel in 1923. We give here a qualitative account of the theory and its principal conclusions. The calculation itself, which is a profound example of how a seemingly intractable problem can be formulated and then resolved by drawing on physical insight, is described in *Further information 5.1*.

Oppositely charged ions attract one another. As a result, anions are more likely to be found near cations in solution, and vice versa (Fig. 5.60). Overall, the solution is electrically neutral, but near any given ion there is an excess of counter ions (ions of opposite charge). Averaged over time, counter ions are more likely to be found near any given ion. This time-averaged, spherical haze around the central ion, in which counter ions outnumber ions of the same charge as the central ion, has a net charge equal in magnitude but opposite in sign to that on the central ion, and is called its **ionic atmosphere**. The energy, and therefore the chemical potential, of any given central ion is lowered as a result of its electrostatic interaction with its ionic atmosphere. This lowering of energy appears as the difference between the molar Gibbs energy  $G_m$  and the ideal value  $G_m^{\text{ideal}}$  of the solute, and hence can be identified with  $RT \ln \gamma_{\pm}$ . The stabilization of ions by their interaction with their ionic atmospheres is part of the explanation why chemists commonly use dilute solutions, in which the stabilization is less important, to achieve precipitation of ions from electrolyte solutions.

The model leads to the result that at very low concentrations the activity coefficient can be calculated from the **Debye–Hückel limiting law**

$$\log \gamma_{\pm} = -|z_+ z_-| A I^{1/2} \quad \text{Debye–Hückel limiting law} \quad (5.75)$$

where  $A = 0.509$  for an aqueous solution at 25°C and  $I$  is the dimensionless **ionic strength** of the solution:

$$I = \frac{1}{2} \sum_i z_i^2 (b_i / b^{\ominus}) \quad \text{Definition of ionic strength} \quad [5.76]$$

**Fig. 5.60** The picture underlying the Debye–Hückel theory is of a tendency for anions to be found around cations, and of cations to be found around anions (one such local clustering region is shown by the circle). The ions are in ceaseless motion, and the diagram represents a snapshot of their motion. The solutions to which the theory applies are far less concentrated than shown here.

In this expression  $z_i$  is the charge number of an ion  $i$  (positive for cations and negative for anions) and  $b_i$  is its molality. The ionic strength occurs widely wherever ionic solutions are discussed, as we shall see. The sum extends over all the ions present in the solution. For solutions consisting of two types of ion at molalities  $b_+$  and  $b_-$ ,

$$I = \frac{1}{2}(b_+z_+^2 + b_-z_-^2)/b^\ominus \quad (5.77)$$

The ionic strength emphasizes the charges of the ions because the charge numbers occur as their squares. Table 5.4 summarizes the relation of ionic strength and molality in an easily usable form.

#### • A brief illustration

The mean activity coefficient of  $5.0 \text{ mmol kg}^{-1} \text{ KCl(aq)}$  at  $25^\circ\text{C}$  is calculated by writing

$$I = \frac{1}{2}(b_+ + b_-)/b^\ominus = b/b^\ominus$$

where  $b$  is the molality of the solution (and  $b_+ = b_- = b$ ). Then, from eqn 5.75,

$$\log \gamma_\pm = -0.509 \times (5.0 \times 10^{-3})^{1/2} = -0.036$$

Hence,  $\gamma_\pm = 0.92$ . The experimental value is 0.927. •

**Self-test 5.10** Calculate the ionic strength and the mean activity coefficient of  $1.00 \text{ mmol kg}^{-1} \text{ CaCl}_2\text{(aq)}$  at  $25^\circ\text{C}$ . [3.00 mmol  $\text{kg}^{-1}$ , 0.880]

The name ‘limiting law’ is applied to eqn 5.75 because ionic solutions of moderate molalities may have activity coefficients that differ from the values given by this expression, yet all solutions are expected to conform as  $b \rightarrow 0$ . Table 5.5 lists some experimental values of activity coefficients for salts of various valence types. Figure 5.61 shows some

**Table 5.4** Ionic strength and molality,  $I = kb/b^\ominus$

| $k$      | $X^-$ | $X^{2-}$ | $X^{3-}$ | $X^{4-}$ |
|----------|-------|----------|----------|----------|
| $M^+$    | 1     | 3        | 6        | 10       |
| $M^{2+}$ | 3     | 4        | 15       | 12       |
| $M^{3+}$ | 6     | 15       | 9        | 42       |
| $M^{4+}$ | 10    | 12       | 42       | 16       |

For example, the ionic strength of an  $M_2X_3$  solution of molality  $b$ , which is understood to give  $M^{3+}$  and  $X^{2-}$  ions in solution is  $15b/b^\ominus$ .

**Table 5.5\*** Mean activity coefficients in water at 298 K

| $b/b^\ominus$ | KCl   | $\text{CaCl}_2$ |
|---------------|-------|-----------------|
| 0.001         | 0.966 | 0.888           |
| 0.01          | 0.902 | 0.732           |
| 0.1           | 0.770 | 0.524           |
| 1.0           | 0.607 | 0.725           |

\* More values are given in the Data section.

**Fig. 5.61** An experimental test of the Debye–Hückel limiting law. Although there are marked deviations for moderate ionic strengths, the limiting slopes as  $I \rightarrow 0$  are in good agreement with the theory, so the law can be used for extrapolating data to very low molalities.

**Fig. 5.62** The extended Debye–Hückel law gives agreement with experiment over a wider range of molalities (as shown here for a 1,1-electrolyte), but it fails at higher molalities.

**interActivity** Consider the plot of  $\log \gamma_{\pm}$  against  $I^{1/2}$  with  $B = 1.50$  and  $C = 0$  as a representation of experimental data for a certain 1,1-electrolyte. Over what range of ionic strengths does the application of the limiting law lead to an error in the value of the activity coefficient of less than 10 per cent of the value predicted by the extended law?

of these values plotted against  $I^{1/2}$ , and compares them with the theoretical straight lines calculated from eqn 5.75. The agreement at very low molalities (less than about 1 mmol kg<sup>-1</sup>, depending on charge type) is impressive, and convincing evidence in support of the model. Nevertheless, the departures from the theoretical curves above these molalities are large, and show that the approximations are valid only at very low concentrations.

### (c) The extended Debye–Hückel law

When the ionic strength of the solution is too high for the limiting law to be valid, the activity coefficient may be estimated from the **extended Debye–Hückel law**:

$$\log \gamma_{\pm} = -\frac{A |z_+ z_-| I^{1/2}}{1 + B I^{1/2}} + C I \quad \text{Extended Debye–Hückel law} \quad (5.78)$$

where  $B$  and  $C$  are dimensionless constants. Although  $B$  can be interpreted as a measure of the closest approach of the ions, it (like  $C$ ) is best regarded as an adjustable empirical parameter. A curve drawn in this way is shown in Fig. 5.62. It is clear that eqn 5.78 accounts for some activity coefficients over a moderate range of dilute solutions (up to about 0.1 mol kg<sup>-1</sup>); nevertheless it remains very poor near 1 mol kg<sup>-1</sup>.

Current theories of activity coefficients for ionic solutes take an indirect route. They set up a theory for the dependence of the activity coefficient of the solvent on the concentration of the solute, and then use the Gibbs–Duhem equation (eqn 5.12) to estimate the activity coefficient of the solute. The results are reasonably reliable for solutions with molalities greater than about 0.1 mol kg<sup>-1</sup> and are valuable for the discussion of mixed salt solutions, such as sea water.

## Checklist of key equations

| Property                                        | Equation                                                                                                                                            | Comment                                                              |

## Further information

### Further information 5.1 The Debye–Hückel theory of ionic solution

Imagine a solution in which all the ions have their actual positions, but in which their Coulombic interactions have been turned off. The difference in molar Gibbs energy between the ideal and real solutions is equal to  $w_e$ , the electrical work of charging the system in this arrangement. For a salt  $M_pX_q$ , we write

$$w_e = \overbrace{(p\mu_+ + q\mu_-)}^{G_m} - \overbrace{(p\mu_+^{\text{ideal}} + q\mu_-^{\text{ideal}})}^{G_m^{\text{ideal}}} \quad (5.79)$$

$$= p(\mu_+ - \mu_+^{\text{ideal}}) + q(\mu_- - \mu_-^{\text{ideal}})$$

From eqn 5.71 we write

$$\mu_+ - \mu_+^{\text{ideal}} = \mu_- - \mu_-^{\text{ideal}} = RT \ln \gamma_{\pm}$$

So it follows that

$$\ln \gamma_{\pm} = \frac{w_e}{sRT} \quad s = p + q \quad (5.80)$$

This equation tells us that we must first find the final distribution of the ions and then the work of charging them in that distribution.

The Coulomb potential at a distance  $r$  from an isolated ion of charge  $z_i e$  in a medium of permittivity  $\epsilon$  is

$$\phi_i = \frac{Z_i}{r} \quad Z_i = \frac{z_i e}{4\pi\epsilon} \quad (5.81)$$

The ionic atmosphere causes the potential to decay with distance more sharply than this expression implies. Such shielding is a familiar problem in electrostatics, and its effect is taken into account by replacing the Coulomb potential by the **shielded Coulomb potential**, an expression of the form

$$\phi_i = \frac{Z_i}{r} e^{-r/r_D} \quad \text{Shielded Coulomb potential} \quad (5.82)$$

where  $r_D$  is called the **Debye length**. When  $r_D$  is large, the shielded potential is virtually the same as the unshielded potential. When it is small, the shielded potential is much smaller than the unshielded potential, even for short distances (Fig. 5.63).

To calculate  $r_D$ , we need to know how the **charge density**,  $\rho_i$ , of the ionic atmosphere, the charge in a small region divided by the volume of the region, varies with distance from the ion. This step draws on another standard result of electrostatics, in which charge density and potential are related by **Poisson's equation**:

$$\nabla^2 \phi = -\frac{\rho}{\epsilon} \quad \text{Poisson's equation} \quad (5.83a)$$

where  $\nabla^2 = (\partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2)$  is called the *laplacian*. Because we are considering only a spherical ionic atmosphere, we can use a simplified form of this equation in which the charge density varies only with distance from the central ion:

$$\frac{1}{r^2} \frac{d}{dr} \left( r^2 \frac{d\phi_i}{dr} \right) = -\frac{\rho_i}{\epsilon} \quad (5.83b)$$

Substitution of the expression for the shielded potential, eqn 5.82, results in

**Fig. 5.63** The variation of the shielded Coulomb potential with distance for different values of the Debye length,  $r_D/a$ . The smaller the Debye length, the more sharply the potential decays to zero. In each case,  $a$  is an arbitrary unit of length.

**interActivity** Write an expression for the difference between the unshielded and shielded Coulomb potentials evaluated at  $r_D$ . Then plot this expression against  $r_D$  and provide a physical interpretation for the shape of the plot.

$$r_D^2 = -\frac{\epsilon \phi_i}{\rho_i} \quad (5.84)$$

To solve this equation we need to relate  $\rho_i$  and  $\phi_i$ .

For the next step we draw on the fact that the energy of an ion depends on its closeness to the central ion, and then use the Boltzmann distribution (see *Fundamentals F.5a*) to work out the probability that an ion will be found at each distance. The energy of an ion of charge  $z_j e$  at a distance where it experiences the potential  $\phi_i$  of the central ion  $i$  relative to its energy when it is far away in the bulk solution is its charge times the potential:

$$E = z_j e \phi_i \quad (5.85)$$

Therefore, according to the Boltzmann distribution, the ratio of the molar concentration,  $c_j$ , of ions at a distance  $r$  and the molar concentration in the bulk,  $c_j^\circ$ , where the energy is zero, is

$$\frac{c_j}{c_j^\circ} = e^{-E/kT} \quad (5.86)$$

The charge density,  $\rho_i$ , at a distance  $r$  from the ion  $i$  is the molar concentration of each type of ion multiplied by the charge per mole of ions,  $z_i e N_A$ . The quantity  $e N_A$ , the magnitude of the charge per mole of electrons, is Faraday's constant,  $F = 96.48 \text{ kC mol}^{-1}$ . It follows that

$$\rho_i = c_+ z_+ F + c_- z_- F = c_+^\circ z_+ F e^{-z_+ e \phi_i / kT} + c_-^\circ z_- F e^{-z_- e \phi_i / kT} \quad (5.87)$$

At this stage we need to simplify the expression to avoid the awkward exponential terms. Because the average electrostatic interaction energy is small compared with  $kT$  we may use  $e^{-x} = 1 - x + \frac{1}{2}x^2 - \dots$  and ignore all terms higher than  $x$  to write eqn 5.87 as

$$\begin{aligned}\rho_i &= c_+^o z_+ F \left( 1 - \frac{z_+ e \phi_i}{kT} + \dots \right) + c_-^o z_- F \left( 1 - \frac{z_- e \phi_i}{kT} + \dots \right) \\ &= (c_+^o z_+ + c_-^o z_-) F - (c_+^o z_+^2 + c_-^o z_-^2) F \frac{e \phi_i}{kT} + \dots\end{aligned}$$

Replacing  $e$  by  $F/N_A$  and  $N_A k$  by  $R$  results in the following expression:

$$\rho_i = (c_+^o z_+ + c_-^o z_-) F - (c_+^o z_+^2 + c_-^o z_-^2) \frac{F^2 \phi_i}{RT} + \dots \quad (5.88)$$

The first term in the expansion is zero because it is the charge density in the bulk, uniform solution, and the solution is electrically neutral. The unwritten terms are assumed to be too small to be significant. The one remaining term can be expressed in terms of the ionic strength, eqn 5.76, by noting that in the dilute aqueous solutions we are considering there is little difference between molality and molar concentration, and  $c \approx bp$ , where  $p$  is the mass density of the solvent

$$c_+^o z_+^2 + c_-^o z_-^2 \approx (b_+^o z_+^2 + b_-^o z_-^2) \rho = 2Ib^o \rho \quad (5.89)$$

With these approximations, eqn 5.88 becomes

$$\rho_i = -\frac{2\rho F^2 I b^o \phi_i}{RT} \quad (5.90)$$

We can now solve eqn 5.84 for  $r_D$ :

$$r_D = \left( \frac{\epsilon RT}{2\rho F^2 I b^o} \right)^{1/2} \quad \text{Debye length} \quad (5.91)$$

To calculate the activity coefficient we need to find the electrical work of charging the central ion when it is surrounded by its atmosphere. To do so, we need to know the potential at the ion due to its atmosphere,  $\phi_{\text{atmos}}$ . This potential is the difference between the total potential, given by eqn 5.82, and the potential due to the central ion itself:

$$\phi_{\text{atmos}} = \phi - \phi_{\text{central ion}} = Z_i \left( \frac{e^{-r/r_D}}{r} - \frac{1}{r} \right) \quad (5.92a)$$

The potential at the central ion (at  $r = 0$ ) is obtained by taking the limit of this expression as  $r \rightarrow 0$  and is

$$\phi_{\text{atmos}}(0) = \frac{Z_i}{r_D} \quad (5.92b)$$

This expression shows us that the potential of the ionic atmosphere is equivalent to the potential arising from a single charge of equal magnitude but opposite sign to that of the central ion and located at a distance  $r_D$  from the ion. If the charge of the central ion were  $Q$  and not  $z_i e$ , then the potential due to its atmosphere would be

$$\phi_{\text{atmos}}(0) = -\frac{Q}{4\pi\epsilon r_D} \quad (5.92c)$$

The work of adding a charge  $dQ$  to a region where the electrical potential is  $\phi_{\text{atmos}}(0)$  is

$$dw_e = \phi_{\text{atmos}}(0) dQ \quad (5.93)$$

Therefore, the total molar work of fully charging the ions is

$$\begin{aligned}w_e &= N_A \int_0^{z_i e} \phi_{\text{atmos}}(0) dQ = -\frac{N_A}{4\pi\epsilon r_D} \int_0^{z_i e} Q dQ \\ &= -\frac{N_A z_i^2 e^2}{8\pi\epsilon r_D} = -\frac{z_i^2 F^2}{8\pi\epsilon N_A r_D}\end{aligned} \quad (5.94)$$

where in the last step we have used  $F = N_A e$ . It follows from eqn 5.80 that the mean activity coefficient of the ions is

$$\ln \gamma_{\pm} = \frac{pw_{e+} + qw_{e-}}{sRT} = -\frac{(pz_+^2 + qz_-^2)F^2}{8\pi\epsilon s N_A RT r_D} \quad (5.95a)$$

However, for neutrality  $pz_+ + qz_- = 0$ ; therefore

$$\ln \gamma_{\pm} = -\frac{|z_+ z_-| F^2}{8\pi\epsilon N_A RT r_D} \quad (5.95b)$$

(For this step, multiply  $pz_+ + qz_- = 0$  by  $p$  and also, separately, by  $q$ ; add the two expressions and rearrange the result by using  $p + q = s$  and  $z_+ z_- = -|z_+ z_-|$ .) Replacing  $r_D$  with the expression in eqn 5.91 gives

$$\begin{aligned}\ln \gamma_{\pm} &= -\frac{|z_+ z_-| F^2}{8\pi\epsilon N_A RT} \left( \frac{2\rho F^2 I b^o}{\epsilon RT} \right)^{1/2} \\ &= -|z_+ z_-| \left\{ \frac{F^3}{4\pi N_A} \left( \frac{\rho b^o}{2\epsilon^3 R^3 T^3} \right)^{1/2} \right\} I^{1/2}\end{aligned} \quad (5.96a)$$

where we have grouped terms in such a way as to show that this expression is beginning to take the form of eqn 5.75. Indeed, conversion to common logarithms (by using  $\ln x = \ln 10 \times \log x$ ) gives

$$\log \gamma_{\pm} = -|z_+ z_-| \left\{ \frac{F^3}{4\pi N_A \ln 10} \left( \frac{\rho b^o}{2\epsilon^3 R^3 T^3} \right)^{1/2} \right\} I^{1/2} \quad (5.96b)$$

which is eqn 5.75 ( $\log \gamma_{\pm} = -|z_+ z_-| AI^{1/2}$ ) with

$$A = \frac{F^3}{4\pi N_A \ln 10} \left( \frac{\rho b^o}{2\epsilon^3 R^3 T^3} \right)^{1/2} \quad (5.97)$$

## Discussion questions

**5.1** State and justify the thermodynamic criterion for solution–vapour equilibrium.

**5.2** How is Raoult's law modified so as to describe the vapour pressure of real solutions?

**5.3** Explain the origin of colligative properties.

**5.4** Explain what is meant by a regular solution.

**5.5** Describe the general features of the Debye–Hückel theory of electrolyte solutions.

**5.6** What factors determine the number of theoretical plates required to achieve a desired degree of separation in fractional distillation?

**5.7** Draw phase diagrams for the following types of systems. Label the regions and intersections of the diagrams, stating what materials (possibly compounds or azeotropes) are present and whether they are solid, liquid, or gas. (a) Two-component, temperature–composition, solid–liquid diagram, one compound AB formed that melts congruently, negligible solid–solid

solubility; (b) two-component, temperature–composition, solid–liquid diagram, one compound of formula  $AB_2$  that melts incongruently, negligible solid–solid solubility; (c) two-component, constant temperature–composition, liquid–vapour diagram, formation of an azeotrope at  $x_B = 0.333$ , complete miscibility.

## Exercises

**5.1(a)** The partial molar volumes of acetone (propanone) and chloroform (trichloromethane) in a mixture in which the mole fraction of  $CHCl_3$  is 0.4693 are  $74.166 \text{ cm}^3 \text{ mol}^{-1}$  and  $80.235 \text{ cm}^3 \text{ mol}^{-1}$ , respectively. What is the volume of a solution of mass 1.000 kg?

**5.1(b)** The partial molar volumes of two liquids A and B in a mixture in which the mole fraction of A is 0.3713 are  $188.2 \text{ cm}^3 \text{ mol}^{-1}$  and  $176.14 \text{ cm}^3 \text{ mol}^{-1}$ , respectively. The molar masses of the A and B are  $241.1 \text{ g mol}^{-1}$  and  $198.2 \text{ g mol}^{-1}$ . What is the volume of a solution of mass 1.000 kg?

**5.2(a)** At  $25^\circ\text{C}$ , the density of a 50 per cent by mass ethanol–water solution is  $0.914 \text{ g cm}^{-3}$ . Given that the partial molar volume of water in the solution is  $17.4 \text{ cm}^3 \text{ mol}^{-1}$ , calculate the partial molar volume of the ethanol.

**5.2(b)** At  $20^\circ\text{C}$ , the density of a 20 per cent by mass ethanol/water solution is  $968.7 \text{ kg m}^{-3}$ . Given that the partial molar volume of ethanol in the solution is  $52.2 \text{ cm}^3 \text{ mol}^{-1}$ , calculate the partial molar volume of the water.

**5.3(a)** At 300 K, the partial vapour pressures of HCl (that is, the partial pressure of the HCl vapour) in liquid  $\text{GeCl}_4$  are as follows:

|                             |       |       |       |
|-----------------------------|-------|-------|-------|
| $x_{\text{HCl}}$            | 0.005 | 0.012 | 0.019 |
| $p_{\text{HCl}}/\text{kPa}$ | 32.0  | 76.9  | 121.8 |

Show that the solution obeys Henry's law in this range of mole fractions, and calculate Henry's law constant at 300 K.

**5.3(b)** At 310 K, the partial vapour pressures of a substance B dissolved in a liquid A are as follows:

|                  |       |       |       |
|------------------|-------|-------|-------|
| $x_B$            | 0.010 | 0.015 | 0.020 |
| $p_B/\text{kPa}$ | 82.0  | 122.0 | 166.1 |

Show that the solution obeys Henry's law in this range of mole fractions, and calculate Henry's law constant at 310 K.

**5.4(a)** Predict the partial vapour pressure of HCl above its solution in liquid germanium tetrachloride of molality  $0.10 \text{ mol kg}^{-1}$ . For data, see Exercise 5.3a.

**5.4(b)** Predict the partial vapour pressure of the component B above its solution in A in Exercise 5.3b when the molality of B is  $0.25 \text{ mol kg}^{-1}$ . The molar mass of A is  $74.1 \text{ g mol}^{-1}$ .

**5.5(a)** The vapour pressure of benzene is 53.3 kPa at  $60.6^\circ\text{C}$ , but it fell to 51.5 kPa when 19.0 g of an involatile organic compound was dissolved in 500 g of benzene. Calculate the molar mass of the compound.

**5.5(b)** The vapour pressure of 2-propanol is 50.00 kPa at  $338.8^\circ\text{C}$ , but it fell to 49.62 kPa when 8.69 g of an involatile organic compound was dissolved in 250 g of 2-propanol. Calculate the molar mass of the compound.

**5.6(a)** The addition of 100 g of a compound to 750 g of  $\text{CCl}_4$  lowered the freezing point of the solvent by 10.5 K. Calculate the molar mass of the compound.

**5.6(b)** The addition of 5.00 g of a compound to 250 g of naphthalene lowered the freezing point of the solvent by 0.780 K. Calculate the molar mass of the compound.

**5.7(a)** The osmotic pressure of an aqueous solution at 300 K is 120 kPa. Calculate the freezing point of the solution.

**5.7(b)** The osmotic pressure of an aqueous solution at 288 K is 99.0 kPa. Calculate the freezing point of the solution.

**5.8(a)** Consider a container of volume  $5.0 \text{ dm}^3$  that is divided into two compartments of equal size. In the left compartment there is nitrogen at 1.0 atm and  $25^\circ\text{C}$ ; in the right compartment there is hydrogen at the same temperature and pressure. Calculate the entropy and Gibbs energy of mixing when the partition is removed. Assume that the gases are perfect.

**5.8(b)** Consider a container of volume  $250 \text{ cm}^3$  that is divided into two compartments of equal size. In the left compartment there is argon at 100 kPa and  $0^\circ\text{C}$ ; in the right compartment there is neon at the same temperature and pressure. Calculate the entropy and Gibbs energy of mixing when the partition is removed. Assume that the gases are perfect.

**5.9(a)** Air is a mixture with a composition given in *Example 1.3*. Calculate the entropy of mixing when it is prepared from the pure (and perfect) gases.

**5.9(b)** Calculate the Gibbs energy, entropy, and enthalpy of mixing when 1.00 mol  $\text{C}_6\text{H}_{14}$  (hexane) is mixed with 1.00 mol  $\text{C}_7\text{H}_{16}$  (heptane) at 298 K; treat the solution as ideal.

**5.10(a)** What proportions of hexane and heptane should be mixed (a) by mole fraction, (b) by mass in order to achieve the greatest entropy of mixing?

**5.10(b)** What proportions of benzene and ethylbenzene should be mixed (a) by mole fraction, (b) by mass in order to achieve the greatest entropy of mixing?

**5.11(a)** Use Henry's law and the data in Table 5.1 to calculate the solubility (as a molality) of  $\text{CO}_2$  in water at  $25^\circ\text{C}$  when its partial pressure is (a) 0.10 atm, (b) 1.00 atm.

**5.11(b)** The mole fractions of  $\text{N}_2$  and  $\text{O}_2$  in air at sea level are approximately 0.78 and 0.21. Calculate the molalities of the solution formed in an open flask of water at  $25^\circ\text{C}$ .

**5.12(a)** A water carbonating plant is available for use in the home and operates by providing carbon dioxide at 5.0 atm. Estimate the molar concentration of the soda water it produces.

**5.12(b)** After some weeks of use, the pressure in the water carbonating plant mentioned in the previous exercise has fallen to 2.0 atm. Estimate the molar concentration of the soda water it produces at this stage.

**5.13(a)** The enthalpy of fusion of anthracene is  $28.8 \text{ kJ mol}^{-1}$  and its melting point is  $217^\circ\text{C}$ . Calculate its ideal solubility in benzene at  $25^\circ\text{C}$ .

**5.13(b)** Predict the ideal solubility of lead in bismuth at  $280^\circ\text{C}$  given that its melting point is  $327^\circ\text{C}$  and its enthalpy of fusion is  $5.2 \text{ kJ mol}^{-1}$ .

**5.14(a)** The osmotic pressure of solutions of polystyrene in toluene were measured at  $25^\circ\text{C}$  and the pressure was expressed in terms of the height of the solvent of density  $1.004 \text{ g cm}^{-3}$ :

|                        |       |       |       |        |
|------------------------|-------|-------|-------|--------|
| $c/(\text{g dm}^{-3})$ | 2.042 | 6.613 | 9.521 | 12.602 |
| $h/\text{cm}$          | 0.592 | 1.910 | 2.750 | 3.600  |

Calculate the molar mass of the polymer.

**5.14(b)** The molar mass of an enzyme was determined by dissolving it in water, measuring the osmotic pressure at 20°C, and extrapolating the data to zero concentration. The following data were obtained:

|                         |       |       |       |        |
|-------------------------|-------|-------|-------|--------|
| $c/(\text{mg cm}^{-3})$ | 3.221 | 4.618 | 5.112 | 6.722  |
| $h/\text{cm}$           | 5.746 | 8.238 | 9.119 | 11.990 |

Calculate the molar mass of the enzyme.

**5.15(a)** Substances A and B are both volatile liquids with  $p_A^* = 300$  Torr,  $p_B^* = 250$  Torr, and  $K_B = 200$  Torr (concentration expressed in mole fraction). When  $x_A = 0.9$ ,  $b_B = 2.22 \text{ mol kg}^{-1}$ ,  $p_A = 250$  Torr, and  $p_B = 25$  Torr. Calculate the activities and activity coefficients of A and B. Use the mole fraction, Raoult's law basis system for A and the Henry's law basis system (both mole fractions and molalities) for B.

**5.15(b)** Given that  $p^*(\text{H}_2\text{O}) = 0.02308 \text{ atm}$  and  $p(\text{H}_2\text{O}) = 0.02239 \text{ atm}$  in a solution in which 0.122 kg of a non-volatile solute ( $M = 241 \text{ g mol}^{-1}$ ) is dissolved in 0.920 kg water at 293 K, calculate the activity and activity coefficient of water in the solution.

**5.16(a)** A dilute solution of bromine in carbon tetrachloride behaves as an ideal-dilute solution. The vapour pressure of pure  $\text{CCl}_4$  is 33.85 Torr at 298 K. The Henry's law constant when the concentration of  $\text{Br}_2$  is expressed as a mole fraction is 122.36 Torr. Calculate the vapour pressure of each component, the total pressure, and the composition of the vapour phase when the mole fraction of  $\text{Br}_2$  is 0.050, on the assumption that the conditions of the ideal-dilute solution are satisfied at this concentration.

**5.16(b)** Benzene and toluene form nearly ideal solutions. The boiling point of pure benzene is 80.1°C. Calculate the chemical potential of benzene relative to that of pure benzene when  $x_{\text{benzene}} = 0.30$  at its boiling point. If the activity coefficient of benzene in this solution were actually 0.93 rather than 1.00, what would be its vapour pressure?

**5.17(a)** By measuring the equilibrium between liquid and vapour phases of an acetone(A)/methanol(M) solution at 57.2°C at 1.00 atm, it was found that  $x_A = 0.400$  when  $y_A = 0.516$ . Calculate the activities and activity coefficients of both components in this solution on the Raoult's law basis. The vapour pressures of the pure components at this temperature are:  $p_A^* = 105 \text{ kPa}$  and  $p_M^* = 73.5 \text{ kPa}$ . ( $x_A$  is the mole fraction in the liquid and  $y_A$  the mole fraction in the vapour.)

**5.17(b)** By measuring the equilibrium between liquid and vapour phases of a solution at 30°C at 1.00 atm, it was found that  $x_A = 0.220$  when  $y_A = 0.314$ . Calculate the activities and activity coefficients of both components in this solution on the Raoult's law basis. The vapour pressures of the pure components at this temperature are:  $p_A^* = 73.0 \text{ kPa}$  and  $p_B^* = 92.1 \text{ kPa}$ . ( $x_A$  is the mole fraction in the liquid and  $y_A$  the mole fraction in the vapour.)

**5.18(a)** Calculate the ionic strength of a solution that is 0.10 mol  $\text{kg}^{-1}$  in  $\text{KCl}(\text{aq})$  and 0.20 mol  $\text{kg}^{-1}$  in  $\text{CuSO}_4(\text{aq})$ .

**5.18(b)** Calculate the ionic strength of a solution that is 0.040 mol  $\text{kg}^{-1}$  in  $\text{K}_3[\text{Fe}(\text{CN})_6](\text{aq})$ , 0.030 mol  $\text{kg}^{-1}$  in  $\text{KCl}(\text{aq})$ , and 0.050 mol  $\text{kg}^{-1}$  in  $\text{NaBr}(\text{aq})$ .

**5.19(a)** Calculate the masses of (a)  $\text{Ca}(\text{NO}_3)_2$  and, separately, (b)  $\text{NaCl}$  to add to a 0.150 mol  $\text{kg}^{-1}$  solution of  $\text{KNO}_3(\text{aq})$  containing 500 g of solvent to raise its ionic strength to 0.250.

**5.19(b)** Calculate the masses of (a)  $\text{KNO}_3$  and, separately, (b)  $\text{Ba}(\text{NO}_3)_2$  to add to a 0.110 mol  $\text{kg}^{-1}$  solution of  $\text{KNO}_3(\text{aq})$  containing 500 g of solvent to raise its ionic strength to 1.00.

**5.20(a)** Estimate the mean ionic activity coefficient and activity of  $\text{CaCl}_2$  in a solution that is 0.010 mol  $\text{kg}^{-1}$   $\text{CaCl}_2(\text{aq})$  and 0.030 mol  $\text{kg}^{-1}$   $\text{NaF}(\text{aq})$ .

**5.20(b)** Estimate the mean ionic activity coefficient and activity of  $\text{NaCl}$  in a solution that is 0.020 mol  $\text{kg}^{-1}$   $\text{NaCl}(\text{aq})$  and 0.035 mol  $\text{kg}^{-1}$   $\text{Ca}(\text{NO}_3)_2(\text{aq})$ .

**5.21(a)** The mean activity coefficients of  $\text{HBr}$  in three dilute aqueous solutions at 25°C are 0.930 (at 5.0 mmol  $\text{kg}^{-1}$ ), 0.907 (at 10.0 mmol  $\text{kg}^{-1}$ ), and 0.879 (at 20.0 mmol  $\text{kg}^{-1}$ ). Estimate the value of  $B$  in the extended Debye–Hückel law. Set  $C = 0$ .

**5.21(b)** The mean activity coefficients of  $\text{KCl}$  in three dilute aqueous solutions at 25°C are 0.927 (at 5.0 mmol  $\text{kg}^{-1}$ ), 0.902 (at 10.0 mmol  $\text{kg}^{-1}$ ), and 0.816 (at 50.0 mmol  $\text{kg}^{-1}$ ). Estimate the value of  $B$  in the extended Debye–Hückel law. Set  $C = 0$ .

**5.22(a)** At 90°C, the vapour pressure of methylbenzene is 53.3 kPa and that of 1,2-dimethylbenzene is 20.0 kPa. What is the composition of a liquid mixture that boils at 90°C when the pressure is 0.50 atm? What is the composition of the vapour produced?

**5.22(b)** At 90°C, the vapour pressure of 1,2-dimethylbenzene is 20 kPa and that of 1,3-dimethylbenzene is 18 kPa. What is the composition of a liquid mixture that boils at 90°C when the pressure is 19 kPa? What is the composition of the vapour produced?

**5.23(a)** The vapour pressure of pure liquid A at 300 K is 76.7 kPa and that of pure liquid B is 52.0 kPa. These two compounds form ideal liquid and gaseous mixtures. Consider the equilibrium composition of a mixture in which the mole fraction of A in the vapour is 0.350. Calculate the total pressure of the vapour and the composition of the liquid mixture.

**5.23(b)** The vapour pressure of pure liquid A at 293 K is 68.8 kPa and that of pure liquid B is 82.1 kPa. These two compounds form ideal liquid and gaseous mixtures. Consider the equilibrium composition of a mixture in which the mole fraction of A in the vapour is 0.612. Calculate the total pressure of the vapour and the composition of the liquid mixture.

**5.24(a)** It is found that the boiling point of a binary solution of A and B with  $x_A = 0.6589$  is 88°C. At this temperature the vapour pressures of pure A and B are 127.6 kPa and 50.60 kPa, respectively. (a) Is this solution ideal? (b) What is the initial composition of the vapour above the solution?

**5.24(b)** It is found that the boiling point of a binary solution of A and B with  $x_A = 0.4217$  is 96°C. At this temperature the vapour pressures of pure A and B are 110.1 kPa and 76.5 kPa, respectively. (a) Is this solution ideal? (b) What is the initial composition of the vapour above the solution?

**5.25(a)** Dibromoethene (DE,  $p_{\text{DE}}^* = 22.9 \text{ kPa}$  at 358 K) and dibromopropene (DP,  $p_{\text{DP}}^* = 17.1 \text{ kPa}$  at 358 K) form a nearly ideal solution. If  $z_{\text{DE}} = 0.60$ , what is (a)  $p_{\text{total}}$  when the system is all liquid, (b) the composition of the vapour when the system is still almost all liquid?

**5.25(b)** Benzene and toluene form nearly ideal solutions. Consider an equimolar solution of benzene and toluene. At 20°C the vapour pressures of pure benzene and toluene are 9.9 kPa and 2.9 kPa, respectively. The solution is boiled by reducing the external pressure below the vapour pressure. Calculate (a) the pressure when boiling begins, (b) the composition of each component in the vapour, and (c) the vapour pressure when only a few drops of liquid remain. Assume that the rate of vaporization is low enough for the temperature to remain constant at 20°C.

**5.26(a)** The following temperature/composition data were obtained for a mixture of octane (O) and methylbenzene (M) at 1.00 atm, where  $x$  is the mole fraction in the liquid and  $y$  the mole fraction in the vapour at equilibrium.

|                         |       |       |       |       |       |       |       |       |
|-------------------------|-------|-------|-------|-------|-------|-------|-------|-------|
| $\theta/^\circ\text{C}$ | 110.9 | 112.0 | 114.0 | 115.8 | 117.3 | 119.0 | 121.1 | 123.0 |
| $x_{\text{M}}$          | 0.908 | 0.795 | 0.615 | 0.527 | 0.408 | 0.300 | 0.203 | 0.097 |
| $y_{\text{M}}$          | 0.923 | 0.836 | 0.698 | 0.624 | 0.527 | 0.410 | 0.297 | 0.164 |

The boiling points are 110.6°C and 125.6°C, for M and O, respectively. Plot the temperature/composition diagram for the mixture. What is the composition of the vapour in equilibrium with the liquid of composition (a)  $x_{\text{M}} = 0.250$  and (b)  $x_{\text{O}} = 0.250$ ?

**5.26(b)** The following temperature/composition data were obtained for a mixture of two liquids A and B at 1.00 atm, where  $x$  is the mole fraction in the liquid and  $y$  the mole fraction in the vapour at equilibrium.

|                         |      |      |      |      |      |       |
|-------------------------|------|------|------|------|------|-------|
| $\theta/^\circ\text{C}$ | 125  | 130  | 135  | 140  | 145  | 150   |
| $x_A$                   | 0.91 | 0.65 | 0.45 | 0.30 | 0.18 | 0.098 |
| $y_A$                   | 0.99 | 0.91 | 0.77 | 0.61 | 0.45 | 0.25  |

The boiling points are  $124^\circ\text{C}$  for A and  $155^\circ\text{C}$  for B. Plot the temperature/composition diagram for the mixture. What is the composition of the vapour in equilibrium with the liquid of composition (a)  $x_A = 0.50$  and (b)  $x_B = 0.33$ ?

**5.27(a)** Methylethyl ether (A) and diborane,  $\text{B}_2\text{H}_6$  (B), form a compound which melts congruently at 133 K. The system exhibits two eutectics, one at 25 mol per cent B and 123 K and a second at 90 mol per cent B and 104 K. The melting points of pure A and B are 131 K and 110 K, respectively. Sketch the phase diagram for this system. Assume negligible solid–solid solubility.

**5.27(b)** Sketch the phase diagram of the system  $\text{NH}_3/\text{N}_2\text{H}_4$  given that the two substances do not form a compound with each other, that  $\text{NH}_3$  freezes at  $-78^\circ\text{C}$  and  $\text{N}_2\text{H}_4$  freezes at  $+2^\circ\text{C}$ , and that a eutectic is formed when the mole fraction of  $\text{N}_2\text{H}_4$  is 0.07 and that the eutectic melts at  $-80^\circ\text{C}$ .

**5.28(a)** Figure 5.64 shows the phase diagram for two partially miscible liquids, which can be taken to be that for water (A) and 2-methyl-1-propanol (B). Describe what will be observed when a mixture of composition  $x_B = 0.8$  is heated, at each stage giving the number, composition, and relative amounts of the phases present.

Fig. 5.64

**5.28(b)** Figure 5.65 is the phase diagram for silver and tin. Label the regions, and describe what will be observed when liquids of compositions  $a$  and  $b$  are cooled to 200 K.

Fig. 5.65

**5.29(a)** Indicate on the phase diagram in Fig. 5.66 the feature that denotes incongruent melting. What is the composition of the eutectic mixture and at what temperature does it melt?

Fig. 5.66

**5.29(b)** Indicate on the phase diagram in Fig. 5.67 the feature that denotes incongruent melting. What is the composition of the eutectic mixture and at what temperature does it melt?

Fig. 5.67

**5.30(a)** Sketch the cooling curves for the isopleths  $a$  and  $b$  in Fig. 5.66.

**5.30(b)** Sketch the cooling curves for the isopleths  $a$  and  $b$  in Fig. 5.67.

**5.31(a)** Use the phase diagram in Fig. 5.65 to state (a) the solubility of Ag in Sn at  $800^\circ\text{C}$  and (b) the solubility of  $\text{Ag}_3\text{Sn}$  in Ag at  $460^\circ\text{C}$ , (c) the solubility of  $\text{Ag}_3\text{Sn}$  in Ag at  $300^\circ\text{C}$ .

**5.31(b)** Use the phase diagram in Fig. 5.66 to state (a) the solubility of B in A at  $390^\circ\text{C}$  and (b) the solubility of  $\text{AB}_2$  in B at  $300^\circ\text{C}$ .

**5.32(a)** Figure 5.68 shows the experimentally determined phase diagrams for the nearly ideal solution of hexane and heptane. (a) Label the regions of the diagrams as to which phases are present. (b) For a solution containing 1 mol each of hexane and heptane molecules, estimate the vapour pressure at  $70^\circ\text{C}$  when vaporization on reduction of the external pressure just begins. (c) What is the vapour pressure of the solution at  $70^\circ\text{C}$  when just one drop of liquid remains. (d) Estimate from the figures the mole fraction of hexane in the liquid and vapour phases for the conditions of part b. (e) What are the mole fractions for the conditions of part c? (f) At  $85^\circ\text{C}$  and 760 Torr, what are the amounts of substance in the liquid and vapour phases when  $z_{\text{heptane}} = 0.40$ ?

Fig. 5.68

**5.32(b)** Uranium tetrafluoride and zirconium tetrafluoride melt at  $1035^\circ\text{C}$  and  $912^\circ\text{C}$ , respectively. They form a continuous series of solid solutions with a minimum melting temperature of  $765^\circ\text{C}$  and composition  $x(\text{ZrF}_4) = 0.77$ . At  $900^\circ\text{C}$ , the liquid solution of composition  $x(\text{ZrF}_4) = 0.28$  is in equilibrium with a solid solution of composition  $x(\text{ZrF}_4) = 0.14$ . At  $850^\circ\text{C}$  the two compositions are 0.87 and 0.90, respectively. Sketch the phase diagram for this

system and state what is observed when a liquid of composition  $x(\text{ZrF}_4) = 0.40$  is cooled slowly from  $900^\circ\text{C}$  to  $500^\circ\text{C}$ .

**5.33(a)** Methane (melting point 91 K) and tetrafluoromethane (melting point 89 K) do not form solid solutions with each other, and as liquids they are only partially miscible. The upper critical temperature of the liquid mixture is 94 K at  $x(\text{CF}_4) = 0.43$  and the eutectic temperature is 84 K at  $x(\text{CF}_4) = 0.88$ . At 86 K, the phase in equilibrium with the tetrafluoromethane-rich solution changes from solid methane to a methane-rich liquid. At that temperature, the two liquid solutions that are in mutual equilibrium have the compositions  $x(\text{CF}_4) = 0.10$  and  $x(\text{CF}_4) = 0.80$ . Sketch the phase diagram.

**5.33(b)** Describe the phase changes that take place when a liquid mixture of 4.0 mol  $\text{B}_2\text{H}_6$  (melting point 131 K) and 1.0 mol  $\text{CH}_3\text{OCH}_3$  (melting point 135 K) is cooled from 140 K to 90 K. These substances form a compound  $(\text{CH}_3)_2\text{OB}_2\text{H}_6$  that melts congruently at 133 K. The system exhibits one eutectic at  $x(\text{B}_2\text{H}_6) = 0.25$  and 123 K and another at  $x(\text{B}_2\text{H}_6) = 0.90$  and 104 K.

**5.34(a)** Refer to the information in Exercise 5.33a and sketch the cooling curves for liquid mixtures in which  $x(\text{CF}_4)$  is (a) 0.10, (b) 0.30, (c) 0.50, (d) 0.80, and (e) 0.95.

**5.34(b)** Refer to the information in Exercise 5.33b and sketch the cooling curves for liquid mixtures in which  $x(\text{B}_2\text{H}_6)$  is (a) 0.10, (b) 0.30, (c) 0.50, (d) 0.80, and (e) 0.95.

**5.35(a)** Hexane and perfluorohexane show partial miscibility below  $22.70^\circ\text{C}$ . The critical concentration at the upper critical temperature is  $x = 0.355$ , where  $x$  is the mole fraction of  $\text{C}_6\text{F}_{14}$ . At  $22.0^\circ\text{C}$  the two solutions in equilibrium have  $x = 0.24$  and  $x = 0.48$ , respectively, and at  $21.5^\circ\text{C}$  the mole fractions are 0.22 and 0.51. Sketch the phase diagram. Describe the phase changes that occur when perfluorohexane is added to a fixed amount of hexane at (a)  $23^\circ\text{C}$ , (b)  $22^\circ\text{C}$ .

**5.35(b)** Two liquids, A and B, show partial miscibility below  $52.4^\circ\text{C}$ . The critical concentration at the upper critical temperature is  $x = 0.459$ , where  $x$  is the mole fraction of A. At  $40.0^\circ\text{C}$  the two solutions in equilibrium have  $x = 0.22$  and  $x = 0.60$ , respectively, and at  $42.5^\circ\text{C}$  the mole fractions are 0.24 and 0.48. Sketch the phase diagram. Describe the phase changes that occur when B is added to a fixed amount of A at (a)  $48^\circ\text{C}$ , (b)  $52.4^\circ\text{C}$ .

## Problems\*

### Numerical problems

**5.1** The following table gives the mole fraction of methylbenzene (A) in liquid and gaseous mixtures with butanone at equilibrium at  $303.15\text{ K}$  and the total pressure  $p$ . Take the vapour to be perfect and calculate the partial pressures of the two components. Plot them against their respective mole fractions in the liquid mixture and find the Henry's law constants for the two components.

|                |         |        |        |        |        |        |

**5.2** The volume of an aqueous solution of NaCl at  $25^\circ\text{C}$  was measured at a series of molalities  $b$ , and it was found that the volume fitted the expression

$v = 1003 + 16.62x + 1.77x^{3/2} + 0.12x^2$  where  $v = V/\text{cm}^3$ ,  $V$  is the volume of a solution formed from 1.000 kg of water, and  $x = b/b^\circ$ . Calculate the partial molar volume of the components in a solution of molality  $0.100\text{ mol kg}^{-1}$ .

**5.3** At  $18^\circ\text{C}$  the total volume  $V$  of a solution formed from  $\text{MgSO}_4$  and 1.000 kg of water fits the expression  $v = 1001.21 + 34.69(x - 0.070)^2$ , where  $v = V/\text{cm}^3$  and  $x = b/b^\circ$ . Calculate the partial molar volumes of the salt and the solvent when in a solution of molality  $0.050\text{ mol kg}^{-1}$ .

**5.4** The densities of aqueous solutions of copper(II) sulfate at  $20^\circ\text{C}$  were measured as set out below. Determine and plot the partial molar volume of  $\text{CuSO}_4$  in the range of the measurements.

|                             |       |       |       |       |
|-----------------------------|-------|-------|-------|-------|
| $m(\text{CuSO}_4)/\text{g}$ | 5     | 10    | 15    | 20    |
| $\rho/(\text{g cm}^{-3})$   | 1.051 | 1.107 | 1.167 | 1.230 |

where  $m(\text{CuSO}_4)$  is the mass of  $\text{CuSO}_4$  dissolved in 100 g of solution.

**5.5** What proportions of ethanol and water should be mixed in order to produce  $100\text{ cm}^3$  of a mixture containing 50 per cent by mass of ethanol?

\* Problems denoted with the symbol ‡ were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

What change in volume is brought about by adding 1.00 cm<sup>3</sup> of ethanol to the mixture? (Use data from Fig. 5.1.)

**5.6** Potassium fluoride is very soluble in glacial acetic acid and the solutions have a number of unusual properties. In an attempt to understand them, freezing point depression data were obtained by taking a solution of known molality and then diluting it several times (J. Emsley, *J. Chem. Soc. A*, 2702 (1971)). The following data were obtained:

|                          |       |       |       |       |       |
|--------------------------|-------|-------|-------|-------|-------|
| $b/(\text{mol kg}^{-1})$ | 0.015 | 0.037 | 0.077 | 0.295 | 0.602 |
| $\Delta T/K$             | 0.115 | 0.295 | 0.470 | 1.381 | 2.67  |

Calculate the apparent molar mass of the solute and suggest an interpretation. Use  $\Delta_{\text{fus}}H = 11.4 \text{ kJ mol}^{-1}$  and  $T_f^* = 290 \text{ K}$ .

**5.7** In a study of the properties of an aqueous solution of  $\text{Th}(\text{NO}_3)_4$  (by A. Apelblat, D. Azoulay, and A. Sahar, *J. Chem. Soc. Faraday Trans., I*, 1618, (1973)), a freezing point depression of 0.0703 K was observed for an aqueous solution of molality 9.6 mmol kg<sup>-1</sup>. What is the apparent number of ions per formula unit?

**5.8** The table below lists the vapour pressures of mixtures of iodoethane (I) and ethyl acetate (A) at 50°C. Find the activity coefficients of both components on (a) the Raoult's law basis, (b) the Henry's law basis with iodoethane as solute.

|                  |        |        |        |        |        |        |
|------------------|--------|--------|--------|--------|--------|--------|
| $x_I$            | 0      | 0.0579 | 0.1095 | 0.1918 | 0.2353 | 0.3718 |
| $p_I/\text{kPa}$ | 0      | 3.73   | 7.03   | 11.7   | 14.05  | 20.72  |
| $p_A/\text{kPa}$ | 37.38  | 35.48  | 33.64  | 30.85  | 29.44  | 25.05  |
| $x_I$            | 0.5478 | 0.6349 | 0.8253 | 0.9093 | 1.0000 |        |
| $p_I/\text{kPa}$ | 28.44  | 31.88  | 39.58  | 43.00  | 47.12  |        |
| $p_A/\text{kPa}$ | 19.23  | 16.39  | 8.88   | 5.09   | 0      |        |

**5.9** Plot the vapour pressure data for a mixture of benzene (B) and acetic acid (A) given below and plot the vapour pressure/composition curve for the mixture at 50°C. Then confirm that Raoult's and Henry's laws are obeyed in the appropriate regions. Deduce the activities and activity coefficients of the components on the Raoult's law basis and then, taking B as the solute, its activity and activity coefficient on a Henry's law basis. Finally, evaluate the excess Gibbs energy of the mixture over the composition range spanned by the data.

|                  |        |        |        |        |        |        |
|------------------|--------|--------|--------|--------|--------|--------|
| $x_A$            | 0.0160 | 0.0439 | 0.0835 | 0.1138 | 0.1714 |        |
| $p_A/\text{kPa}$ | 0.484  | 0.967  | 1.535  | 1.89   | 2.45   |        |
| $p_B/\text{kPa}$ | 35.05  | 34.29  | 33.28  | 32.64  | 30.90  |        |
| $x_A$            | 0.2973 | 0.3696 | 0.5834 | 0.6604 | 0.8437 | 0.9931 |
| $p_A/\text{kPa}$ | 3.31   | 3.83   | 4.84   | 5.36   | 6.76   | 7.29   |
| $p_B/\text{kPa}$ | 28.16  | 26.08  | 20.42  | 18.01  | 10.0   | 0.47   |

**5.10†** Aminabhavi *et al.* examined mixtures of cyclohexane with various long-chain alkanes (T.M. Aminabhavi, *et al.*, *J. Chem. Eng. Data* 41, 526 (1996)). Among their data are the following measurements of the density of a mixture of cyclohexane and pentadecane as a function of mole fraction of cyclohexane ( $x_c$ ) at 298.15 K:

|                           |        |        |        |
|---------------------------|--------|--------|--------|
| $x_c$                     | 0.6965 | 0.7988 | 0.9004 |
| $\rho/(\text{g cm}^{-3})$ | 0.7661 | 0.7674 | 0.7697 |

Compute the partial molar volume for each component in a mixture which has a mole fraction cyclohexane of 0.7988.

**5.11†** Comelli and Francesconi examined mixtures of propionic acid with various other organic liquids at 313.15 K (F. Comelli and R. Francesconi, *J. Chem. Eng. Data* 41, 101 (1996)). They report the excess volume of mixing propionic acid with oxane as  $V^E = x_1x_2\{a_0 + a_1(x_1 - x_2)\}$ , where  $x_1$  is the mole fraction of propionic acid,  $x_2$  that of oxane,  $a_0 = -2.4697 \text{ cm}^3 \text{ mol}^{-1}$ ,

and  $a_1 = 0.0608 \text{ cm}^3 \text{ mol}^{-1}$ . The density of propionic acid at this temperature is  $0.97174 \text{ g cm}^{-3}$ ; that of oxane is  $0.86398 \text{ g cm}^{-3}$ . (a) Derive an expression for the partial molar volume of each component at this temperature. (b) Compute the partial molar volume for each component in an equimolar mixture.

**5.12†** Francesconi, Lunelli, and Comelli studied the liquid–vapour equilibria of trichloromethane and 1,2-epoxybutane at several temperatures (Francesconi, B. *et al.*, *J. Chem. Eng. Data* 41, 310 (1996)). Among their data are the following measurements of the mole fractions of trichloromethane in the liquid phase ( $x_T$ ) and the vapour phase ( $y_T$ ) at 298.15 K as a function of pressure.

|                |       |       |       |       |       |       |       |       |
|----------------|-------|-------|-------|-------|-------|-------|-------|-------|
| $p/\text{kPa}$ | 23.40 | 21.75 | 20.25 | 18.75 | 18.15 | 20.25 | 22.50 | 26.30 |
| $x$            | 0     | 0.129 | 0.228 | 0.353 | 0.511 | 0.700 | 0.810 | 1     |
| $y$            | 0     | 0.065 | 0.145 | 0.285 | 0.535 | 0.805 | 0.915 | 1     |

Compute the activity coefficients of both components on the basis of Raoult's law.

**5.13†** Chen and Lee studied the liquid–vapour equilibria of cyclohexanol with several gases at elevated pressures (J.-T. Chen and M.-J. Lee, *J. Chem. Eng. Data* 41, 339 (1996)). Among their data are the following measurements of the mole fractions of cyclohexanol in the vapour phase ( $y$ ) and the liquid phase ( $x$ ) at 393.15 K as a function of pressure.

|                  |        |        |        |         |         |         |
|------------------|--------|--------|--------|---------|---------|---------|
| $p/\text{bar}$   | 10.0   | 20.0   | 30.0   | 40.0    | 60.0    | 80.0    |
| $y_{\text{cyc}}$ | 0.0267 | 0.0149 | 0.0112 | 0.00947 | 0.00835 | 0.00921 |
| $x_{\text{cyc}}$ | 0.9741 | 0.9464 | 0.9204 | 0.892   | 0.836   | 0.773   |

Determine the Henry's law constant of  $\text{CO}_2$  in cyclohexanol, and compute the activity coefficient of  $\text{CO}_2$ .

**5.14†** Equation 5.37 indicates that solubility is an exponential function of temperature. The data in the table below gives the solubility,  $S$ , of calcium acetate in water as a function of temperature.

|                          |      |      |      |      |      |
|--------------------------|------|------|------|------|------|
| $\theta/^\circ\text{C}$  | 0    | 20   | 40   | 60   | 80   |
| $S/(\text{mol dm}^{-3})$ | 36.4 | 34.9 | 33.7 | 32.7 | 31.7 |

Determine the extent to which the data fit the exponential  $S = S_0 e^{\tau/T}$  and obtain values for  $S_0$  and  $\tau$ . Express these constants in terms of properties of the solute.

**5.15** The excess Gibbs energy of solutions of methylcyclohexane (MCH) and tetrahydrofuran (THF) at 303.15 K was found to fit the expression

$$G^E = RTx(1-x)\{0.4857 - 0.1077(2x-1) + 0.0191(2x-1)^2\}$$

where  $x$  is the mole fraction of the methylcyclohexane. Calculate the Gibbs energy of mixing when a mixture of 1.00 mol of MCH and 3.00 mol of THF is prepared.

**5.16** The mean activity coefficients for aqueous solutions of NaCl at 25°C are given below. Confirm that they support the Debye–Hückel limiting law and that an improved fit is obtained with the extended law.

|                           |        |        |        |        |        |
|---------------------------|--------|--------|--------|--------|--------|
| $b/(\text{mmol kg}^{-1})$ | 1.0    | 2.0    | 5.0    | 10.0   | 20.0   |
| $\gamma_{\pm}$            | 0.9649 | 0.9519 | 0.9275 | 0.9024 | 0.8712 |

**5.17†** 1-Butanol and chlorobenzene form a minimum-boiling azeotropic system. The mole fraction of 1-butanol in the liquid ( $x$ ) and vapour ( $y$ ) phases at 1.000 atm is given below for a variety of boiling temperatures (H. Artigas, *et al.*, *J. Chem. Eng. Data* 42, 132 (1997)).

|              |        |        |        |        |        |        |        |
|--------------|--------|--------|--------|--------|--------|--------|--------|
| $T/\text{K}$ | 396.57 | 393.94 | 391.60 | 390.15 | 389.03 | 388.66 | 388.57 |
| $x$          | 0.1065 | 0.1700 | 0.2646 | 0.3687 | 0.5017 | 0.6091 | 0.7171 |
| $y$          | 0.2859 | 0.3691 | 0.4505 | 0.5138 | 0.5840 | 0.6409 | 0.7070 |

Pure chlorobenzene boils at 404.86 K. (a) Construct the chlorobenzene-rich portion of the phase diagram from the data. (b) Estimate the temperature at which a solution whose mole fraction of 1-butanol is 0.300 begins to boil.

(c) State the compositions and relative proportions of the two phases present after a solution initially 0.300 1-butanol is heated to 393.94 K.

**5.18‡** An, Zhao, Jiang, and Shen investigated the liquid–liquid coexistence curve of *N,N*-dimethylacetamide and heptane (X. An, *et al.*, *J. Chem. Thermodynamics* 28, 1221 (1996)). Mole fractions of *N,N*-dimethylacetamide in the upper ( $x_1$ ) and lower ( $x_2$ ) phases of a two-phase region are given below as a function of temperature:

|       |         |         |         |         |         |
|-------|---------|---------|---------|---------|---------|
| $T/K$ | 309.820 | 309.422 | 309.031 | 308.006 | 306.686 |
| $x_1$ | 0.473   | 0.400   | 0.371   | 0.326   | 0.293   |
| $x_2$ | 0.529   | 0.601   | 0.625   | 0.657   | 0.690   |
| $T/K$ | 304.553 | 301.803 | 299.097 | 296.000 | 294.534 |
| $x_1$ | 0.255   | 0.218   | 0.193   | 0.168   | 0.157   |
| $x_2$ | 0.724   | 0.758   | 0.783   | 0.804   | 0.814   |

(a) Plot the phase diagram. (b) State the proportions and compositions of the two phases that form from mixing 0.750 mol of *N,N*-dimethylacetamide with 0.250 mol of heptane at 296.0 K. To what temperature must the mixture be heated to form a single-phase mixture?

**5.19‡** The following data have been obtained for the liquid–vapour equilibrium compositions of mixtures of nitrogen and oxygen at 100 kPa.

|                               |      |     |     |     |     |     |     |      |
|-------------------------------|------|-----|-----|-----|-----|-----|-----|------|
| $T/K$                         | 77.3 | 78  | 80  | 82  | 84  | 86  | 88  | 90.2 |
| $x(\text{O}_2)$               | 0    | 10  | 34  | 54  | 70  | 82  | 92  | 100  |
| $y(\text{O}_2)$               | 0    | 2   | 11  | 22  | 35  | 52  | 73  | 100  |
| $p^*(\text{O}_2)/\text{Torr}$ | 154  | 171 | 225 | 294 | 377 | 479 | 601 | 760  |

Plot the data on a temperature–composition diagram and determine the extent to which it fits the predictions for an ideal solution by calculating the activity coefficients of  $\text{O}_2$  at each composition.

**5.20** Phosphorus and sulfur form a series of binary compounds. The best characterized are  $\text{P}_4\text{S}_3$ ,  $\text{P}_4\text{S}_7$ , and  $\text{P}_4\text{S}_{10}$ , all of which melt congruently. Assuming that only these three binary compounds of the two elements exist, (a) draw schematically only the P/S phase diagram. Label each region of the diagram with the substance that exists in that region and indicate its phase. Label the horizontal axis as  $x_s$  and give the numerical values of  $x_s$  that correspond to the compounds. The melting point of pure phosphorus is 44°C and that of pure sulfur is 119°C. (b) Draw, schematically, the cooling curve for a mixture of composition  $x_s = 0.28$ . Assume that a eutectic occurs at  $x_s = 0.2$  and negligible solid–solid solubility.

**5.21** The table below gives the break and halt temperatures found in the cooling curves of two metals A and B. Construct a phase diagram consistent with the data of these curves. Label the regions of the diagram, stating what phases and substances are present. Give the probable formulas of any compounds that form.

| $100x_B$ | $\theta_{\text{break}}/^\circ\text{C}$ | $\theta_{\text{halt},1}/^\circ\text{C}$ | $\theta_{\text{halt},2}/^\circ\text{C}$ |
|----------|----------------------------------------|-----------------------------------------|-----------------------------------------|
| 0        |                                        | 1100                                    |                                         |
| 10.0     | 1060                                   | 700                                     |                                         |
| 20.0     | 1000                                   | 700                                     |                                         |
| 30.0     | 940                                    | 700                                     | 400                                     |
| 40.0     | 850                                    | 700                                     | 400                                     |
| 50.0     | 750                                    | 700                                     | 400                                     |
| 60.0     | 670                                    | 400                                     |                                         |
| 70.0     | 550                                    | 400                                     |                                         |
| 80.0     |                                        | 400                                     |                                         |
| 90.0     | 450                                    | 400                                     |                                         |
| 100.0    |                                        | 500                                     |                                         |

**5.22** Consider the phase diagram in Fig. 5.69, which represents a solid–liquid equilibrium. Label all regions of the diagram according to the chemical species that exist in that region and their phases. Indicate the number of species and phases present at the points labelled *b*, *d*, *e*, *f*, *g*, and *k*. Sketch cooling curves for compositions  $x_B = 0.16$ , 0.23, 0.57, 0.67, and 0.84.

Fig. 5.69

**5.23** Sketch the phase diagram for the Mg/Cu system using the following information:  $\theta_f(\text{Mg}) = 648^\circ\text{C}$ ,  $\theta_f(\text{Cu}) = 1085^\circ\text{C}$ ; two intermetallic compounds are formed with  $\theta_f(\text{MgCu}_2) = 800^\circ\text{C}$  and  $\theta_f(\text{Mg}_2\text{Cu}) = 580^\circ\text{C}$ ; eutectics of mass percentage Mg composition and melting points 10 per cent ( $690^\circ\text{C}$ ), 33 per cent ( $560^\circ\text{C}$ ), and 65 per cent ( $380^\circ\text{C}$ ). A sample of Mg/Cu alloy containing 25 per cent Mg by mass was prepared in a crucible heated to  $800^\circ\text{C}$  in an inert atmosphere. Describe what will be observed if the melt is cooled slowly to room temperature. Specify the composition and relative abundances of the phases and sketch the cooling curve.

**5.24‡** Figure 5.70 shows  $\Delta_{\text{mix}}G(x_B, T)$  for a mixture of copper and lead.

(a) What does the graph reveal about the miscibility of copper and lead and the spontaneity of solution formation? What is the variance ( $F$ ) at (i) 1500 K, (ii) 1100 K? (b) Suppose that at 1500 K a mixture of composition (i)  $x_{\text{Pb}} = 0.1$ , (ii)  $x_{\text{Pb}} = 0.7$ , is slowly cooled to 1100 K. What is the equilibrium composition of the final mixture? Include an estimate of the relative amounts of each phase. (c) What is the solubility of (i) lead in copper, (ii) copper in lead at 1100 K?

Fig. 5.70

**5.25‡** The temperature/composition diagram for the Ca/Si binary system is shown in Fig. 5.71. (a) Identify eutectics, congruent melting compounds, and incongruent melting compounds. (b) If a 20 per cent by atom composition melt of silicon at  $1500^\circ\text{C}$  is cooled to  $1000^\circ\text{C}$ , what phases (and phase composition) would be at equilibrium? Estimate the relative amounts of each phase. (c) Describe the equilibrium phases observed when an 80 per cent

Fig. 5.71

by atom composition Si melt is cooled to 1030°C. What phases, and relative amounts, would be at equilibrium at a temperature (i) slightly higher than 1030°C, (ii) slightly lower than 1030°C? Draw a graph of the mole percentages of both Si(s) and CaSi<sub>2</sub>(s) as a function of mole percentage of melt that is freezing at 1030°C.

**5.26** Iron(II) chloride (melting point 677°C) and potassium chloride (melting point 776°C) form the compounds KFeCl<sub>3</sub> and K<sub>2</sub>FeCl<sub>4</sub> at elevated temperatures. KFeCl<sub>3</sub> melts congruently at 399°C and K<sub>2</sub>FeCl<sub>4</sub> melts incongruently at 380°C. Eutectics are formed with compositions  $x = 0.38$  (melting point 351°C) and  $x = 0.54$  (melting point 393°C), where  $x$  is the mole fraction of FeCl<sub>2</sub>. The KCl solubility curve intersects the K<sub>2</sub>FeCl<sub>4</sub> curve at  $x = 0.34$ . Sketch the phase diagram. State the phases that are in equilibrium when a mixture of composition  $x = 0.36$  is cooled from 400°C to 300°C.

### Theoretical problems

**5.27** The excess Gibbs energy of a certain binary mixture is equal to  $gRTx(1-x)$  where  $g$  is a constant and  $x$  is the mole fraction of a solute A. Find an expression for the chemical potential of A in the mixture and sketch its dependence on the composition.

**5.28** Use the Gibbs–Duhem equation to derive the Gibbs–Duhem–Margules equation

$$\left( \frac{\partial \ln f_A}{\partial \ln x_A} \right)_{p,T} = \left( \frac{\partial \ln f_B}{\partial \ln x_B} \right)_{p,T}$$

where  $f$  is the fugacity. Use the relation to show that, when the fugacities are replaced by pressures, if Raoult's law applies to one component in a mixture then Henry's law must apply to the other.

**5.29** Use the Gibbs–Duhem equation to show that the partial molar volume (or any partial molar property) of a component B can be obtained if the partial molar volume (or other property) of A is known for all compositions up to the one of interest. Do this by proving that

$$V_B = V_B^* - \int_{V_A^*}^{V_A} \frac{x_A}{1-x_A} dV_A$$

Use the following data (which are for 298 K) to evaluate the integral graphically to find the partial molar volume of acetone at  $x = 0.500$ .

|                                      |       |       |       |       |       |       |       |
|--------------------------------------|-------|-------|-------|-------|-------|-------|-------|
| $x(\text{CHCl}_3)$                   | 0     | 0.194 | 0.385 | 0.559 | 0.788 | 0.889 | 1.000 |
| $V_m/(\text{cm}^3 \text{ mol}^{-1})$ | 73.99 | 75.29 | 76.50 | 77.55 | 79.08 | 79.82 | 80.67 |

**5.30** Use the Gibbs–Helmholtz equation to find an expression for  $d \ln x_A$  in terms of  $dT$ . Integrate  $d \ln x_A$  from  $x_A = 0$  to the value of interest, and integrate the right-hand side from the transition temperature for the pure liquid A to

the value in the solution. Show that, if the enthalpy of transition is constant, then eqns 5.31 and 5.34 are obtained.

**5.31** The osmotic coefficient  $\phi$  is defined as  $\phi = -(x_A/x_B) \ln a_A$ . By writing  $r = x_B/x_A$ , and using the Gibbs–Duhem equation, show that we can calculate the activity of B from the activities of A over a composition range by using the formula

$$\ln \left( \frac{a_B}{r} \right) = \phi - \phi(0) + \int_0^r \left( \frac{\phi-1}{r} \right) dr$$

**5.32** Show that the osmotic pressure of a real solution is given by  $\Pi V = -RT \ln a_A$ . Go on to show that, provided the concentration of the solution is low, this expression takes the form  $\Pi V = \phi RT[B]$  and hence that the osmotic coefficient  $\phi$  (which is defined in Problem 5.31) may be determined from osmometry.

**5.33** Show that the freezing-point depression of a real solution in which the solvent of molar mass  $M$  has activity  $a_A$  obeys

$$\frac{d \ln a_A}{d(\Delta T)} = -\frac{M}{K_f}$$

and use the Gibbs–Duhem equation to show that

$$\frac{d \ln a_B}{d(\Delta T)} = -\frac{1}{b_B K_f}$$

where  $a_B$  is the solute activity and  $b_B$  is its molality. Use the Debye–Hückel limiting law to show that the osmotic coefficient ( $\phi$ , Problem 5.31) is given by  $\phi = 1 - \frac{1}{3} A' I$  with  $A' = 2.303A$  and  $I = b/b^\circ$ .

### Applications: to biology and materials science

**5.34** Haemoglobin, the red blood protein responsible for oxygen transport, binds about 1.34 cm<sup>3</sup> of oxygen per gram. Normal blood has a haemoglobin concentration of 150 g dm<sup>-3</sup>. Haemoglobin in the lungs is about 97 per cent saturated with oxygen, but in the capillary is only about 75 per cent saturated. What volume of oxygen is given up by 100 cm<sup>3</sup> of blood flowing from the lungs in the capillary?

**5.35** For the calculation of the solubility  $c$  of a gas in a solvent, it is often convenient to use the expression  $c = Kp$ , where  $K$  is the Henry's law constant. Breathing air at high pressures, such as in scuba diving, results in an increased concentration of dissolved nitrogen. The Henry's law constant for the solubility of nitrogen is 0.18 μg/(g H<sub>2</sub>O atm). What mass of nitrogen is dissolved in 100 g of water saturated with air at 4.0 atm and 20°C? compare your answer to that for 100 g of water saturated with air at 1.0 atm. (Air is 78.08 mole per cent N<sub>2</sub>.) If nitrogen is four times as soluble in fatty tissues as in water, what is the increase in nitrogen concentration in fatty tissue in going from 1 atm to 4 atm?

**5.36** We saw in Impact I5.1 that dialysis may be used to study the binding of small molecules to macromolecules, such as an inhibitor to an enzyme, an antibiotic to DNA, and any other instance of cooperation or inhibition by small molecules attaching to large ones. To see how this is possible, suppose that inside the dialysis bag the molar concentration of the macromolecule M is  $[M]$  and the total concentration of small molecule A is  $[A]_{\text{in}}$ . This total concentration is the sum of the concentrations of free A and bound A, which we write  $[A]_{\text{free}}$  and  $[A]_{\text{bound}}$ , respectively. At equilibrium,  $\mu_{A,\text{free}} = \mu_{A,\text{out}}$ , which implies that  $[A]_{\text{free}} = [A]_{\text{out}}$ , provided the activity coefficient of A is the same in both solutions. Therefore, by measuring the concentration of A in the solution outside the bag, we can find the concentration of unbound A in the macromolecule solution and, from the difference  $[A]_{\text{in}} - [A]_{\text{free}} = [A]_{\text{in}} - [A]_{\text{out}}$ , the concentration of bound A. Now we explore the quantitative consequences of the experimental arrangement just described. (a) The average number of A molecules bound to M molecules,  $\nu$ , is

$$v = \frac{[A]_{\text{bound}}}{[M]} = \frac{[A]_{\text{in}} - [A]_{\text{out}}}{[M]}$$

The bound and unbound A molecules are in equilibrium,  $M + A \rightleftharpoons MA$ . Recall from introductory chemistry that we may write the equilibrium constant for binding,  $K$ , as

$$K = \frac{[MA]}{[M]_{\text{free}}[A]_{\text{free}}}$$

Now show that

$$K = \frac{v}{(1-v)[A]_{\text{out}}}$$

(b) If there are  $N$  identical and independent binding sites on each macromolecule, each macromolecule behaves like  $N$  separate smaller macromolecules, with the same value of  $K$  for each site. It follows that the average number of A molecules per site is  $v/N$ . Show that, in this case, we may write the *Scatchard equation*:

$$\frac{v}{[A]_{\text{out}}} = KN - Kv$$

(c) To apply the Scatchard equation, consider the binding of ethidium bromide (EB) to a short piece of DNA by a process called *intercalation*, in which the aromatic ethidium cation fits between two adjacent DNA base pairs. An equilibrium dialysis experiment was used to study the binding of ethidium bromide (EB) to a short piece of DNA. A  $1.00 \mu\text{mol dm}^{-3}$  aqueous solution of the DNA sample was dialysed against an excess of EB. The following data were obtained for the total concentration of EB:

| [EB]/( $\mu\text{mol dm}^{-3}$ ) |       |       |       |       |       |
|----------------------------------|-------|-------|-------|-------|-------|
| Side without DNA                 | 0.042 | 0.092 | 0.204 | 0.526 | 1.150 |
| Side with DNA                    | 0.292 | 0.590 | 1.204 | 2.531 | 4.150 |

From these data, make a Scatchard plot and evaluate the intrinsic equilibrium constant,  $K$ , and total number of sites per DNA molecule. Is the identical and independent sites model for binding applicable?

**5.37** The form of the Scatchard equation given in Problem 5.36 applies only when the macromolecule has identical and independent binding sites. For non-identical independent binding sites, the Scatchard equation is

$$\frac{v}{[A]_{\text{out}}} = \sum_i \frac{N_i K_i}{1 + K_i [A]_{\text{out}}}$$

Plot  $v/[A]$  for the following cases. (a) There are four independent sites on an enzyme molecule and the intrinsic binding constant is  $K = 1.0 \times 10^7$ . (b) There are a total of six sites per polymer. Four of the sites are identical and have an intrinsic binding constant of  $1 \times 10^5$ . The binding constants for the other two sites are  $2 \times 10^6$ .

**5.38** The addition of a small amount of a salt, such as  $(\text{NH}_4)_2\text{SO}_4$ , to a solution containing a charged protein increases the solubility of the protein in water. This observation is called the *salting-in effect*. However, the addition of large amounts of salt can decrease the solubility of the protein to such an extent that the protein precipitates from solution. This observation is called the *salting-out effect* and is used widely by biochemists to isolate and purify proteins. Consider the equilibrium  $\text{PX}_v(\text{s}) \rightleftharpoons \text{P}^{v+}(\text{aq}) + v \text{X}^-(\text{aq})$ , where  $\text{P}^{v+}$  is a polycationic protein of charge  $+v$  and  $\text{X}^-$  is its counter ion. Use Le Chatelier's principle and the physical principles behind the Debye-Hückel theory to provide a molecular interpretation for the salting-in and salting-out effects.

**5.39†** Polymer scientists often report their data in rather strange units. For example, in the determination of molar masses of polymers in solution by

osmometry, osmotic pressures are often reported in grams per square centimetre ( $\text{g cm}^{-2}$ ) and concentrations in grams per cubic centimetre ( $\text{g cm}^{-3}$ ). (a) With these choices of units, what would be the units of  $R$  in the van't Hoff equation? (b) The data in the table below on the concentration dependence of the osmotic pressure of polyisobutene in chlorobenzene at  $25^\circ\text{C}$  have been adapted from J. Leonard and H. Daoust (*J. Polymer Sci.* 57, 53 (1962)). From these data, determine the molar mass of polyisobutene by plotting  $\Pi/c$  against  $c$ . (c) Theta solvents are solvents for which the second osmotic coefficient is zero; for 'poor' solvents the plot is linear and for good solvents the plot is nonlinear. From your plot, how would you classify chlorobenzene as a solvent for polyisobutene? Rationalize the result in terms of the molecular structure of the polymer and solvent. (d) Determine the second and third osmotic virial coefficients by fitting the curve to the virial form of the osmotic pressure equation. (e) Experimentally, it is often found that the virial expansion can be represented as

$$\Pi/c = RT/M (1 + B'c + gB'^2c^2 + \dots)$$

and, in good solvents, the parameter  $g$  is often about 0.25. With terms beyond the second power ignored, obtain an equation for  $(\Pi/c)^{1/2}$  and plot this quantity against  $c$ . Determine the second and third virial coefficients from the plot and compare to the values from the first plot. Does this plot confirm the assumed value of  $g$ ?

|                                                      |        |       |       |       |       |      |
|------------------------------------------------------|--------|-------|-------|-------|-------|------|
| $10^{-2}(\Pi/c)/(\text{g cm}^{-2}/\text{g cm}^{-3})$ | 2.6    | 2.9   | 3.6   | 4.3   | 6.0   | 12.0 |
| $c/(\text{g cm}^{-3})$                               | 0.0050 | 0.010 | 0.020 | 0.033 | 0.057 | 0.10 |
| $10^{-2}(\Pi/c)/(\text{g cm}^{-2}/\text{g cm}^{-3})$ | 19.0   | 31.0  | 38.0  | 52    | 63    |      |
| $c/(\text{g cm}^{-3})$                               | 0.145  | 0.195 | 0.245 | 0.27  | 0.29  |      |

**5.40†** K. Sato, F.R. Eirich, and J.E. Mark (*J. Polymer Sci., Polym. Phys.* 14, 619 (1976)) have reported the data in the table below for the osmotic pressures of polychloroprene ( $\rho = 1.25 \text{ g cm}^{-3}$ ) in toluene ( $\rho = 0.858 \text{ g cm}^{-3}$ ) at  $30^\circ\text{C}$ . Determine the molar mass of polychloroprene and its second osmotic virial coefficient.

|                         |      |      |      |      |      |
|-------------------------|------|------|------|------|------|
| $c/(\text{mg cm}^{-3})$ | 1.33 | 2.10 | 4.52 | 7.18 | 9.87 |
| $\Pi/(\text{N m}^{-2})$ | 30   | 51   | 132  | 246  | 390  |

**5.41** The compound *p*-azoxyanisole forms a liquid crystal. 5.0 g of the solid was placed in a tube, which was then evacuated and sealed. Use the phase rule to prove that the solid will melt at a definite temperature and that the liquid crystal phase will make a transition to a normal liquid phase at a definite temperature.

**5.42** Some polymers can form liquid crystal mesophases with unusual physical properties. For example, liquid crystalline Kevlar (3) is strong enough to be the material of choice for bulletproof vests and is stable at temperatures up to 600 K. What molecular interactions contribute to the formation, thermal stability, and mechanical strength of liquid crystal mesophases in Kevlar?

# Chemical equilibrium

This chapter develops the concept of chemical potential and shows how it is used to account for the equilibrium composition of chemical reactions. The equilibrium composition corresponds to a minimum in the Gibbs energy plotted against the extent of reaction. By locating this minimum we establish the relation between the equilibrium constant and the standard Gibbs energy of reaction. The thermodynamic formulation of equilibrium enables us to establish the quantitative effects of changes in the conditions. The same principles can be applied to the description of the thermodynamic properties of reactions that take place in electrochemical cells, in which the reaction drives electrons through an external circuit. Thermodynamic arguments can be used to derive an expression for the electric potential of such cells and this potential can be related to their composition. There are two major topics developed in this connection. One is the definition and tabulation of standard potentials; the second is the use of these standard potentials to determine the equilibrium constants and other thermodynamic properties of chemical reactions.

Chemical reactions tend to move towards a dynamic equilibrium in which both reactants and products are present but have no further tendency to undergo net change. In some cases, the concentration of products in the equilibrium mixture is so much greater than that of the unchanged reactants that for all practical purposes the reaction is 'complete'. However, in many important cases the equilibrium mixture has significant concentrations of both reactants and products. In this chapter we see how to use thermodynamics to predict the equilibrium composition under any reaction conditions and understand the underlying molecular processes.

Because many reactions involve the transfer of electrons, they can be studied (and utilized) by allowing them to take place in an electrochemical cell. Electrochemistry is in part a major application of thermodynamic concepts to chemical equilibria as well as being of great technological importance. The final sections of the chapter show how to apply ideas relating to chemical equilibria to this vitally important field.

## Spontaneous chemical reactions

We have seen that the direction of spontaneous change at constant temperature and pressure is towards lower values of the Gibbs energy,  $G$ . The idea is entirely general, and in this chapter we apply it to the discussion of chemical reactions.

## 6.1 The Gibbs energy minimum

**Key points** (a) The reaction Gibbs energy is the slope of the plot of Gibbs energy against extent of reaction. (b) Reactions are either exergonic or endergonic.

We locate the equilibrium composition of a reaction mixture by calculating the Gibbs energy of the reaction mixture and identifying the composition that corresponds to minimum  $G$ . Here we proceed in two steps: first, we consider a very simple equilibrium, and then we generalize it.

### (a) The reaction Gibbs energy

Consider the equilibrium  $A \rightleftharpoons B$ . Even though this reaction looks trivial, there are many examples of it, such as the isomerization of pentane to 2-methylbutane and the conversion of L-alanine to D-alanine. Suppose an infinitesimal amount  $d\xi$  of A turns into B; then the change in the amount of A present is  $dn_A = -d\xi$  and the change in the amount of B present is  $dn_B = +d\xi$ . The quantity  $\xi$  (xi) is called the **extent of reaction**; it has the dimensions of amount of substance and is reported in moles. When the extent of reaction changes by a finite amount  $\Delta\xi$ , the amount of A present changes from  $n_{A,0}$  to  $n_{A,0} - \Delta\xi$  and the amount of B changes from  $n_{B,0}$  to  $n_{B,0} + \Delta\xi$ .

#### • A brief illustration

If initially 2.0 mol A is present and we wait until  $\Delta\xi = +1.5$  mol, then the amount of A remaining will be 0.5 mol. The amount of B formed will be 1.5 mol. •

The **reaction Gibbs energy**,  $\Delta_r G$ , is defined as the slope of the graph of the Gibbs energy plotted against the extent of reaction:

$$\Delta_r G = \left( \frac{\partial G}{\partial \xi} \right)_{p,T} \quad \text{Definition of reaction Gibbs energy} \quad (6.1)$$

Although  $\Delta$  normally signifies a *difference* in values, here it signifies a *derivative*, the slope of  $G$  with respect to  $\xi$ . However, to see that there is a close relationship with the normal usage, suppose the reaction advances by  $d\xi$ . The corresponding change in Gibbs energy is

$$dG = \mu_A dn_A + \mu_B dn_B = -\mu_A d\xi + \mu_B d\xi = (\mu_B - \mu_A) d\xi$$

This equation can be reorganized into

$$\left( \frac{\partial G}{\partial \xi} \right)_{p,T} = \mu_B - \mu_A$$

That is,

$$\Delta_r G = \mu_B - \mu_A \quad (6.2)$$

We see that  $\Delta_r G$  can also be interpreted as the difference between the chemical potentials (the partial molar Gibbs energies) of the reactants and products *at the composition of the reaction mixture*.

Because chemical potentials vary with composition, the slope of the plot of Gibbs energy against extent of reaction, and therefore the reaction Gibbs energy, changes as the reaction proceeds. The spontaneous direction of reaction lies in the direction of decreasing  $G$  (that is, down the slope of  $G$  plotted against  $\xi$ ). Thus we see from eqn 6.2 that the reaction  $A \rightarrow B$  is spontaneous when  $\mu_A > \mu_B$ , whereas the reverse reaction is spontaneous when  $\mu_B > \mu_A$ . The slope is zero, and the reaction is at equilibrium and spontaneous in neither direction, when

$$\Delta_r G = 0$$

Condition of  
equilibrium (6.3)

This condition occurs when  $\mu_B = \mu_A$  (Fig. 6.1). It follows that, if we can find the composition of the reaction mixture that ensures  $\mu_B = \mu_A$ , then we can identify the composition of the reaction mixture at equilibrium. Note that the chemical potential is now fulfilling the role its name suggests: it represents the potential for chemical change, and equilibrium is attained when these potentials are in balance.

### (b) Exergonic and endergonic reactions

We can express the spontaneity of a reaction at constant temperature and pressure in terms of the reaction Gibbs energy:

If  $\Delta_r G < 0$ , the forward reaction is spontaneous.

If  $\Delta_r G > 0$ , the reverse reaction is spontaneous.

If  $\Delta_r G = 0$ , the reaction is at equilibrium.

A reaction for which  $\Delta_r G < 0$  is called **exergonic** (from the Greek words for work-producing). The name signifies that, because the process is spontaneous, it can be used to drive another process, such as another reaction, or used to do non-expansion work. A simple mechanical analogy is a pair of weights joined by a string (Fig. 6.2): the lighter of the pair of weights will be pulled up as the heavier weight falls down. Although the lighter weight has a natural tendency to move downward, its coupling to the heavier weight results in it being raised. In biological cells, the oxidation of carbohydrates act as the heavy weight that drives other reactions forward and results in the formation of proteins from amino acids, muscle contraction, and brain activity. A reaction for which  $\Delta_r G > 0$  is called **endergonic** (signifying work-consuming). The reaction can be made to occur only by doing work on it, such as electrolysing water to reverse its spontaneous formation reaction.

#### IMPACT ON BIOCHEMISTRY

##### 16.1 Energy conversion in biological cells

The whole of life's activities depends on the coupling of exergonic and endergonic reactions, for the oxidation of food drives other reactions forward. In biological cells, the energy released by the oxidation of foods is stored in adenosine triphosphate (ATP, 1). The essence of the action of ATP is its ability to lose its terminal phosphate group by hydrolysis and to form adenosine diphosphate (ADP):

**Fig. 6.1** As the reaction advances (represented by motion from left to right along the horizontal axis) the slope of the Gibbs energy changes. Equilibrium corresponds to zero slope, at the foot of the valley.

**Fig. 6.2** If two weights are coupled as shown here, then the heavier weight will move the lighter weight in its non-spontaneous direction: overall, the process is still spontaneous. The weights are the analogues of two chemical reactions: a reaction with a large negative  $\Delta G$  can force another reaction with a less negative  $\Delta G$  to run in its non-spontaneous direction.

where  $P_i^-$  denotes an inorganic phosphate group, such as  $H_2PO_4^-$ . The biological standard values (Section 5.11d) for ATP hydrolysis at 37°C (310 K, blood temperature) are  $\Delta_r G^\ominus = -31 \text{ kJ mol}^{-1}$ ,  $\Delta_r H^\ominus = -20 \text{ kJ mol}^{-1}$ , and  $\Delta_r S^\ominus = +34 \text{ J K}^{-1} \text{ mol}^{-1}$ . The hydrolysis is therefore exergonic ( $\Delta_r G^\ominus < 0$ ) under these conditions and 31 kJ mol<sup>-1</sup> is available for driving other reactions. Moreover, because the reaction entropy is large, the reaction Gibbs energy is sensitive to temperature. In view of its exergonicity the ADP-phosphate bond has been called a ‘high-energy phosphate bond’. The name is intended to signify a high tendency to undergo reaction, and should not be confused with ‘strong’ bond. In fact, even in the biological sense it is not of very ‘high energy’. The action of ATP depends on it being intermediate in activity. Thus ATP acts as a phosphate donor to a number of acceptors (for example, glucose), but is recharged by more powerful phosphate donors in a number of biochemical processes.

The oxidation of glucose to  $CO_2$  and  $H_2O$  by  $O_2$  is an example of how the breakdown of foods is coupled to the formation of ATP in the cell. The process begins with *glycolysis*, a partial oxidation of glucose by nicotinamide adenine dinucleotide ( $NAD^+$ , 2) to pyruvate ion,  $CH_3COCO_2^-$ , continues with the *citric acid cycle*, which oxidizes pyruvate to  $CO_2$ , and ends with *oxidative phosphorylation*, which reduces  $O_2$  to  $H_2O$ . Glycolysis is the main source of energy during *anaerobic metabolism*, a form of metabolism in which inhaled  $O_2$  does not play a role. The citric acid cycle and oxidative phosphorylation are the main mechanisms for the extraction of energy from carbohydrates during *aerobic metabolism*, a form of metabolism in which inhaled  $O_2$  does play a role.

At blood temperature,  $\Delta_r G^\ominus = -147 \text{ kJ mol}^{-1}$  for the oxidation of glucose by  $NAD^+$  to pyruvate ions. The oxidation of one glucose molecule is coupled to the conversion of two ADP molecules to two ATP molecules, so the net reaction of glycolysis is

The standard reaction Gibbs energy is  $(-147) - 2(-31) \text{ kJ mol}^{-1} = -85 \text{ kJ mol}^{-1}$ ; the reaction is exergonic and can be used to drive other reactions.

The standard Gibbs energy of combustion of glucose is  $-2880 \text{ kJ mol}^{-1}$ , so terminating its oxidation at pyruvate is a poor use of resources. In the presence of  $O_2$ , pyruvate is oxidized further during the citric acid cycle:

where FAD is flavin adenine dinucleotide (3). The NADH and  $FADH_2$  go on to reduce  $O_2$  during oxidative phosphorylation, which also produces ATP. The citric acid cycle and oxidative phosphorylation generate as many as 38 ATP molecules for each glucose molecule consumed. Each mole of ATP molecules extracts 31 kJ from the 2880 kJ supplied by 1 mol  $C_6H_{12}O_6$  (180 g of glucose), so 1178 kJ is stored for later use. Therefore, aerobic oxidation of glucose is much more efficient than glycolysis.

In the cell, each ATP molecule can be used to drive an endergonic reaction for which  $\Delta_r G^\ominus$  does not exceed  $+31 \text{ kJ mol}^{-1}$ . (In an actual cell the composition may be far from standard, and the ATP reaction might be much more potent.) For example, the biosynthesis of sucrose from glucose and fructose can be driven by plant enzymes because the reaction is endergonic to the extent  $\Delta_r G^\ominus = +23 \text{ kJ mol}^{-1}$ . The biosynthesis of proteins is strongly endergonic, not only on account of the enthalpy change but also on account of the large decrease in entropy that occurs when many amino acids are assembled into a precisely determined sequence. For instance, the formation of a peptide link is endergonic, with  $\Delta_r G^\ominus = +17 \text{ kJ mol}^{-1}$ , but the biosynthesis occurs

indirectly and is equivalent to the consumption of three ATP molecules for each link. In a moderately small protein like myoglobin, with about 150 peptide links, the construction alone requires 450 ATP molecules, and therefore about 12 mol of glucose molecules for 1 mol of protein molecules.

## 6.2 The description of equilibrium

**Key points** (a) The reaction Gibbs energy depends logarithmically on the reaction quotient. When the reaction Gibbs energy is zero the reaction quotient has a value called the equilibrium constant. (b) The results are readily extended to a general reaction. (c) Under ideal conditions, the thermodynamic equilibrium constant may be approximated by expressing it in terms of concentrations and partial pressures. (d) The presence of the enthalpy and entropy contributions to  $K$  are related to the role of the Boltzmann distribution of molecules over the available states. (e) The biological standard state is defined at pH = 7.

With the background established, we are now ready to see how to apply thermodynamics to the description of chemical equilibrium.

### (a) Perfect gas equilibria

When A and B are perfect gases we can use eqn 5.14 ( $\mu = \mu^\ominus + RT \ln p$ , with  $p$  interpreted as  $p/p^\ominus$ ) to write

$$\begin{aligned}\Delta_r G &= \mu_B - \mu_A = (\mu_B^\ominus + RT \ln p_B) - (\mu_A^\ominus + RT \ln p_A) \\ &= \Delta_r G^\ominus + RT \ln \frac{p_B}{p_A}\end{aligned}\quad (6.4)^\circ$$

If we denote the ratio of partial pressures by  $Q$ , we obtain

$$\Delta_r G = \Delta_r G^\ominus + RT \ln Q \quad Q = \frac{p_B}{p_A} \quad (6.5)^\circ$$

The ratio  $Q$  is an example of a **reaction quotient**. It ranges from 0 when  $p_B = 0$  (corresponding to pure A) to infinity when  $p_A = 0$  (corresponding to pure B). The **standard reaction Gibbs energy**,  $\Delta_r G^\ominus$ , is defined (like the standard reaction enthalpy) as the difference in the standard molar Gibbs energies of the reactants and products. For our reaction

$$\Delta_r G^\ominus = G_m^\ominus(B) - G_m^\ominus(A) = \mu_B^\ominus - \mu_A^\ominus \quad (6.6)$$

Note that in the definition of  $\Delta_r G^\ominus$ , the  $\Delta_r$  has its normal meaning as the difference ‘products – reactants’. In Section 3.6 we saw that the difference in standard molar Gibbs energies of the products and reactants is equal to the difference in their standard Gibbs energies of formation, so in practice we calculate  $\Delta_r G^\ominus$  from

$$\Delta_r G^\ominus = \Delta_f G^\ominus(B) - \Delta_f G^\ominus(A) \quad (6.7)$$

At equilibrium  $\Delta_r G = 0$ . The ratio of partial pressures at equilibrium is denoted  $K$ , and eqn 6.5 becomes

$$0 = \Delta_r G^\ominus + RT \ln K$$

which rearranges to

$$RT \ln K = -\Delta_r G^\ominus \quad K = \left( \frac{p_B}{p_A} \right)_{\text{equilibrium}} \quad (6.8)^\circ$$

**Fig. 6.3** If the mixing of reactants and products is ignored, then the Gibbs energy changes linearly from its initial value (pure reactants) to its final value (pure products) and the slope of the line is  $\Delta_r G^\circ$ . However, as products are produced, there is a further contribution to the Gibbs energy arising from their mixing (lowest curve). The sum of the two contributions has a minimum. That minimum corresponds to the equilibrium composition of the system.

This relation is a special case of one of the most important equations in chemical thermodynamics: it is the link between tables of thermodynamic data, such as those in the *Data section* and the chemically important **equilibrium constant,  $K$** .

In molecular terms, the minimum in the Gibbs energy, which corresponds to  $\Delta_r G = 0$ , stems from the Gibbs energy of mixing of the two gases. To see the role of mixing, consider the reaction  $A \rightarrow B$ . If only the enthalpy were important, then  $H$  and therefore  $G$  would change linearly from its value for pure reactants to its value for pure products. The slope of this straight line is a constant and equal to  $\Delta_r G^\circ$  at all stages of the reaction and there is no intermediate minimum in the graph (Fig. 6.3). However, when we take entropy into account, there is an additional contribution to the Gibbs energy that is given by eqn 5.25 ( $\Delta_{\text{mix}} G = nRT(x_A \ln x_A + x_B \ln x_B)$ ). This expression makes a U-shaped contribution to the total change in Gibbs energy. As can be seen from Fig. 6.3, when it is included there is an intermediate minimum in the total Gibbs energy, and its position corresponds to the equilibrium composition of the reaction mixture.

We see from eqn 6.8 that, when  $\Delta_r G^\circ > 0$ ,  $K < 1$ . Therefore, at equilibrium the partial pressure of A exceeds that of B, which means that the reactant A is favoured in the equilibrium. When  $\Delta_r G^\circ < 0$ ,  $K > 1$ , so at equilibrium the partial pressure of B exceeds that of A. Now the product B is favoured in the equilibrium.

### (b) The general case of a reaction

We can now extend the argument that led to eqn 6.8 to a general reaction. We saw in Section 2.8a that a chemical reaction may be expressed symbolically in terms of stoichiometric numbers as

$$0 = \sum_J \nu_J J \quad \text{Symbolic form of a chemical equation} \quad (6.9)$$

where  $J$  denotes the substances and the  $\nu_J$  are the corresponding stoichiometric numbers in the chemical equation. In the reaction  $2A + B \rightarrow 3C + D$ , for instance, these numbers have the values  $\nu_A = -2$ ,  $\nu_B = -1$ ,  $\nu_C = +3$ , and  $\nu_D = +1$ . A stoichiometric number is positive for products and negative for reactants. We define the extent of reaction  $\xi$  so that, if it changes by  $\Delta\xi$ , then the change in the amount of any species  $J$  is  $\nu_J \Delta\xi$ .

With these points in mind and with the reaction Gibbs energy,  $\Delta_r G$ , defined in the same way as before (eqn 6.1) we show in the following *Justification* that the Gibbs energy of reaction can always be written

#### A note on good practice A

common remark is that ‘a reaction is spontaneous if  $\Delta_r G^\circ < 0$ ’. However, whether or not a reaction is spontaneous at a particular composition depends on the value of  $\Delta_r G$  at that composition, not  $\Delta_r G^\circ$ . It is far better to interpret the sign of  $\Delta_r G^\circ$  as indicating whether  $K$  is greater or smaller than 1. The forward reaction is spontaneous ( $\Delta_r G < 0$ ) when  $Q < K$  and the reverse reaction is spontaneous when  $Q > K$ .

$$\Delta_r G = \Delta_r G^\ominus + RT \ln Q \quad \text{Reaction Gibbs energy at an arbitrary stage} \quad (6.10)$$

with the standard reaction Gibbs energy calculated from

$$\Delta_r G^\ominus = \sum_{\text{Products}} \nu \Delta_f G^\ominus - \sum_{\text{Reactants}} \nu \Delta_f G^\ominus \quad \text{Procedure for calculating standard reaction Gibbs energy} \quad (6.11a)$$

where the  $\nu$  are the (positive) stoichiometric coefficients. More formally,

$$\Delta_r G^\ominus = \sum_J \nu_J \Delta_f G^\ominus(J) \quad \text{Formal expression} \quad (6.11b)$$

where the  $\nu_J$  are the (signed) stoichiometric numbers. The reaction quotient,  $Q$ , has the form

$$Q = \frac{\text{activities of products}}{\text{activities of reactants}} \quad \text{General form of reaction quotient} \quad (6.12a)$$

with each species raised to the power given by its stoichiometric coefficient. More formally, to write the general expression for  $Q$  we introduce the symbol  $\Pi$  to denote the product of what follows it (just as  $\Sigma$  denotes the sum), and define  $Q$  as

$$Q = \prod_J a_J^{\nu_J} \quad \text{Definition of reaction quotient} \quad (6.12b)$$

Because reactants have negative stoichiometric numbers, they automatically appear as the denominator when the product is written out explicitly. Recall from Table 5.3 that, for pure solids and liquids, the activity is 1, so such substances make no contribution to  $Q$  even though they may appear in the chemical equation.

### • A brief illustration

Consider the reaction  $2A + 3B \rightarrow C + 2D$ , in which case  $\nu_A = -2$ ,  $\nu_B = -3$ ,  $\nu_C = +1$ , and  $\nu_D = +2$ . The reaction quotient is then

$$Q = a_A^{-2} a_B^{-3} a_C a_D^2 = \frac{a_C a_D^2}{a_A^2 a_B^3} \quad \bullet$$

**Justification 6.1** *The dependence of the reaction Gibbs energy on the reaction quotient*

Consider a reaction with stoichiometric numbers  $\nu_J$ . When the reaction advances by  $d\xi$ , the amounts of reactants and products change by  $dn_J = \nu_J d\xi$ . The resulting infinitesimal change in the Gibbs energy at constant temperature and pressure is

$$dG = \sum_J \mu_J dn_J = \sum_J \mu_J \nu_J d\xi = \left( \sum_J \nu_J \mu_J \right) d\xi$$

It follows that

$$\Delta_r G = \left( \frac{\partial G}{\partial \xi} \right)_{p,T} = \sum_J \nu_J \mu_J$$

To make further progress, we note that the chemical potential of a species J is related to its activity by eqn 5.56 ( $\mu_J = \mu_J^\circ + RT \ln a_J$ ). When this expression is substituted into the expression above for  $\Delta_r G$  we obtain

$$\begin{aligned}\Delta_r G &= \overbrace{\sum_J \nu_J \mu_J^\circ}^{\Delta_r G^\circ} + RT \sum_J \nu_J \ln a_J \\ &= \Delta_r G^\circ + RT \sum_J \ln a_J^{\nu_J} = \Delta_r G^\circ + RT \ln \overbrace{\prod_J a_J^{\nu_J}}^Q \\ &= \Delta_r G^\circ + RT \ln Q\end{aligned}$$

with Q given by eqn 6.12b.

#### A brief comment

In the second line we use first  $a \ln x = \ln x^a$  and then  $\ln x + \ln y + \dots = \ln xy \dots$ , so

$$\sum_i \ln x_i = \ln \left( \prod_i x_i \right).$$

Now we conclude the argument, starting from eqn 6.10. At equilibrium, the slope of G is zero:  $\Delta_r G = 0$ . The activities then have their equilibrium values and we can write

$$K = \left( \prod_J a_J^{\nu_J} \right)_{\text{equilibrium}} \quad \text{Definition of equilibrium constant} \quad [6.13]$$

This expression has the same form as Q but is evaluated using equilibrium activities. From now on, we shall not write the ‘equilibrium’ subscript explicitly, and will rely on the context to make it clear that for K we use equilibrium values and for Q we use the values at the specified stage of the reaction. An equilibrium constant K expressed in terms of activities (or fugacities) is called a **thermodynamic equilibrium constant**. Note that, because activities are dimensionless numbers, the thermodynamic equilibrium constant is also dimensionless. In elementary applications, the activities that occur in eqn 6.13 are often replaced by:

- molalities, by replacing  $a_J$  by  $b_J/b^\circ$ , where  $b^\circ = 1 \text{ mol kg}^{-1}$
- molar concentrations, by replacing  $a_J$  by  $[J]/c^\circ$ , where  $c^\circ = 1 \text{ mol dm}^{-3}$
- partial pressures, by replacing  $a_J$  by  $p_J/p^\circ$ , where  $p^\circ = 1 \text{ bar}$

In such cases, the resulting expressions are only approximations. The approximation is particularly severe for electrolyte solutions, for in them activity coefficients differ from 1 even in very dilute solutions (Section 5.13).

#### • A brief illustration

The equilibrium constant for the heterogeneous equilibrium  $\text{CaCO}_3(\text{s}) \rightleftharpoons \text{CaO}(\text{s}) + \text{CO}_2(\text{g})$  is

$$K = a_{\text{CaCO}_3(\text{s})}^{-1} a_{\text{CaO}(\text{s})} a_{\text{CO}_2(\text{g})} = \frac{\overbrace{a_{\text{CaO}(\text{s})} a_{\text{CO}_2(\text{g})}}^1}{\underbrace{a_{\text{CaCO}_3(\text{s})}}_1} = a_{\text{CO}_2}$$

(Table 5.3). Provided the carbon dioxide can be treated as a perfect gas, we can go on to write

$$K \approx p_{\text{CO}_2}/p^\circ$$

and conclude that in this case the equilibrium constant is the numerical value of the decomposition vapour pressure of calcium carbonate. •

At this point we set  $\Delta_r G = 0$  in eqn 6.10 and replace  $Q$  by  $K$ . We immediately obtain

$$RT \ln K = -\Delta_r G^\ominus \quad \text{Thermodynamic equilibrium constant} \quad (6.14)$$

This is an exact and highly important thermodynamic relation, for it enables us to calculate the equilibrium constant of any reaction from tables of thermodynamic data, and hence to predict the equilibrium composition of the reaction mixture.

### A brief comment

In Chapter 16 we shall see that the right-hand side of eqn 6.14 may be expressed in terms of spectroscopic data for gas-phase species; so this expression also provides a link between spectroscopy and equilibrium composition.

#### Example 6.1 Calculating an equilibrium constant

Calculate the equilibrium constant for the ammonia synthesis reaction,  $\text{N}_2(\text{g}) + 3 \text{H}_2(\text{g}) \rightleftharpoons 2 \text{NH}_3(\text{g})$ , at 298 K and show how  $K$  is related to the partial pressures of the species at equilibrium when the overall pressure is low enough for the gases to be treated as perfect.

**Method** Calculate the standard reaction Gibbs energy from eqn 6.11 and convert it to the value of the equilibrium constant by using eqn 6.14. The expression for the equilibrium constant is obtained from eqn 6.13, and because the gases are taken to be perfect, we replace each activity by the ratio  $p_i/p^\ominus$ , where  $p_i$  is the partial pressure of species  $i$ .

**Answer** The standard Gibbs energy of the reaction is

$$\begin{aligned} \Delta_r G^\ominus &= 2\Delta_f G^\ominus(\text{NH}_3, \text{g}) - \{\Delta_f G^\ominus(\text{N}_2, \text{g}) + 3\Delta_f G^\ominus(\text{H}_2, \text{g})\} \\ &= 2\Delta_f G^\ominus(\text{NH}_3, \text{g}) = 2 \times (-16.5 \text{ kJ mol}^{-1}) \end{aligned}$$

Then,

$$\ln K = -\frac{2 \times (-16.5 \times 10^3 \text{ J mol}^{-1})}{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})} = \frac{2 \times 16.5 \times 10^3}{8.3145 \times 298}$$

Hence,  $K = 6.1 \times 10^5$ . This result is thermodynamically exact. The thermodynamic equilibrium constant for the reaction is

$$K = \frac{a_{\text{NH}_3}^2}{a_{\text{N}_2} a_{\text{H}_2}^3}$$

and this ratio has the value we have just calculated. At low overall pressures, the activities can be replaced by the ratios  $p_i/p^\ominus$  and an approximate form of the equilibrium constant is

$$K = \frac{(p_{\text{NH}_3}/p^\ominus)^2}{(p_{\text{N}_2}/p^\ominus)(p_{\text{H}_2}/p^\ominus)^3} = \frac{p_{\text{NH}_3}^2/p^{\ominus 2}}{p_{\text{N}_2} p_{\text{H}_2}^3}$$

**Self-test 6.1** Evaluate the equilibrium constant for  $\text{N}_2\text{O}_4(\text{g}) \rightleftharpoons 2 \text{NO}_2(\text{g})$  at 298 K. [ $K = 0.15$ ]

#### Example 6.2 Estimating the degree of dissociation at equilibrium

The *degree of dissociation* (or *extent of dissociation*,  $\alpha$ ) is defined as the fraction of reactant that has decomposed; if the initial amount of reactant is  $n$  and the amount at equilibrium is  $n_{\text{eq}}$ , then  $\alpha = (n - n_{\text{eq}})/n$ . The standard reaction Gibbs energy for the decomposition  $\text{H}_2\text{O}(\text{g}) \rightarrow \text{H}_2(\text{g}) + \frac{1}{2} \text{O}_2(\text{g})$  is  $+118.08 \text{ kJ mol}^{-1}$  at 2300 K. What is the degree of dissociation of  $\text{H}_2\text{O}$  at 2300 K and 1.00 bar?

**Method** The equilibrium constant is obtained from the standard Gibbs energy of reaction by using eqn 6.14, so the task is to relate the degree of dissociation,  $\alpha$ , to  $K$  and then to find its numerical value. Proceed by expressing the equilibrium compositions in terms of  $\alpha$ , and solve for  $\alpha$  in terms of  $K$ . Because the standard reaction Gibbs energy is large and positive, we can anticipate that  $K$  will be small, and hence that  $\alpha \ll 1$ , which opens the way to making approximations to obtain its numerical value.

**Answer** The equilibrium constant is obtained from eqn 6.14 in the form

$$\begin{aligned}\ln K &= -\frac{\Delta_r G^\ominus}{RT} = -\frac{(+118.08 \times 10^3 \text{ J mol}^{-1})}{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (2300 \text{ K})} \\ &= -\frac{118.08 \times 10^3}{8.3145 \times 2300}\end{aligned}$$

It follows that  $K = 2.08 \times 10^{-3}$ . The equilibrium composition can be expressed in terms of  $\alpha$  by drawing up the following table:

|                             | H <sub>2</sub> O                          | H <sub>2</sub>                         | O <sub>2</sub>                                    |                                 |
|-----------------------------|-------------------------------------------|----------------------------------------|---------------------------------------------------|---------------------------------|
| Initial amount              | $n$                                       | 0                                      | 0                                                 |                                 |
| Change to reach equilibrium | $-\alpha n$                               | $+\alpha n$                            | $+\frac{1}{2}\alpha n$                            |                                 |
| Amount at equilibrium       | $(1-\alpha)n$                             | $\alpha n$                             | $\frac{1}{2}\alpha n$                             | Total: $(1+\frac{1}{2}\alpha)n$ |
| Mole fraction, $x_j$        | $\frac{1-\alpha}{1+\frac{1}{2}\alpha}$    | $\frac{\alpha}{1+\frac{1}{2}\alpha}$   | $\frac{\frac{1}{2}\alpha}{1+\frac{1}{2}\alpha}$   |                                 |
| Partial pressure, $p_j$     | $\frac{(1-\alpha)p}{1+\frac{1}{2}\alpha}$ | $\frac{\alpha p}{1+\frac{1}{2}\alpha}$ | $\frac{\frac{1}{2}\alpha p}{1+\frac{1}{2}\alpha}$ |                                 |

where, for the entries in the last row, we have used  $p_j = x_j p$  (eqn 1.13). The equilibrium constant is therefore

$$K = \frac{p_{\text{H}_2} p_{\text{O}_2}^{1/2}}{p_{\text{H}_2\text{O}}} = \frac{\alpha^{3/2} p^{1/2}}{(1-\alpha)(2+\alpha)^{1/2}}$$

In this expression, we have written  $p$  in place of  $p/p^\ominus$ , to simplify its appearance. Now make the approximation that  $\alpha \ll 1$ , and hence obtain

$$K \approx \frac{\alpha^{3/2} p^{1/2}}{2^{1/2}}$$

Under the stated condition,  $p = 1.00$  bar (that is,  $p/p^\ominus = 1.00$ ), so  $\alpha \approx (2^{1/2} K)^{2/3} = 0.0205$ . That is, about 2 per cent of the water has decomposed.

**A note on good practice** Always check that the approximation is consistent with the final answer. In this case  $\alpha \ll 1$  in accord with the original assumption.

**Self-test 6.2** Given that the standard Gibbs energy of reaction at 2000 K is +135.2 kJ mol<sup>-1</sup> for the same reaction, suppose that steam at 200 kPa is passed through a furnace tube at that temperature. Calculate the mole fraction of O<sub>2</sub> present in the output gas stream. [0.00221]

### (c) The relation between equilibrium constants

Equilibrium constants in terms of activities are exact, but it is often necessary to relate them to concentrations. Formally, we need to know the activity coefficients, and then to use  $a_j = \gamma_j x_j$ ,  $a_j = \gamma_j b_j/b^\ominus$ , or  $a_j = [J]/c^\ominus$ , where  $x_j$  is a mole fraction,  $b_j$  is a molality,

and  $[J]$  is a molar concentration. For example, if we were interested in the composition in terms of molality for an equilibrium of the form  $A + B \rightleftharpoons C + D$ , where all four species are solutes, we would write

$$K = \frac{a_C a_D}{a_A a_B} = \frac{\gamma_C \gamma_D}{\gamma_A \gamma_B} \times \frac{b_C b_D}{b_A b_B} = K_\gamma K_b \quad (6.15)$$

The activity coefficients must be evaluated at the equilibrium composition of the mixture (for instance, by using one of the Debye–Hückel expressions, Section 5.13b), which may involve a complicated calculation, because the activity coefficients are known only if the equilibrium composition is already known. In elementary applications, and to begin the iterative calculation of the concentrations in a real example, the assumption is often made that the activity coefficients are all so close to unity that  $K_\gamma = 1$ . Then we obtain the result widely used in elementary chemistry that  $K \approx K_b$ , and equilibria are discussed in terms of molalities (or molar concentrations) themselves.

A special case arises when we need to express the equilibrium constant of a gas-phase reaction in terms of molar concentrations instead of the partial pressures that appear in the thermodynamic equilibrium constant. Provided we can treat the gases as perfect, the  $p_j$  that appear in  $K$  can be replaced by  $[J]RT$ , and

$$K = \prod_j (a_j)^{v_j} = \prod_j \left( \frac{p_j}{p^\ominus} \right)^{v_j} = \prod_j [J]^{v_j} \left( \frac{RT}{p^\ominus} \right)^{v_j} = \prod_j [J]^{v_j} \times \prod_j \left( \frac{RT}{p^\ominus} \right)^{v_j}$$

The (dimensionless) equilibrium constant  $K_c$  is defined as

$$K_c = \prod_j \left( \frac{[J]}{c^\ominus} \right)^{v_j} \quad \text{Definition of } K_c \text{ for gas-phase reactions} \quad [6.16]$$

It follows that

$$K = K_c \times \prod_j \left( \frac{c^\ominus RT}{p^\ominus} \right)^{v_j} \quad (6.17a)$$

If now we write  $\Delta v = \sum_j v_j$ , which is easier to think of as  $v(\text{products}) - v(\text{reactants})$ , then the relation between  $K$  and  $K_c$  for a gas-phase reaction is

$$K = K_c \times \left( \frac{c^\ominus RT}{p^\ominus} \right)^{\Delta v} \quad \text{Relation between } K \text{ and } K_c \text{ for gas-phase reactions} \quad (6.17b)$$

The term in parentheses works out as  $T/(12.03 \text{ K})$ .

### • A brief illustration

For the reaction  $N_2(g) + 3 H_2(g) \rightarrow 2 NH_3(g)$ ,  $\Delta v = 2 - 4 = -2$ , so

$$K = K_c \times \left( \frac{T}{12.03 \text{ K}} \right)^{-2} = K_c \times \left( \frac{12.03 \text{ K}}{T} \right)^2$$

At 298.15 K the relation is

$$K = K_c \times \left( \frac{12.03 \text{ K}}{298.15 \text{ K}} \right)^2 = \frac{K_c}{614.2}$$

so  $K_c = 614.2K$ . Note that both  $K$  and  $K_c$  are dimensionless. •

**Fig. 6.4** The Boltzmann distribution of populations over the energy levels of two species A and B with similar densities of energy levels; the reaction  $A \rightarrow B$  is endothermic in this example. The bulk of the population is associated with the species A, so that species is dominant at equilibrium.

**Fig. 6.5** Even though the reaction  $A \rightarrow B$  is endothermic, the density of energy levels in B is so much greater than that in A that the population associated with B is greater than that associated with A, so B is dominant at equilibrium.

#### (d) Molecular interpretation of the equilibrium constant

We can obtain a deeper insight into the origin and significance of the equilibrium constant by considering the Boltzmann distribution of molecules over the available states of a system composed of reactants and products (*Fundamentals F.5a*). When atoms can exchange partners, as in a reaction, the available states of the system include arrangements in which the atoms are present in the form of reactants and in the form of products: these arrangements have their characteristic sets of energy levels, but the Boltzmann distribution does not distinguish between their identities, only their energies. The atoms distribute themselves over both sets of energy levels in accord with the Boltzmann distribution (Fig. 6.4). At a given temperature, there will be a specific distribution of populations, and hence a specific composition of the reaction mixture.

It can be appreciated from the illustration that, if the reactants and products both have similar arrays of molecular energy levels, then the dominant species in a reaction mixture at equilibrium will be the species with the lower set of energy levels. However, the fact that the Gibbs energy occurs in the expression is a signal that entropy plays a role as well as energy. Its role can be appreciated by referring to Fig. 6.5. We see that, although the B energy levels lie higher than the A energy levels, in this instance they are much more closely spaced. As a result, their total population may be considerable and B could even dominate in the reaction mixture at equilibrium. Closely spaced energy levels correlate with a high entropy (Section 3.2b), so in this case we see that entropy effects dominate adverse energy effects. This competition is mirrored in eqn 6.14, as can be seen most clearly by using  $\Delta_r G^\ominus = \Delta_r H^\ominus - T\Delta_r S^\ominus$  and writing it in the form

$$K = e^{-\Delta_r H^\ominus/RT} e^{\Delta_r S^\ominus/R} \quad (6.18)$$

Note that a positive reaction enthalpy results in a lowering of the equilibrium constant (that is, an endothermic reaction can be expected to have an equilibrium composition that favours the reactants). However, if there is positive reaction entropy, then the equilibrium composition may favour products, despite the endothermic character of the reaction.

#### (e) Equilibria in biological systems

We saw in Section 5.11d that for biological systems it is appropriate to adopt the biological standard state, in which  $a_{H^+} = 10^{-7}$  and  $pH = -\log a_{H^+} = 7$ . The relation between the thermodynamic and biological standard Gibbs energies of reaction for a reaction of the form

can be found by using eqn. 5.63. First, the general expression for the reaction Gibbs energy of this reaction is

$$\Delta_r G = \Delta_r G^\ominus + RT \ln \frac{a_P}{a_R a_{H^+}^\nu} = \Delta_r G^\ominus + RT \ln \frac{a_P}{a_R} - \nu RT \ln a_{H^+}$$

In the biological standard state, both P and R are at unit activity. Therefore, by using  $\ln x = \ln 10 \log x$ , this expression becomes

$$\Delta_r G = \Delta_r G^\ominus - \nu RT \ln 10 \log a_{H^+} = \Delta_r G^\ominus + \nu RT \ln 10 \, pH$$

For the full specification of the biological state, we set  $pH = 7$ , and hence obtain

$$\Delta_r G^\oplus = \Delta_r G^\ominus + 7\nu RT \ln 10$$

Conversion to biological  
standard value

$$(6.19b)$$

Note that there is no difference between the two standard values if hydrogen ions are not involved in the reaction ( $\nu = 0$ ).

• **A brief illustration**

Consider the reaction  $\text{NADH}(\text{aq}) + \text{H}^+(\text{aq}) \rightarrow \text{NAD}^+(\text{aq}) + \text{H}_2(\text{g})$  at  $37^\circ\text{C}$ , for which  $\Delta_r G^\ominus = -21.8 \text{ kJ mol}^{-1}$ . It follows that, because  $\nu = 1$  and  $7 \ln 10 = 16.1$ ,

$$\begin{aligned}\Delta_r G^\oplus &= -21.8 \text{ kJ mol}^{-1} + 16.1 \times (8.3145 \times 10^{-3} \text{ kJ K}^{-1} \text{ mol}^{-1}) \times (310 \text{ K}) \\ &= +19.7 \text{ kJ mol}^{-1}\end{aligned}$$

Note that the biological standard value is opposite in sign (in this example) to the thermodynamic standard value: the much lower concentration of hydronium ions (by seven orders of magnitude) at  $\text{pH} = 7$  in place of  $\text{pH} = 0$ , has resulted in the reverse reaction becoming spontaneous under the new standard conditions. •

**Self-test 6.3** For a particular reaction of the form  $\text{A} \rightarrow \text{B} + 2 \text{H}^+$  in aqueous solution, it was found that  $\Delta_r G^\ominus = +20 \text{ kJ mol}^{-1}$  at  $28^\circ\text{C}$ . Estimate the value of  $\Delta_r G^\oplus$ .  
[ $-61 \text{ kJ mol}^{-1}$ ]

## The response of equilibria to the conditions

Equilibria respond to changes in pressure, temperature, and concentrations of reactants and products. The equilibrium constant for a reaction is not affected by the presence of a catalyst or an enzyme (a biological catalyst). As we shall see in detail in Chapter 22, catalysts increase the rate at which equilibrium is attained but do not affect its position. However, it is important to note that in industry reactions rarely reach equilibrium, partly on account of the rates at which reactants mix.

### 6.3 How equilibria respond to changes of pressure

**Key point** The thermodynamic equilibrium constant is independent of pressure. The response of composition to changes in the conditions is summarized by Le Chatelier's principle.

The equilibrium constant depends on the value of  $\Delta_r G^\ominus$ , which is defined at a single, standard pressure. The value of  $\Delta_r G^\ominus$ , and hence of  $K$ , is therefore independent of the pressure at which the equilibrium is actually established. In other words, at a given temperature  $K$  is a constant.

The conclusion that  $K$  is independent of pressure does not necessarily mean that the equilibrium composition is independent of the pressure, and its effect depends on how the pressure is applied. The pressure within a reaction vessel can be increased by injecting an inert gas into it. However, so long as the gases are perfect, this addition of gas leaves all the partial pressures of the reacting gases unchanged: the partial pressure of a perfect gas is the pressure it would exert if it were alone in the container, so the presence of another gas has no effect. It follows that pressurization by the addition of an inert gas has no effect on the equilibrium composition of the system (provided the gases are perfect). Alternatively, the pressure of the system may be increased by confining the gases to a smaller volume (that is, by compression). Now the individual partial pressures are changed but their ratio (as it appears in the equilibrium constant) remains the same. Consider, for instance, the perfect gas equilibrium  $\text{A} \rightleftharpoons 2 \text{B}$ , for which the equilibrium constant is

**Fig. 6.6** When a reaction at equilibrium is compressed (from *a* to *b*), the reaction responds by reducing the number of molecules in the gas phase (in this case by producing the dimers represented by the linked spheres).

**Fig. 6.7** The pressure dependence of the degree of dissociation,  $\alpha$ , at equilibrium for an  $A(g) \rightleftharpoons 2B(g)$  reaction for different values of the equilibrium constant  $K$ . The value  $\alpha = 0$  corresponds to pure A;  $\alpha = 1$  corresponds to pure B.

$$K = \frac{p_B^2}{p_A p^\ominus}$$

The right-hand side of this expression remains constant only if an increase in  $p_A$  cancels an increase in the *square* of  $p_B$ . This relatively steep increase of  $p_A$  compared to  $p_B$  will occur if the equilibrium composition shifts in favour of A at the expense of B. Then the number of A molecules will increase as the volume of the container is decreased and its partial pressure will rise more rapidly than can be ascribed to a simple change in volume alone (Fig. 6.6).

The increase in the number of A molecules and the corresponding decrease in the number of B molecules in the equilibrium  $A \rightleftharpoons 2B$  is a special case of a principle proposed by the French chemist Henri Le Chatelier, which states that:

A system at equilibrium, when subjected to a disturbance, responds in a way that tends to minimize the effect of the disturbance.

Le Chatelier's principle

The principle implies that, if a system at equilibrium is compressed, then the reaction will adjust so as to minimize the increase in pressure. This it can do by reducing the number of particles in the gas phase, which implies a shift  $A \leftarrow 2B$ .

To treat the effect of compression quantitatively, we suppose that there is an amount  $n$  of A present initially (and no B). At equilibrium the amount of A is  $(1 - \alpha)n$  and the amount of B is  $2\alpha n$ , where  $\alpha$  is the degree of dissociation of A into 2B. It follows that the mole fractions present at equilibrium are

$$x_A = \frac{(1 - \alpha)n}{(1 - \alpha)n + 2\alpha n} = \frac{1 - \alpha}{1 + \alpha} \quad x_B = \frac{2\alpha}{1 + \alpha}$$

The equilibrium constant for the reaction is

$$K = \frac{p_B^2}{p_A p^\ominus} = \frac{x_B^2 p^2}{x_A p p^\ominus} = \frac{4\alpha^2 (p/p^\ominus)}{1 - \alpha^2}$$

which rearranges to

$$\alpha = \left( \frac{1}{1 + 4p/Kp^\ominus} \right)^{1/2} \quad (6.20)$$

This formula shows that, even though  $K$  is independent of pressure, the amounts of A and B do depend on pressure (Fig. 6.7). It also shows that, as  $p$  is increased,  $\alpha$  decreases, in accord with Le Chatelier's principle.

#### • A brief illustration

To predict the effect of an increase in pressure on the composition of the ammonia synthesis at equilibrium (see Example 6.1), we note that the number of gas molecules decreases (from 4 to 2). So, Le Chatelier's principle predicts that an increase in pressure will favour the product. The equilibrium constant is

$$K = \frac{p_{\text{NH}_3}^2 p^\ominus^2}{p_{\text{N}_2} p_{\text{H}_2}^3} = \frac{x_{\text{NH}_3}^2 p^2 p^\ominus^2}{x_{\text{N}_2} x_{\text{H}_2}^3 p^4} = \frac{K_x p^\ominus^2}{p^2}$$

where  $K_x$  is the part of the equilibrium constant expression that contains the equilibrium mole fractions of reactants and products (note that, unlike  $K$  itself,  $K_x$  is not an equilibrium constant). Therefore, doubling the pressure must increase  $K_x$  by a factor of 4 to preserve the value of  $K$ . •

**Self-test 6.4** Predict the effect of a tenfold pressure increase on the equilibrium composition of the reaction  $3 \text{N}_2(\text{g}) + \text{H}_2(\text{g}) \rightarrow 2 \text{N}_3\text{H}(\text{g})$ .

[100-fold increase in  $K_x$ ]

## 6.4 The response of equilibria to changes of temperature

**Key points** (a) The dependence of the equilibrium constant on the temperature is expressed by the van't Hoff equation and can be explained in terms of the distribution of molecules over the available states. (b) Integration of the van't Hoff equation gives an expression that relates the equilibrium constant to temperature.

Le Chatelier's principle predicts that a system at equilibrium will tend to shift in the endothermic direction if the temperature is raised, for then energy is absorbed as heat and the rise in temperature is opposed. Conversely, an equilibrium can be expected to shift in the exothermic direction if the temperature is lowered, for then energy is released and the reduction in temperature is opposed. These conclusions can be summarized as follows:

Exothermic reactions: increased temperature favours the reactants.

Endothermic reactions: increased temperature favours the products.

We shall now justify these remarks and see how to express the changes quantitatively.

### (a) The van't Hoff equation

The **van't Hoff equation**, which is derived in the *Justification* below, is an expression for the slope of a plot of the equilibrium constant (specifically,  $\ln K$ ) as a function of temperature. It may be expressed in either of two ways:

$$(a) \frac{d \ln K}{dT} = \frac{\Delta_r H^\ominus}{RT^2} \quad (b) \frac{d \ln K}{d(1/T)} = -\frac{\Delta_r H^\ominus}{R} \quad \text{van't Hoff equation} \quad (6.21)$$

#### Justification 6.2 The van't Hoff equation

From eqn 6.14, we know that

$$\ln K = -\frac{\Delta_r G^\ominus}{RT}$$

Differentiation of  $\ln K$  with respect to temperature then gives

$$\frac{d \ln K}{dT} = -\frac{1}{R} \frac{d(\Delta_r G^\ominus/T)}{dT}$$

The differentials are complete (that is, they are not partial derivatives) because  $K$  and  $\Delta_r G^\ominus$  depend only on temperature, not on pressure. To develop this equation we use the Gibbs–Helmholtz equation (eqn 3.56) in the form

$$\frac{d(\Delta_r G^\ominus/T)}{dT} = -\frac{\Delta_r H^\ominus}{T^2}$$

where  $\Delta_r H^\ominus$  is the standard reaction enthalpy at the temperature  $T$ . Combining the two equations gives the van't Hoff equation, eqn 6.21a. The second form of the equation is obtained by noting that

$$\frac{d(1/T)}{dT} = -\frac{1}{T^2}, \quad \text{so} \quad dT = -T^2 d(1/T)$$

It follows that eqn 6.21a can be rewritten as

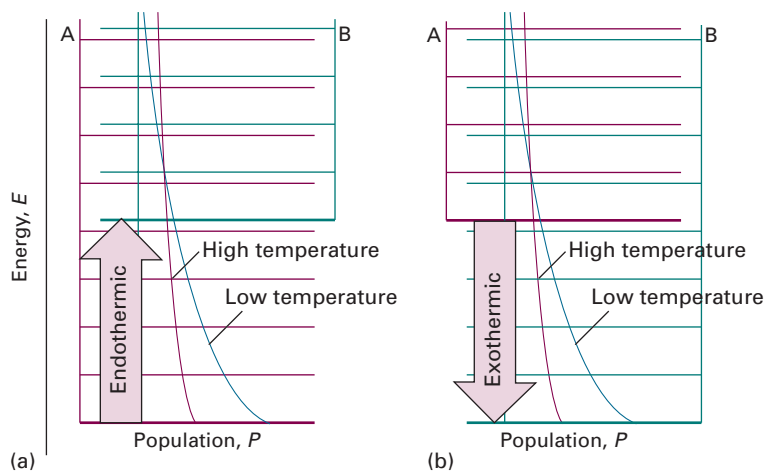

$$-\frac{d \ln K}{T^2 d(1/T)} = \frac{\Delta_r H^\circ}{RT^2}$$

which simplifies into eqn 6.21b.

Equation 6.21a shows that  $d \ln K/dT < 0$  (and therefore that  $dK/dT < 0$ ) for a reaction that is exothermic under standard conditions ( $\Delta_r H^\circ < 0$ ). A negative slope means that  $\ln K$ , and therefore  $K$  itself, decreases as the temperature rises. Therefore, as asserted above, in the case of an exothermic reaction the equilibrium shifts away from products. The opposite occurs in the case of endothermic reactions.

Insight into the thermodynamic basis of this behaviour comes from the expression  $\Delta_r G^\circ = \Delta_r H^\circ - T\Delta_r S^\circ$  written in the form  $-\Delta_r G^\circ/T = -\Delta_r H^\circ/T + \Delta_r S^\circ$ . When the reaction is exothermic,  $-\Delta_r H^\circ/T$  corresponds to a positive change of entropy of the surroundings and favours the formation of products. When the temperature is raised,  $-\Delta_r H^\circ/T$  decreases, and the increasing entropy of the surroundings has a less important role. As a result, the equilibrium lies less to the right. When the reaction is endothermic, the principal factor is the increasing entropy of the reaction system. The importance of the unfavourable change of entropy of the surroundings is reduced if the temperature is raised (because then  $-\Delta_r H^\circ/T$  is smaller), and the reaction is able to shift towards products.

These remarks have a molecular basis that stems from the Boltzmann distribution of molecules over the available energy levels (*Fundamentals F.5a*). The typical arrangement of energy levels for an endothermic reaction is shown in Fig. 6.8a. When the temperature is increased, the Boltzmann distribution adjusts and the populations change as shown. The change corresponds to an increased population of the higher energy states at the expense of the population of the lower energy states. We see that the states that arise from the B molecules become more populated at the expense of the A molecules. Therefore, the total population of B states increases, and B becomes more abundant in the equilibrium mixture. Conversely, if the reaction is exothermic (Fig. 6.8b), then an increase in temperature increases the population of the A states (which start at higher energy) at the expense of the B states, so the reactants become more abundant.

**Fig. 6.8** The effect of temperature on a chemical equilibrium can be interpreted in terms of the change in the Boltzmann distribution with temperature and the effect of that change in the population of the species. (a) In an endothermic reaction, the population of B increases at the expense of A as the temperature is raised. (b) In an exothermic reaction, the opposite happens.

**Example 6.3** *Measuring a reaction enthalpy*

The data below show the temperature variation of the equilibrium constant of the reaction  $\text{Ag}_2\text{CO}_3(\text{s}) \rightleftharpoons \text{Ag}_2\text{O}(\text{s}) + \text{CO}_2(\text{g})$ . Calculate the standard reaction enthalpy of the decomposition.

|              |                       |                       |                       |      |
|--------------|-----------------------|-----------------------|-----------------------|------|
| $T/\text{K}$ | 350                   | 400                   | 450                   | 500  |
| $K$          | $3.98 \times 10^{-4}$ | $1.41 \times 10^{-2}$ | $1.86 \times 10^{-1}$ | 1.48 |

**Method** It follows from eqn 6.21b that, provided the reaction enthalpy can be assumed to be independent of temperature, a plot of  $-\ln K$  against  $1/T$  should be a straight line of slope  $\Delta_r H^\circ/R$ .

**Answer** We draw up the following table:

|                      |      |      |      |       |
|----------------------|------|------|------|-------|
| $T/\text{K}$         | 350  | 400  | 450  | 500   |
| $(10^3 \text{ K})/T$ | 2.86 | 2.50 | 2.22 | 2.00  |
| $-\ln K$             | 7.83 | 4.26 | 1.68 | -0.39 |

These points are plotted in Fig. 6.9. The slope of the graph is  $+9.6 \times 10^3$ , so

$$\Delta_r H^\circ = (+9.6 \times 10^3 \text{ K}) \times R = +80 \text{ kJ mol}^{-1}$$

**Self-test 6.5** The equilibrium constant of the reaction  $2 \text{SO}_2(\text{g}) + \text{O}_2(\text{g}) \rightleftharpoons 2 \text{SO}_3(\text{g})$  is  $4.0 \times 10^{24}$  at 300 K,  $2.5 \times 10^{10}$  at 500 K, and  $3.0 \times 10^4$  at 700 K. Estimate the reaction enthalpy at 500 K.  $[-200 \text{ kJ mol}^{-1}]$

The temperature dependence of the equilibrium constant provides a non-calorimetric method of determining  $\Delta_r H^\circ$ . A drawback is that the reaction enthalpy is actually temperature-dependent, so the plot is not expected to be perfectly linear. However, the temperature dependence is weak in many cases, so the plot is reasonably straight. In practice, the method is not very accurate, but it is often the only method available.

**(b) The value of  $K$  at different temperatures**

To find the value of the equilibrium constant at a temperature  $T_2$  in terms of its value  $K_1$  at another temperature  $T_1$ , we integrate eqn 6.21b between these two temperatures:

$$\ln K_2 - \ln K_1 = -\frac{1}{R} \int_{1/T_1}^{1/T_2} \Delta_r H^\circ d(1/T) \quad (6.22)$$

If we suppose that  $\Delta_r H^\circ$  varies only slightly with temperature over the temperature range of interest, then we may take it outside the integral. It follows that

$$\ln K_2 - \ln K_1 = -\frac{\Delta_r H^\circ}{R} \left( \frac{1}{T_2} - \frac{1}{T_1} \right) \quad (6.23)$$

Temperature  
dependence of  $K$

**• A brief illustration**

To estimate the equilibrium constant for the synthesis of ammonia at 500 K from its value at 298 K ( $6.1 \times 10^5$  for the reaction as written in Example 6.1) we use the standard reaction enthalpy, which can be obtained from Table 2.8 in the *Data section* by using  $\Delta_r H^\circ = 2\Delta_f H^\circ(\text{NH}_3, \text{g})$ , and assume that its value is constant over the range of temperatures. Then, with  $\Delta_r H^\circ = -92.2 \text{ kJ mol}^{-1}$ , from eqn 6.23 we find

**Fig. 6.9** When  $-\ln K$  is plotted against  $1/T$ , a straight line is expected with slope equal to  $\Delta_r H^\circ/R$  if the standard reaction enthalpy does not vary appreciably with temperature. This is a non-calorimetric method for the measurement of reaction enthalpies.

$$\ln K_2 = \ln(6.1 \times 10^5) - \frac{(-92.2 \times 10^3 \text{ J mol}^{-1})}{8.3145 \text{ J K}^{-1} \text{ mol}^{-1}} \left( \frac{1}{500 \text{ K}} - \frac{1}{298 \text{ K}} \right)$$

$$= -1.71$$

It follows that  $K_2 = 0.18$ , a lower value than at 298 K, as expected for this exothermic reaction. ●

**Self-test 6.6** The equilibrium constant for  $\text{N}_2\text{O}_4(\text{g}) \rightleftharpoons 2 \text{NO}_2(\text{g})$  was calculated in Self-test 6.1. Estimate its value at 100°C. [15]

### IMPACT ON TECHNOLOGY

#### 16.2 Supramolecular chemistry

There is currently considerable interest in assemblies of molecules that are too small to be regarded as bulk matter yet too large to be regarded as individual molecules: this is the domain of supramolecular chemistry. Supramolecular surfactant assemblies and macromolecules are common host systems employed to solubilize guest molecules by taking advantage of intermolecular forces. Numerous applications use these organized media to encapsulate small molecules to create a host–guest system in which the new microenvironment for the guest substantially modifies its properties. Cyclodextrins, for example, are ring-like oligomers composed of glucopyranose units. A cyclodextrin molecule has a hydrophilic exterior and a hydrophobic interior that readily forms inclusion complexes with nonpolar guest molecules. Solubilization of the guest in the cyclodextrin core is governed by a temperature-dependent equilibrium constant that can be studied by making a van't Hoff plot to determine the thermodynamic properties of the complex formation process.

The guest molecule often possesses spectroscopic properties, such as its absorption and fluorescence wavelengths and intensities (Chapter 13), that enable the extent of encapsulation to be measured. For example, for reasons explained in Section 13.4b, the fluorescence wavelength and intensity of the chalcone pigment DMATP (**4**) are highly sensitive to the polarity of the pigment's environment. The emission spectrum in water is centred on 559 nm, but as the pigment is incorporated in the hydrophobic interior of  $\beta$ -cyclodextrin (the macromolecule formed with seven glucopyranone units) the emission shifts to 543 nm (Fig. 6.10). Incorporation of the pigment in the macromolecule also significantly enhances the DMATP fluorescence emission intensity. The equilibrium constant for the formation of the 1:1 inclusion complex consisting of one DMATP molecule in one  $\beta$ -cyclodextrin cavity can be calculated from a plot of  $1/(I_f - I_f^0)$  against  $1/[\text{CD}]$ :

$$\frac{1}{I_f - I_f^0} = \frac{1}{I_f^\infty - I_f^0} + \frac{1}{(I_f^\infty - I_f^0)K_{\text{eq}}[\text{CD}]}$$

Benesi–Hildebrand equation

**Fig. 6.10** The variation of fluorescence intensity (arbitrary units) of DMATP at  $10 \mu\text{mol dm}^{-3}$  with concentration of  $\beta$ -cyclodextrin. (M. Gaber, T. A. Fayed, S. A. El-Daly, and Y. S. El-Sayed, *Photochem. Photobiol. Sci.*, 2008, 7, 257.)

$I_f$  is the fluorescence intensity at 543 nm at a given cyclodextrin concentration  $[\text{CD}]$ ,  $I_f^0$  is the fluorescence intensity at this wavelength in the absence of host macro-molecule, and  $I_f^\infty$  is the fluorescence emission intensity when all DMATP molecules at a fixed concentration are complexed within hosts.

For DMATP/ $\beta$ -CD (Fig. 6.11) the equilibrium constant falls as temperature is raised, with  $K_{\text{eq}} = 682, 326, 170$ , and  $59$  at  $25, 35, 45$ , and  $55^\circ\text{C}$ , respectively. The corresponding van't Hoff plot of  $\ln K_{\text{eq}}$  against  $1/T$  yields a straight line (Fig. 6.12) from which it can be inferred that the standard enthalpy and entropy of formation of the complex are  $-64.7 \text{ kJ mol}^{-1}$  and  $-162.3 \text{ J K}^{-1} \text{ mol}^{-1}$ , respectively. The highly exothermic complexation process is consistent with the affinity of the hydrophobic DMATP molecule for the cyclodextrin cavity. The overall negative entropy change upon encapsulation of the guest molecule is expected as a consequence of the restricted motion of the guest within the host cavity. The expulsion of water molecules from the cyclodextrin cavity as DMATP is entrapped gives rise to a positive contribution to the entropy of the water molecules, but the magnitude of this change is significantly less than that of the decrease in entropy of the DMATP guest. Nevertheless, the overall entropy change for the formation of the 1:1 inclusion complex is more negative than often observed for cyclodextrin systems, suggesting that the CD host also experiences restricted motion upon complex formation. Thus, the van't Hoff analysis of the complex formation not only yields the typical thermodynamics parameters for the process but also provides insights into the process on a molecular level.

## Equilibrium electrochemistry

The discussion has been general and applies to all reactions. One very special case that has enormous fundamental, technological, and economic significance concerns reactions that take place in electrochemical cells. Moreover, the ability to make very precise measurements of potential differences ('voltages') means that electrochemical methods can be used to determine thermodynamic properties of reactions that may be inaccessible by other methods.

An **electrochemical cell** consists of two **electrodes**, or metallic conductors, in contact with an **electrolyte**, an ionic conductor (which may be a solution, a liquid, or a solid). An electrode and its electrolyte comprise an **electrode compartment**. The two electrodes may share the same compartment. The various kinds of electrode are summarized in Table 6.1. Any 'inert metal' shown as part of the specification is present to act as a source or sink of electrons, but takes no other part in the reaction other than acting as a catalyst for it. If the electrolytes are different, the two compartments may be joined by a **salt bridge**, which is a tube containing a concentrated electrolyte solution (for instance, potassium chloride in agar jelly) that completes the electrical

**Fig. 6.11** Benesi-Hildebrand plots of the fluorescence intensity from the DMATP/ $\beta$ -CD inclusion complex at 543 nm at various temperatures as a function of  $\beta$ -cyclodextrin concentration (based on the reference for Fig. 6.10).

**Fig. 6.12** van't Hoff plots for the DMATP/ $\beta$ -CD equilibrium (based on the reference for Fig. 6.10).

**Table 6.1** Varieties of electrode

| Electrode type       | Designation                                                      | Redox couple                     | Half-reaction                                                                    |

| Redox                | $\text{Pt(s)}   \text{M}^+(\text{aq}), \text{M}^{2+}(\text{aq})$ | $\text{M}^{2+}/\text{M}^+$       | $\text{M}^{2+}(\text{aq}) + \text{e}^- \rightarrow \text{M}^+(\text{aq})$        |

circuit and enables the cell to function. A **galvanic cell** is an electrochemical cell that produces electricity as a result of the spontaneous reaction occurring inside it. An **electrolytic cell** is an electrochemical cell in which a non-spontaneous reaction is driven by an external source of current.

## 6.5 Half-reactions and electrodes

**Key point** A redox reaction is expressed as the difference of two reduction half-reactions; each one defines a redox couple.

It will be familiar from introductory chemistry courses that **oxidation** is the removal of electrons from a species, a **reduction** is the addition of electrons to a species, and a **redox reaction** is a reaction in which there is a transfer of electrons from one species to another. The electron transfer may be accompanied by other events, such as atom or ion transfer, but the net effect is electron transfer and hence a change in oxidation number of an element. The **reducing agent** (or *reductant*) is the electron donor; the **oxidizing agent** (or *oxidant*) is the electron acceptor. It should also be familiar that any redox reaction may be expressed as the difference of two reduction **half-reactions**, which are conceptual reactions showing the gain of electrons. Even reactions that are not redox reactions may often be expressed as the difference of two reduction half-reactions. The reduced and oxidized species in a half-reaction form a **redox couple**. In general we write a couple as Ox/Red and the corresponding reduction half-reaction as

### • A brief illustration

The dissolution of silver chloride in water  $\text{AgCl(s)} \rightarrow \text{Ag}^+(\text{aq}) + \text{Cl}^-(\text{aq})$ , which is not a redox reaction, can be expressed as the difference of the following two reduction half-reactions:

The redox couples are  $\text{AgCl/Ag}$ ,  $\text{Cl}^-$  and  $\text{Ag}^+/\text{Ag}$ , respectively. •

**Self-test 6.7** Express the formation of  $\text{H}_2\text{O}$  from  $\text{H}_2$  and  $\text{O}_2$  in acidic solution (a redox reaction) as the difference of two reduction half-reactions.

We shall often find it useful to express the composition of an electrode compartment in terms of the reaction quotient,  $Q$ , for the half-reaction. This quotient is defined like the reaction quotient for the overall reaction, but the electrons are ignored because they are stateless.

### • A brief illustration

The reaction quotient for the reduction of  $\text{O}_2$  to  $\text{H}_2\text{O}$  in acid solution,  $\text{O}_2(\text{g}) + 4 \text{H}^+(\text{aq}) + 4 \text{e}^- \rightarrow 2 \text{H}_2\text{O(l)}$ , is

$$Q = \frac{a_{\text{H}_2\text{O}}^2}{a_{\text{H}^+}^4 a_{\text{O}_2}} \approx \frac{p^\ominus}{a_{\text{H}^+}^4 p_{\text{O}_2}}$$

The approximations used in the second step are that the activity of water is 1 (because the solution is dilute) and the oxygen behaves as a perfect gas, so  $a_{\text{O}_2} \approx p_{\text{O}_2}/p^\ominus$ . •

**Self-test 6.8** Write the half-reaction and the reaction quotient for a chlorine gas electrode.  
 $[\text{Cl}_2(\text{g}) + 2 \text{e}^- \rightarrow 2 \text{Cl}^-(\text{aq}), Q \approx a_{\text{Cl}^-}^2/p_{\text{Cl}_2}]$

The reduction and oxidation processes responsible for the overall reaction in a cell are separated in space: oxidation takes place at one electrode and reduction takes place at the other. As the reaction proceeds, the electrons released in the oxidation  $\text{Red}_1 \rightarrow \text{Ox}_1 + \nu \text{e}^-$  at one electrode travel through the external circuit and re-enter the cell through the other electrode. There they bring about reduction  $\text{Ox}_2 + \nu \text{e}^- \rightarrow \text{Red}_2$ . The electrode at which oxidation occurs is called the **anode**; the electrode at which reduction occurs is called the **cathode**. In a galvanic cell, the cathode has a higher potential than the anode: the species undergoing reduction,  $\text{Ox}_2$ , withdraws electrons from its electrode (the cathode, Fig. 6.13), so leaving a relative positive charge on it (corresponding to a high potential). At the anode, oxidation results in the transfer of electrons to the electrode, so giving it a relative negative charge (corresponding to a low potential).

## 6.6 Varieties of cells

**Key points** Galvanic cells are classified as electrolyte concentration and electrode concentration cells. (a) A liquid junction potential arises at the junction of two electrolyte solutions. (b) The cell notation specifies the structure of a cell.

The simplest type of cell has a single electrolyte common to both electrodes (as in Fig. 6.13). In some cases it is necessary to immerse the electrodes in different electrolytes, as in the ‘Daniell cell’ in which the redox couple at one electrode is  $\text{Cu}^{2+}/\text{Cu}$  and at the other is  $\text{Zn}^{2+}/\text{Zn}$  (Fig. 6.14). In an **electrolyte concentration cell**, the electrode compartments are identical except for the concentrations of the electrolytes. In an **electrode concentration cell** the electrodes themselves have different concentrations, either because they are gas electrodes operating at different pressures or because they are amalgams (solutions in mercury) with different concentrations.

### (a) Liquid junction potentials

In a cell with two different electrolyte solutions in contact, as in the Daniell cell, there is an additional source of potential difference across the interface of the two electrolytes. This potential is called the **liquid junction potential**,  $E_{\text{lj}}$ . Another example of a junction potential is that between different concentrations of hydrochloric acid. At the junction, the mobile  $\text{H}^+$  ions diffuse into the more dilute solution. The bulkier  $\text{Cl}^-$  ions follow, but initially do so more slowly, which results in a potential difference at the junction. The potential then settles down to a value such that, after that brief initial period, the ions diffuse at the same rates. Electrolyte concentration cells always have a liquid junction; electrode concentration cells do not.

The contribution of the liquid junction to the potential can be reduced (to about 1 to 2 mV) by joining the electrolyte compartments through a salt bridge (Fig. 6.15). The reason for the success of the salt bridge is that, provided the ions dissolved in the jelly have similar mobilities, then the liquid junction potentials at either end are largely independent of the concentrations of the two dilute solutions, and so nearly cancel.

### (b) Notation

In the notation for cells, phase boundaries are denoted by a vertical bar. For example,

**Fig. 6.13** When a spontaneous reaction takes place in a galvanic cell, electrons are deposited in one electrode (the site of oxidation, the anode) and collected from another (the site of reduction, the cathode), and so there is a net flow of current, which can be used to do work. Note that the + sign of the cathode can be interpreted as indicating the electrode at which electrons enter the cell, and the – sign of the anode as where the electrons leave the cell.

**Fig. 6.14** One version of the Daniell cell. The copper electrode is the cathode and the zinc electrode is the anode. Electrons leave the cell from the zinc electrode and enter it again through the copper electrode.

**Fig. 6.15** The salt bridge, essentially an inverted U-tube full of concentrated salt solution in a jelly, has two opposing liquid junction potentials that almost cancel.

A liquid junction is denoted by  $:$ , so the cell in Fig. 6.14 is denoted

A double vertical line,  $\parallel$ , denotes an interface for which it is assumed that the junction potential has been eliminated. Thus the cell in Fig. 6.15 is denoted

An example of an electrolyte concentration cell in which the liquid junction potential is assumed to be eliminated is

## 6.7 The cell potential

**Key points** (a) The Nernst equation relates the cell potential to the composition of the reaction mixture. (b) The standard cell potential may be used to calculate the equilibrium constant of the cell reaction.

The current produced by a galvanic cell arises from the spontaneous chemical reaction taking place inside it. The **cell reaction** is the reaction in the cell written on the assumption that the right-hand electrode is the cathode, and hence that the spontaneous reaction is one in which reduction is taking place in the right-hand compartment. Later we see how to predict if the right-hand electrode is in fact the cathode; if it is, then the cell reaction is spontaneous as written. If the left-hand electrode turns out to be the cathode, then the reverse of the corresponding cell reaction is spontaneous.

To write the cell reaction corresponding to a cell diagram, we first write the right-hand half-reaction as a reduction (because we have assumed that to be spontaneous). Then we subtract from it the left-hand reduction half-reaction (for, by implication, that electrode is the site of oxidation). Thus, in the cell  $\text{Zn(s)}|\text{ZnSO}_4(\text{aq})\parallel\text{CuSO}_4(\text{aq})|\text{Cu(s)}$  the two electrodes and their reduction half-reactions are

Hence, the overall cell reaction is the difference:

### (a) The Nernst equation

A cell in which the overall cell reaction has not reached chemical equilibrium can do electrical work as the reaction drives electrons through an external circuit. The work that a given transfer of electrons can accomplish depends on the potential difference between the two electrodes. When the potential difference is large, a given number of electrons travelling between the electrodes can do a large amount of electrical work. When the potential difference is small, the same number of electrons can do only a small amount of work. A cell in which the overall reaction is at equilibrium can do no work, and then the potential difference is zero.

According to the discussion in Section 3.5e, we know that the maximum non-expansion work a system can do is given by eqn 3.41b ( $w_{\text{add,max}} = \Delta G$ ). In electrochemistry, the non-expansion work is identified with electrical work, the system is the cell, and  $\Delta G$  is the Gibbs energy of the cell reaction,  $\Delta_r G$ . Maximum work is produced when a change occurs reversibly. It follows that, to draw thermodynamic conclusions from measurements of the work that a cell can do, we must ensure that the cell is

operating reversibly. Moreover, we saw in Section 6.1a that the reaction Gibbs energy is actually a property relating to a specified composition of the reaction mixture. Therefore, to make use of  $\Delta_r G$  we must ensure that the cell is operating reversibly at a specific, constant composition. Both these conditions are achieved by measuring the cell potential when it is balanced by an exactly opposing source of potential so that the cell reaction occurs reversibly, the composition is constant, and no current flows: in effect, the cell reaction is poised for change, but not actually changing. The resulting potential difference is called the **cell potential**,  $E_{\text{cell}}$ , of the cell.

As we show in the *Justification* below, the relation between the reaction Gibbs energy and the cell potential is

$$-vFE_{\text{cell}} = \Delta_r G \quad \text{The cell potential} \quad (6.25)$$

where  $F$  is Faraday's constant,  $F = eN_A$ , and  $v$  is the stoichiometric coefficient of the electrons in the half-reactions into which the cell reaction can be divided. This equation is the key connection between electrical measurements on the one hand and thermodynamic properties on the other. It will be the basis of all that follows.

**Justification 6.3** *The relation between the cell potential and the reaction Gibbs energy*

We consider the change in  $G$  when the cell reaction advances by an infinitesimal amount  $d\xi$  at some composition. From *Justification 6.1* we can write (at constant temperature and pressure)

$$dG = \Delta_r G d\xi$$

The maximum non-expansion (electrical) work that the reaction can do as it advances by  $d\xi$  at constant temperature and pressure is therefore

$$dw_e = \Delta_r G d\xi$$

This work is infinitesimal, and the composition of the system is virtually constant when it occurs.

Suppose that the reaction advances by  $d\xi$ ; then  $vd\xi$  electrons must travel from the anode to the cathode. The total charge transported between the electrodes when this change occurs is  $-veN_A d\xi$  (because  $vd\xi$  is the amount of electrons and the charge per mole of electrons is  $-eN_A$ ). Hence, the total charge transported is  $-vFd\xi$  because  $eN_A = F$ . The work done when an infinitesimal charge  $-vFd\xi$  travels from the anode to the cathode is equal to the product of the charge and the potential difference  $E_{\text{cell}}$  (see Table 2.1):

$$dw_e = -vFE_{\text{cell}} d\xi$$

When we equate this relation to the one above ( $dw_e = \Delta_r G d\xi$ ), the advancement  $d\xi$  cancels, and we obtain eqn 6.25.

It follows from eqn 6.25 that, by knowing the reaction Gibbs energy at a specified composition, we can state the cell potential at that composition. Note that a negative reaction Gibbs energy, corresponding to a spontaneous cell reaction, corresponds to a positive cell potential. Another way of looking at the content of eqn 6.25 is that it shows that the driving power of a cell (that is, its potential) is proportional to the slope of the Gibbs energy with respect to the extent of reaction. It is plausible that a reaction that is far from equilibrium (when the slope is steep) has a strong tendency to drive electrons through an external circuit (Fig. 6.16). When the slope is close to zero (when the cell reaction is close to equilibrium), the cell potential is small.

**A note on good practice** The cell potential was formerly, and is still widely, called the *electromotive force* (emf) of the cell. IUPAC prefers the term 'cell potential' because a potential difference is not a force.

**Fig. 6.16** A spontaneous reaction occurs in the direction of decreasing Gibbs energy and can be expressed in terms of the cell potential,  $E_{\text{cell}}$ . The reaction is spontaneous as written (from left to right on the illustration) when  $E_{\text{cell}} > 0$ . The reverse reaction is spontaneous when  $E_{\text{cell}} < 0$ . When the cell reaction is at equilibrium, the cell potential is zero.

• **A brief illustration**

Equation 6.25 provides an electrical method for measuring a reaction Gibbs energy at any composition of the reaction mixture: we simply measure the cell potential and convert it to  $\Delta_r G$ . Conversely, if we know the value of  $\Delta_r G$  at a particular composition, then we can predict the cell potential. For example, if  $\Delta_r G = -1 \times 10^5 \text{ J mol}^{-1}$  and  $v = 1$ , then

$$E_{\text{cell}} = -\frac{\Delta_r G}{vF} = -\frac{(-1 \times 10^5 \text{ J mol}^{-1})}{1 \times (9.6485 \times 10^4 \text{ C mol}^{-1})} = 1 \text{ V}$$

where we have used  $1 \text{ J} = 1 \text{ C V}$ . •

We can go on to relate the cell potential to the activities of the participants in the cell reaction. We know that the reaction Gibbs energy is related to the composition of the reaction mixture by eqn 6.10 ( $\Delta_r G = \Delta_r G^\ominus + RT \ln Q$ ); it follows, on division of both sides by  $-vF$ , that

$$E_{\text{cell}} = -\frac{\Delta_r G^\ominus}{vF} - \frac{RT}{vF} \ln Q$$

The first term on the right is written

$$E_{\text{cell}}^\ominus = -\frac{\Delta_r G^\ominus}{vF}$$

Definition of standard cell potential

[6.26]

and called the **standard cell potential**. That is, the standard cell potential is the standard reaction Gibbs energy expressed as a potential difference (in volts). It follows that

$$E_{\text{cell}} = E_{\text{cell}}^\ominus - \frac{RT}{vF} \ln Q$$

Nernst equation

(6.27)

This equation for the cell potential in terms of the composition is called the **Nernst equation**; the dependence that it predicts is summarized in Fig. 6.17. One important application of the Nernst equation is to the determination of the pH of a solution and, with a suitable choice of electrodes, of the concentration of other ions (*Impact I6.3*).

We see from eqn 6.27 that the standard cell potential (which will shortly move to centre stage of the exposition) can be interpreted as the cell potential when all the reactants and products in the cell reaction are in their standard states, for then all activities are 1, so  $Q = 1$  and  $\ln Q = 0$ . However, the fact that the standard cell potential is merely a disguised form of the standard reaction Gibbs energy (eqn 6.26) should always be kept in mind and underlies all its applications.

• **A brief illustration**

Because  $RT/F = 25.7 \text{ mV}$  at  $25^\circ\text{C}$ , a practical form of the Nernst equation is

$$E_{\text{cell}} = E_{\text{cell}}^\ominus - \frac{25.7 \text{ mV}}{v} \ln Q$$

It then follows that, for a reaction in which  $v = 1$ , if  $Q$  is increased by a factor of 10, then the cell potential decreases by  $59.2 \text{ mV}$ . •

**Fig. 6.17** The variation of cell potential with the value of the reaction quotient for the cell reaction for different values of  $v$  (the number of electrons transferred). At  $298 \text{ K}$ ,  $RT/F = 25.69 \text{ mV}$ , so the vertical scale refers to multiples of this value.

**(b) Cells at equilibrium**

A special case of the Nernst equation has great importance in electrochemistry and provides a link to the earlier part of the chapter. Suppose the reaction has reached equilibrium; then  $Q = K$ , where  $K$  is the equilibrium constant of the cell reaction. However, a chemical reaction at equilibrium cannot do work, and hence it generates

zero potential difference between the electrodes of a galvanic cell. Therefore, setting  $E_{\text{cell}} = 0$  and  $Q = K$  in the Nernst equation gives

$$\ln K = \frac{\nu F E_{\text{cell}}^{\circ}}{RT} \quad \text{Equilibrium constant and standard cell potential} \quad (6.28)$$

This very important equation (which could also have been obtained more directly by substituting eqn 6.26 into eqn 6.14) lets us predict equilibrium constants from measured standard cell potentials. However, before we use it extensively, we need to establish a further result.

#### • A brief illustration

Because the standard potential of the Daniell cell is +1.10 V, the equilibrium constant for the cell reaction  $\text{Cu}^{2+}(\text{aq}) + \text{Zn}(\text{s}) \rightarrow \text{Cu}(\text{s}) + \text{Zn}^{2+}(\text{aq})$ , for which  $\nu = 2$ , is  $K = 1.5 \times 10^{37}$  at 298 K. We conclude that the displacement of copper by zinc goes virtually to completion. Note that a cell potential of about 1 V is easily measurable but corresponds to an equilibrium constant that would be impossible to measure by direct chemical analysis. •

## 6.8 Standard electrode potentials

**Key point** The standard potential of a couple is the cell potential in which it forms the right-hand electrode and the left-hand electrode is a standard hydrogen electrode.

A galvanic cell is a combination of two electrodes each of which can be considered to make a characteristic contribution to the overall cell potential. Although it is not possible to measure the contribution of a single electrode, we can define the potential of one of the electrodes as zero and then assign values to others on that basis. The specially selected electrode is the **standard hydrogen electrode (SHE)**:

at all temperatures. To achieve the standard conditions, the activity of the hydrogen ions must be 1 (that is,  $\text{pH} = 0$ ) and the pressure (more precisely, the fugacity) of the hydrogen gas must be 1 bar. The **standard potential**,  $E^{\circ}$ , of another couple is then assigned by constructing a cell in which it is the right-hand electrode and the standard hydrogen electrode is the left-hand electrode.

The procedure for measuring a standard potential can be illustrated by considering a specific case, the silver chloride electrode. The measurement is made on the ‘Harned cell’:

for which the Nernst equation is

$$E_{\text{cell}} = E^{\circ}(\text{AgCl}/\text{Ag}, \text{Cl}^-) - \frac{RT}{F} \ln \frac{a_{\text{H}^+} a_{\text{Cl}^-}}{a_{\text{H}_2}^{1/2}}$$

We shall set  $a_{\text{H}_2} = 1$  from now on, and for simplicity write the standard potential of the  $\text{AgCl}/\text{Ag}, \text{Cl}^-$  electrode as  $E^{\circ}$ ; then

$$E_{\text{cell}} = E^{\circ} - \frac{RT}{F} \ln a_{\text{H}^+} a_{\text{Cl}^-}$$

The activities can be expressed in terms of the molality  $b$  of  $\text{HCl(aq)}$  through  $a_{\text{H}^+} = \gamma_{\pm} b/b^\ominus$  and  $a_{\text{Cl}^-} = \gamma_{\pm} b/b^\ominus$  as we saw in Section 5.13, so

$$E_{\text{cell}} = E^\ominus - \frac{RT}{F} \ln b^2 - \frac{RT}{F} \ln \gamma_{\pm}^2$$

where for simplicity we have replaced  $b/b^\ominus$  by  $b$ . This expression rearranges to

$$E_{\text{cell}} + \frac{2RT}{F} \ln b = E^\ominus - \frac{2RT}{F} \ln \gamma_{\pm} \quad (6.30)$$

From the Debye–Hückel limiting law for a 1,1-electrolyte (eqn 5.75; a 1,1-electrolyte is a solution of singly charged  $\text{M}^+$  and  $\text{X}^-$  ions), we know that  $\ln \gamma_{\pm} \propto -b^{1/2}$ . The natural logarithm used here is proportional to the common logarithm that appears in eqn 5.75 (because  $\ln x = \ln 10 \log x = 2.303 \log x$ ). Therefore, with the constant of proportionality in this relation written as  $(F/2RT)C$ , eqn 6.30 becomes

$$E_{\text{cell}} + \frac{2RT}{F} \ln b = E^\ominus + Cb^{1/2} \quad (6.31)$$

The expression on the left is evaluated at a range of molalities, plotted against  $b^{1/2}$ , and extrapolated to  $b = 0$ . The intercept at  $b^{1/2} = 0$  is the value of  $E^\ominus$  for the silver/silver-chloride electrode. In precise work, the  $b^{1/2}$  term is brought to the left, and a higher-order correction term from the extended Debye–Hückel law is used on the right.

**Fig. 6.18** The plot and the extrapolation used for the experimental measurement of a standard cell potential. The intercept at  $b^{1/2} = 0$  is  $E_{\text{cell}}^\ominus$ .

#### • A brief illustration

The cell potential of  $\text{Pt(s)}|\text{H}_2(\text{g}, p^\ominus)|\text{HCl(aq}, b)|\text{AgCl(s)}|\text{Ag(s)}$  at  $25^\circ\text{C}$  has the following values:

|                            |          |          |          |          |
|----------------------------|----------|----------|----------|----------|
| $b/(10^{-3}b^\ominus)$     | 3.215    | 5.619    | 9.138    | 25.63    |
| $E_{\text{cell}}/\text{V}$ | 0.520 53 | 0.492 57 | 0.468 60 | 0.418 24 |

To determine the standard potential of the cell we draw up the following table, using  $2RT/F = 0.051\,39\text{ V}$ :

|                                              |          |          |          |          |
|----------------------------------------------|----------|----------|----------|----------|
| $b/(10^{-3}b^\ominus)$                       | 3.215    | 5.619    | 9.138    | 25.63    |
| $\{b/(10^{-3}b^\ominus)\}^{1/2}$             | 1.793    | 2.370    | 3.023    | 5.063    |
| $E_{\text{cell}}/\text{V}$                   | 0.520 53 | 0.492 57 | 0.468 60 | 0.418 24 |
| $E_{\text{cell}}/\text{V} + 0.051\,39 \ln b$ | 0.2256   | 0.2263   | 0.2273   | 0.2299   |

The data are plotted in Fig. 6.18; as can be seen, they extrapolate to  $E^\ominus = 0.2232\text{ V}$ . •

**Table 6.2\*** Standard potentials at 298 K

| Couple                                                                          | $E^\ominus/\text{V}$ |
|---------------------------------------------------------------------------------|----------------------|

Table 6.2 lists standard potentials at 298 K. An important feature of the standard potential of cells and standard potentials of electrodes is that they are unchanged if the chemical equation for the cell reaction or a half-reaction is multiplied by a numerical factor. A numerical factor increases the value of the standard Gibbs energy for the reaction. However, it also increases the number of electrons transferred by the same factor, and by eqn 6.26 the value of  $E_{\text{cell}}^\ominus$  remains unchanged. A practical consequence

is that a cell potential is independent of the physical size of the cell. In other words, the cell potential is an intensive property.

The standard potentials in Table 6.2 may be combined to give values for couples that are not listed there. However, to do so, we must take into account the fact that different couples may correspond to the transfer of different numbers of electrons. The procedure is illustrated in the following *Example*.

**Example 6.4** Evaluating a standard potential from two others

Given that the standard potentials of the  $\text{Cu}^{2+}/\text{Cu}$  and  $\text{Cu}^+/\text{Cu}$  couples are +0.340 V and +0.522 V, respectively, evaluate  $E^\circ(\text{Cu}^{2+}, \text{Cu}^+)$ .

**Method** First, we note that reaction Gibbs energies may be added (as in a Hess's law analysis of reaction enthalpies). Therefore, we should convert the  $E^\circ$  values to  $\Delta_r G^\circ$  values by using eqn 6.26, add them appropriately, and then convert the overall  $\Delta_r G^\circ$  to the required  $E^\circ$  by using eqn 6.26 again. This roundabout procedure is necessary because, as we shall see, although the factor  $F$  cancels, the factor  $\nu$  in general does not.

**Answer** The electrode reactions are as follows:

The required reaction is

Because  $(c) = (a) - (b)$ , the standard Gibbs energy of reaction (c) is

$$\Delta_r G^\circ = \Delta_r G^\circ(a) - \Delta_r G^\circ(b) = (-0.158 \text{ V}) \times F$$

Therefore,  $E^\circ = +0.158 \text{ V}$ . Note that the generalization of the calculation we just performed is

$$\nu_c E^\circ(c) = \nu_a E^\circ(a) - \nu_b E^\circ(b) \quad \text{Combination of standard potentials} \quad (6.32)$$

with the  $\nu_i$  the stoichiometric coefficients of the electrons in each half-reaction.

## 6.9 Applications of standard potentials

**Key points** (a) The electrochemical series lists the metallic elements in the order of their reducing power as measured by their standard potentials in aqueous solution: low reduces high. (b) The cell potential is used to measure the activity coefficient of electroactive ions. (c) The standard cell potential is used to infer the equilibrium constant of the cell reaction. (d) Species-selective electrodes contribute a potential that is characteristic of certain ions in solution. (e) The temperature coefficient of the cell potential is used to determine the standard entropy and enthalpy of reaction.

Cell potentials are a convenient source of data on equilibrium constants and the Gibbs energies, enthalpies, and entropies of reactions. In practice the standard values of these quantities are the ones normally determined.

### (a) The electrochemical series

We have seen that for two redox couples,  $\text{Ox}_1/\text{Red}_1$  and  $\text{Ox}_2/\text{Red}_2$ , and the cell

$$\text{Red}_1, \text{Ox}_1 \parallel \text{Red}_2, \text{Ox}_2 \quad E_{\text{cell}}^\circ = E_2^\circ - E_1^\circ \quad \text{Cell convention} \quad (6.33a)$$

**Table 6.3** The electrochemical series of the metals\**Least strongly reducing*

*Most strongly reducing*

\* The complete series can be inferred from Table 6.2.

that the cell reaction

has  $K > 1$  as written if  $E_{\text{cell}}^\circ > 0$ , and therefore if  $E_2^\circ > E_1^\circ$ . Because in the cell reaction  $\text{Red}_1$  reduces  $\text{Ox}_2$ , we can conclude that

$\text{Red}_1$  has a thermodynamic tendency (in the sense  $K > 1$ ) to reduce  $\text{Ox}_2$  if  $E_1^\circ < E_2^\circ$

More briefly: low reduces high.

#### • A brief illustration

Because  $E^\circ(\text{Zn}^{2+}, \text{Zn}) = -0.76 \text{ V} < E^\circ(\text{Cu}^{2+}, \text{Cu}) = +0.34 \text{ V}$ , the reduction of  $\text{Cu}^{2+}$  by Zn is a reaction with  $K > 1$ , so zinc has a thermodynamic tendency to reduce  $\text{Cu}^{2+}$  ions in aqueous solution under standard conditions. •

Table 6.3 shows a part of the **electrochemical series**, the metallic elements (and hydrogen) arranged in the order of their reducing power as measured by their standard potentials in aqueous solution. A metal low in the series (with a lower standard potential) can reduce the ions of metals with higher standard potentials. This conclusion is qualitative. The quantitative value of  $K$  is obtained by doing the calculations we have described previously. For example, to determine whether zinc can displace magnesium from aqueous solutions at 298 K, we note that zinc lies above magnesium in the electrochemical series, so zinc cannot reduce magnesium ions in aqueous solution. Zinc can reduce hydrogen ions, because hydrogen lies higher in the series. However, even for reactions that are thermodynamically favourable, there may be kinetic factors that result in very slow rates of reaction.

#### (b) The determination of activity coefficients

Once the standard potential of an electrode in a cell is known, we can use it to determine mean activity coefficients by measuring the cell potential with the ions at the concentration of interest. For example, the mean activity coefficient of the ions in hydrochloric acid of molality  $b$  is obtained from eqn 6.30 in the form

$$\ln \gamma_{\pm} = \frac{E^\circ - E_{\text{cell}}}{2RT/F} - \ln b \quad \{6.34\}$$

once  $E_{\text{cell}}$  has been measured.

#### (c) The determination of equilibrium constants

The principal use for standard potentials is to calculate the standard potential of a cell formed from any two electrodes. To do so, we subtract the standard potential of the left-hand electrode from the standard potential of the right-hand electrode:

$$E_{\text{cell}}^\circ = E^\circ(\text{right}) - E^\circ(\text{left}) \quad \text{Cell convention} \quad (6.35)$$

Because  $\Delta_r G^\circ = -\nu F E_{\text{cell}}^\circ$ , it then follows that, if the result gives  $E_{\text{cell}}^\circ > 0$ , then the corresponding cell reaction has  $K > 1$ .

#### • A brief illustration

A disproportionation is a reaction in which a species is both oxidized and reduced. To study the disproportionation  $2 \text{Cu}^+(\text{aq}) \rightarrow \text{Cu}(\text{s}) + \text{Cu}^{2+}(\text{aq})$  we combine the following electrodes:

Right-hand electrode:

Left-hand electrode:

where the standard potentials are measured at 298 K. The standard potential of the cell is therefore

$$E_{\text{cell}}^\circ = +0.52 \text{ V} - 0.16 \text{ V} = +0.36 \text{ V}$$

We can now calculate the equilibrium constant of the cell reaction. Because  $\nu = 1$ , from eqn 6.28,

$$\ln K = \frac{0.36 \text{ V}}{0.025 693 \text{ V}} = \frac{0.36}{0.025 693}$$

Hence,  $K = 1.2 \times 10^6$ . •

#### (d) The determination of thermodynamic functions

The standard potential of a cell is related to the standard reaction Gibbs energy through eqn 6.25 ( $\Delta_r G^\circ = -\nu F E_{\text{cell}}^\circ$ ). Therefore, by measuring  $E_{\text{cell}}^\circ$  we can obtain this important thermodynamic quantity. Its value can then be used to calculate the Gibbs energy of formation of ions by using the convention explained in Section 3.6.

##### • A brief illustration

The cell reaction taking place in

is

Therefore, with  $\nu = 1$ , we find

$$\Delta_f G^\circ(\text{Ag}^+, \text{aq}) = -(-F E_{\text{cell}}^\circ) = +77.15 \text{ kJ mol}^{-1}$$

which is in close agreement with the value in Table 2.8 of the *Data section*. •

The temperature coefficient of the standard cell potential,  $dE_{\text{cell}}^\circ/dT$ , gives the standard entropy of the cell reaction. This conclusion follows from the thermodynamic relation  $(\partial G/\partial T)_p = -S$  and eqn 6.26, which combine to give

$$\frac{dE_{\text{cell}}^\circ}{dT} = \frac{\Delta_r S^\circ}{\nu F} \quad \text{Temperature coefficient of standard cell potential} \quad (6.36)$$

The derivative is complete (not partial) because  $E^\circ$ , like  $\Delta_r G^\circ$ , is independent of the pressure. Hence we have an electrochemical technique for obtaining standard reaction entropies and through them the entropies of ions in solution.

Finally, we can combine the results obtained so far and use them to obtain the standard reaction enthalpy:

$$\Delta_r H^\circ = \Delta_r G^\circ + T \Delta_r S^\circ = -\nu F \left( E_{\text{cell}}^\circ - T \frac{dE_{\text{cell}}^\circ}{dT} \right) \quad (6.37)$$

This expression provides a non-calorimetric method for measuring  $\Delta_r H^\circ$  and, through the convention  $\Delta_r H^\circ(\text{H}^+, \text{aq}) = 0$ , the standard enthalpies of formation of ions in solution (Section 2.8). Thus, electrical measurements can be used to calculate all the thermodynamic properties with which this chapter began.

**Example 6.5** Using the temperature coefficient of the cell potential

The standard potential of the cell  $\text{Pt(s)}|\text{H}_2(\text{g})|\text{HBr(aq)}|\text{AgBr(s)}|\text{Ag(s)}$  was measured over a range of temperatures, and the data were found to fit the following polynomial:

$$E_{\text{cell}}^\circ/\text{V} = 0.07131 - 4.99 \times 10^{-4}(T/\text{K} - 298) - 3.45 \times 10^{-6}(T/\text{K} - 298)^2$$

The cell reaction is  $\text{AgBr(s)} + \frac{1}{2} \text{H}_2(\text{g}) \rightarrow \text{Ag(s)} + \text{HBr(aq)}$ . Evaluate the standard reaction Gibbs energy, enthalpy, and entropy at 298 K.

**Method** The standard Gibbs energy of reaction is obtained by using eqn 6.26 after evaluating  $E_{\text{cell}}^\circ$  at 298 K and by using  $1 \text{ V C} = 1 \text{ J}$ . The standard entropy of reaction is obtained by using eqn 6.36, which involves differentiating the polynomial with respect to  $T$  and then setting  $T = 298 \text{ K}$ . The reaction enthalpy is obtained by combining the values of the standard Gibbs energy and entropy.

**Answer** At  $T = 298 \text{ K}$ ,  $E_{\text{cell}}^\circ = +0.07131 \text{ V}$ , so

$$\begin{aligned}\Delta_r G^\circ &= -\nu F E_{\text{cell}}^\circ = -(1) \times (9.6485 \times 10^4 \text{ C mol}^{-1}) \times (+0.07131 \text{ V}) \\ &= -6.880 \times 10^3 \text{ V C mol}^{-1} = -6.880 \text{ kJ mol}^{-1}\end{aligned}$$

The temperature coefficient of the cell potential is

$$\frac{dE_{\text{cell}}^\circ}{dT} = -4.99 \times 10^{-4} \text{ V K}^{-1} - 2(3.45 \times 10^{-6})(T/\text{K} - 298) \text{ V K}^{-1}$$

At  $T = 298 \text{ K}$  this expression evaluates to

$$\frac{dE_{\text{cell}}^\circ}{dT} = -4.99 \times 10^{-4} \text{ V K}^{-1}$$

So, from eqn 6.36, the reaction entropy is

$$\begin{aligned}\Delta_r S^\circ &= 1 \times (9.6485 \times 10^4 \text{ C mol}^{-1}) \times (-4.99 \times 10^{-4} \text{ V K}^{-1}) \\ &= -48.1 \text{ J K}^{-1} \text{ mol}^{-1}\end{aligned}$$

The negative value stems in part from the elimination of gas in the cell reaction. It then follows that

$$\begin{aligned}\Delta_r H^\circ &= \Delta_r G^\circ + T \Delta_r S^\circ = -6.880 \text{ kJ mol}^{-1} + (298 \text{ K}) \times (-0.0482 \text{ kJ K}^{-1} \text{ mol}^{-1}) \\ &= -21.2 \text{ kJ mol}^{-1}\end{aligned}$$

One difficulty with this procedure lies in the accurate measurement of small temperature coefficients of cell potential. Nevertheless, it is another example of the striking ability of thermodynamics to relate the apparently unrelated, in this case to relate electrical measurements to thermal properties.

## IMPACT ON TECHNOLOGY

## 16.3 Species-selective electrodes

An **ion-selective electrode** is an electrode that generates a potential in response to the presence of a solution of specific ions. An example is the **glass electrode** (Fig. 6.19), which is sensitive to hydrogen ion activity, and has a potential proportional to pH. It is filled with a phosphate buffer containing  $\text{Cl}^-$  ions, and conveniently has  $E = 0$  when the external medium is at  $\text{pH} = 6$ . It is necessary to calibrate the glass electrode before use with solutions of known pH.

The responsiveness of a glass electrode to the hydrogen ion activity is a result of complex processes at the interface between the glass membrane and the solutions on either side of it. The membrane itself is permeable to  $\text{Na}^+$  and  $\text{Li}^+$  ions but not to  $\text{H}^+$  ions. Therefore, the potential difference across the glass membrane must arise by a mechanism different from that responsible for biological transmembrane potentials. A clue to the mechanism comes from a detailed inspection of the glass membrane, for each face is coated with a thin layer of hydrated silica (Fig. 6.20). The hydrogen ions in the test solution modify this layer to an extent that depends on their activity in the solution, and the charge modification of the outside layer is transmitted to the inner layer by the  $\text{Na}^+$  and  $\text{Li}^+$  ions in the glass. The hydrogen ion activity gives rise to a membrane potential by this indirect mechanism.

Electrodes sensitive to hydrogen ions, and hence to pH, are typically glasses based on lithium silicate doped with heavy-metal oxides. The glass can also be made responsive to  $\text{Na}^+$ ,  $\text{K}^+$ , and  $\text{NH}_4^+$  ions by being doped with  $\text{Al}_2\text{O}_3$  and  $\text{B}_2\text{O}_3$ .

A suitably adapted glass electrode can be used to detect the presence of certain gases. A simple form of a **gas-sensing electrode** consists of a glass electrode contained in an outer sleeve filled with an aqueous solution and separated from the test solution by a membrane that is permeable to gas. When a gas such as sulfur dioxide or ammonia diffuses into the aqueous solution, it modifies its pH, which in turn affects the potential of the glass electrode. The presence of an enzyme that converts a compound, such as urea or an amino acid, into ammonia, which then affects the pH, can be used to detect these organic compounds.

Somewhat more sophisticated devices are used as ion-selective electrodes that give potentials according to the presence of specific ions present in a test solution. In one arrangement, a porous lipophilic (hydrocarbon-attracting) membrane is attached to a small reservoir of a hydrophobic (water-repelling) liquid, such as dioctylphenylphosphonate, that saturates it (Fig. 6.21). The liquid contains an agent, such as  $(\text{RO})_2\text{PO}_2^-$  with R a  $\text{C}_8$  to  $\text{C}_{18}$  chain, that acts as a kind of solubilizing agent for the ions with which it can form a complex. The complex's ions are able to migrate through the lipophilic membrane, and hence give rise to a transmembrane potential, which is detected by a silver/silver chloride electrode in the interior of the assembly. Electrodes of this construction can be designed to be sensitive to a variety of ionic species, including calcium, zinc, iron, lead, and copper ions.

In theory, the transmembrane potential should be determined entirely by differences in the activity of the species that the electrode was designed to detect. In practice, a small potential difference, called the **asymmetry potential**, is observed even when the activity of the test species is the same on both sides of the membrane. The asymmetry potential is due to the fact that it is not possible to manufacture a membrane material that has the same structure and the same chemical properties throughout. Furthermore, all species-selective electrodes are sensitive to more than one species. For example, a  $\text{Na}^+$  selective electrode also responds, albeit less effectively, to the activity of  $\text{K}^+$  ions in the test solution. As a result of these effects, the potential

**Fig. 6.19** The glass electrode. It is commonly used in conjunction with a calomel electrode that makes contact with the test solution through a salt bridge.

**Fig. 6.20** A section through the wall of a glass electrode.

**Fig. 6.21** The structure of an ion-selective electrode. Chelated ions are able to migrate through the lipophilic membrane.

of an electrode sensitive to species  $X^+$  that is also susceptible to interference by species  $Y^+$  is given by a modified form of the Nernst equation:

$$E_{\text{cell}} = E_{\text{ap}} + \beta \frac{RT}{F} \ln(a_{X^+} + k_{X,Y} a_{Y^+}) \quad (6.38)$$

where  $E_{\text{ap}}$  is the asymmetry potential,  $\beta$  is an experimental parameter that captures deviations from the Nernst equation, and  $k_{X,Y}$  is the **selectivity coefficient** of the electrode and is related to the response of the electrode to the interfering species  $Y^+$ . A value of  $\beta = 1$  indicates that the electrode responds to the activity of ions in solution in a way that is consistent with the Nernst equation and, in practice, most species-selective electrodes of high quality have  $\beta \approx 1$ . The selectivity coefficient, and hence interference effects, can be minimized when designing and manufacturing a species-selective electrode. For precise work, it is necessary to calibrate the response of the electrode by measuring  $E_{\text{ap}}$ ,  $\beta$ , and  $k_{X,Y}$  before performing experiments on solutions of unknown concentration of  $X^+$ .

## Checklist of key equations

## Discussion questions

- 6.1** Explain how the mixing of reactants and products affects the position of chemical equilibrium.
- 6.2** What is the justification for not including a pure liquid or solid in the expression for an equilibrium constant?
- 6.3** Suggest how the thermodynamic equilibrium constant may respond differently to changes in pressure and temperature from the equilibrium constant expressed in terms of partial pressures.
- 6.4** Account for Le Chatelier's principle in terms of thermodynamic quantities.
- 6.5** Explain the molecular basis of the van't Hoff equation for the temperature dependence of  $K$ .
- 6.6** Explain why reactions that are not redox reactions may be used to generate an electric current.
- 6.7** Describe a method for the determination of the standard potential of a redox couple.
- 6.8** Devise a method for the determination of the pH of an aqueous solution.

## Exercises

- 6.1(a)** Consider the reaction  $A \rightarrow 2 B$ . Initially 1.50 mol A is present and no B. What are the amounts of A and B when the extent of reaction is 0.60 mol?
- 6.1(b)** Consider the reaction  $2 A \rightarrow B$ . Initially 1.75 mol A and 0.12 mol B are present. What are the amounts of A and B when the extent of reaction is 0.30 mol?
- 6.2(a)** When the reaction  $A \rightarrow 2 B$  advances by 0.10 mol (that is,  $\Delta\xi = +0.10$  mol) the Gibbs energy of the system changes by  $-6.4$  kJ mol $^{-1}$ . What is the Gibbs energy of reaction at this stage of the reaction?
- 6.2(b)** When the reaction  $2 A \rightarrow B$  advances by 0.051 mol (that is,  $\Delta\xi = +0.051$  mol) the Gibbs energy of the system changes by  $-2.41$  kJ mol $^{-1}$ . What is the Gibbs energy of reaction at this stage of the reaction?
- 6.3(a)** The standard Gibbs energy of the reaction  $N_2(g) + 3 H_2(g) \rightarrow 2 NH_3(g)$  is  $-32.9$  kJ mol $^{-1}$  at 298 K. What is the value of  $\Delta_r G$  when  $Q =$  (a) 0.010, (b) 1.0, (c) 10.0, (d) 100 000, (e) 1 000 000? Estimate (by interpolation) the value of  $K$  from the values you calculate. What is the actual value of  $K$ ?
- 6.3(b)** The standard Gibbs energy of the reaction  $2 NO_2(g) \rightarrow N_2O_4(g)$  is  $-4.73$  kJ mol $^{-1}$  at 298 K. What is the value of  $\Delta_r G$  when  $Q =$  (a) 0.10, (b) 1.0, (c) 10, (d) 100? Estimate (by interpolation) the value of  $K$  from the values you calculate. What is the actual value of  $K$ ?
- 6.4(a)** At 2257 K and 1.00 bar total pressure, water is 1.77 per cent dissociated at equilibrium by way of the reaction  $2 H_2O(g) \rightleftharpoons 2 H_2(g) + O_2(g)$ . Calculate  $K$ .
- 6.4(b)** For the equilibrium,  $N_2O_4(g) \rightleftharpoons 2 NO_2(g)$ , the degree of dissociation,  $\alpha$ , at 298 K is 0.201 at 1.00 bar total pressure. Calculate  $K$ .
- 6.5(a)** Dinitrogen tetroxide is 18.46 per cent dissociated at 25°C and 1.00 bar in the equilibrium  $N_2O_4(g) \rightleftharpoons 2 NO_2(g)$ . Calculate  $K$  at (a) 25°C, (b) 100°C given that  $\Delta_r H^\circ = +56.2$  kJ mol $^{-1}$  over the temperature range.
- 6.5(b)** Molecular bromine is 24 per cent dissociated at 1600 K and 1.00 bar in the equilibrium  $Br_2(g) \rightleftharpoons 2 Br(g)$ . Calculate  $K$  at (a) 1600 K, (b) 2000 K given that  $\Delta_r H^\circ = +112$  kJ mol $^{-1}$  over the temperature range.
- 6.6(a)** From information in the *Data section*, calculate the standard Gibbs energy and the equilibrium constant at (a) 298 K and (b) 400 K for the reaction  $PbO(s) + CO(g) \rightleftharpoons Pb(s) + CO_2(g)$ . Assume that the reaction enthalpy is independent of temperature.
- 6.6(b)** From information in the *Data section*, calculate the standard Gibbs energy and the equilibrium constant at (a) 25°C and (b) 50°C for the reaction  $CH_4(g) + 3 Cl_2(g) \rightleftharpoons CHCl_3(l) + 3 HCl(g)$ . Assume that the reaction enthalpy is independent of temperature.
- 6.7(a)** Establish the relation between  $K$  and  $K_c$  for the reaction  $H_2CO(g) \rightleftharpoons CO(g) + H_2(g)$ .
- 6.7(b)** Establish the relation between  $K$  and  $K_c$  for the reaction  $3 N_2(g) + H_2(g) \rightleftharpoons 2 HN_3(g)$ .
- 6.8(a)** In the gas-phase reaction  $2 A + B \rightleftharpoons 3 C + 2 D$ , it was found that, when 1.00 mol A, 2.00 mol B, and 1.00 mol D were mixed and allowed to come to equilibrium at 25°C, the resulting mixture contained 0.90 mol C at a total pressure of 1.00 bar. Calculate (a) the mole fractions of each species at equilibrium, (b)  $K_p$ , (c)  $K$ , and (d)  $\Delta_r G^\circ$ .
- 6.8(b)** In the gas-phase reaction  $A + B \rightleftharpoons C + 2 D$ , it was found that, when 2.00 mol A, 1.00 mol B, and 3.00 mol D were mixed and allowed to come to equilibrium at 25°C, the resulting mixture contained 0.79 mol C at a total pressure of 1.00 bar. Calculate (a) the mole fractions of each species at equilibrium, (b)  $K_p$ , (c)  $K$ , and (d)  $\Delta_r G^\circ$ .
- 6.9(a)** The standard reaction enthalpy of  $Zn(s) + H_2O(g) \rightarrow ZnO(s) + H_2(g)$  is approximately constant at  $+224$  kJ mol $^{-1}$  from 920 K up to 1280 K. The standard reaction Gibbs energy is  $+33$  kJ mol $^{-1}$  at 1280 K. Estimate the temperature at which the equilibrium constant becomes greater than 1.
- 6.9(b)** The standard enthalpy of a certain reaction is approximately constant at  $+125$  kJ mol $^{-1}$  from 800 K up to 1500 K. The standard reaction Gibbs energy is  $+22$  kJ mol $^{-1}$  at 1120 K. Estimate the temperature at which the equilibrium constant becomes greater than 1.
- 6.10(a)** The equilibrium constant of the reaction  $2 C_3H_6(g) \rightleftharpoons C_2H_4(g) + C_4H_8(g)$  is found to fit the expression  $\ln K = A + B/T + C/T^2$  between 300 K and 600 K, with  $A = -1.04$ ,  $B = -1088$  K, and  $C = 1.51 \times 10^5$  K $^2$ . Calculate the standard reaction enthalpy and standard reaction entropy at 400 K.
- 6.10(b)** The equilibrium constant of a reaction is found to fit the expression  $\ln K = A + B/T + C/T^3$  between 400 K and 500 K with  $A = -2.04$ ,  $B = -1176$  K, and  $C = 2.1 \times 10^7$  K $^3$ . Calculate the standard reaction enthalpy and standard reaction entropy at 450 K.
- 6.11(a)** Establish the relation between  $K$  and  $K_c$  for the reaction  $H_2CO(g) \rightleftharpoons CO(g) + H_2(g)$ .
- 6.11(b)** Establish the relation between  $K$  and  $K_c$  for the reaction  $3 N_2(g) + H_2(g) \rightleftharpoons 2 HN_3(g)$ .
- 6.12(a)** Calculate the values of  $K$  and  $K_c$  for the reaction  $H_2CO(g) \rightleftharpoons CO(g) + H_2(g)$  at (a) 25°C, (b) 100°C.
- 6.12(b)** Calculate the values of  $K$  and  $K_c$  for the reaction  $3 N_2(g) + H_2(g) \rightleftharpoons 2 HN_3(g)$  at (a) 25°C, (b) 100°C.

**6.13(a)** The standard reaction Gibbs energy of the isomerization of borneol ( $C_{10}H_{17}OH$ ) to isoborneol in the gas phase at 503 K is  $+9.4 \text{ kJ mol}^{-1}$ . Calculate the reaction Gibbs energy in a mixture consisting of 0.15 mol of borneol and 0.30 mol of isoborneol when the total pressure is 600 Torr.

**6.13(b)** The equilibrium pressure of  $H_2$  over solid uranium and uranium hydride,  $UH_3$ , at 500 K is 139 Pa. Calculate the standard Gibbs energy of formation of  $UH_3(s)$  at 500 K.

**6.14(a)** Calculate the percentage change in  $K_x$  for the reaction  $H_2CO(g) \rightleftharpoons CO(g) + H_2(g)$  when the total pressure is increased from 1.0 bar to 2.0 bar at constant temperature.

**6.14(b)** Calculate the percentage change in  $K_x$  for the reaction  $CH_3OH(g) + NOCl(g) \rightleftharpoons HCl(g) + CH_3NO_2(g)$  when the total pressure is increased from 1.0 bar to 2.0 bar at constant temperature.

**6.15(a)** The equilibrium constant for the gas-phase isomerization of borneol ( $C_{10}H_{17}OH$ ) to isoborneol at 503 K is 0.106. A mixture consisting of 7.50 g of borneol and 14.0 g of isoborneol in a container of volume  $5.0 \text{ dm}^3$  is heated to 503 K and allowed to come to equilibrium. Calculate the mole fractions of the two substances at equilibrium.

**6.15(b)** The equilibrium constant for the reaction  $N_2(g) + O_2(g) \rightleftharpoons 2 NO(g)$  is  $1.69 \times 10^{-3}$  at 2300 K. A mixture consisting of 5.0 g of nitrogen and 2.0 g of oxygen in a container of volume  $1.0 \text{ dm}^3$  is heated to 2300 K and allowed to come to equilibrium. Calculate the mole fraction of NO at equilibrium.

**6.16(a)** What is the standard enthalpy of a reaction for which the equilibrium constant is (a) doubled, (b) halved when the temperature is increased by 10 K at 298 K?

**6.16(b)** What is the standard enthalpy of a reaction for which the equilibrium constant is (a) doubled, (b) halved when the temperature is increased by 15 K at 310 K?

**6.17(a)** The standard Gibbs energy of formation of  $NH_3(g)$  is  $-16.5 \text{ kJ mol}^{-1}$  at 298 K. What is the reaction Gibbs energy when the partial pressures of the  $N_2$ ,  $H_2$ , and  $NH_3$  (treated as perfect gases) are 3.0 bar, 1.0 bar, and 4.0 bar, respectively? What is the spontaneous direction of the reaction in this case?

**6.17(b)** The dissociation vapour pressure of  $NH_4Cl$  at  $427^\circ\text{C}$  is 608 kPa but at  $459^\circ\text{C}$  it has risen to 1115 kPa. Calculate (a) the equilibrium constant, (b) the standard reaction Gibbs energy, (c) the standard enthalpy, (d) the standard entropy of dissociation, all at  $427^\circ\text{C}$ . Assume that the vapour behaves as a perfect gas and that  $\Delta H^\circ$  and  $\Delta S^\circ$  are independent of temperature in the range given.

**6.18(a)** Estimate the temperature at which  $CaCO_3$  (calcite) decomposes.

**6.18(b)** Estimate the temperature at which  $CuSO_4 \cdot 5H_2O$  undergoes dehydration.

**6.19(a)** For  $CaF_2(s) \rightleftharpoons Ca^{2+}(aq) + 2 F^-(aq)$ ,  $K = 3.9 \times 10^{-11}$  at  $25^\circ\text{C}$  and the standard Gibbs energy of formation of  $CaF_2(s)$  is  $-1167 \text{ kJ mol}^{-1}$ . Calculate the standard Gibbs energy of formation of  $CaF_2(aq)$ .

**6.19(b)** For  $PbI_2(s) \rightleftharpoons Pb^{2+}(aq) + 2 I^-(aq)$ ,  $K = 1.4 \times 10^{-8}$  at  $25^\circ\text{C}$  and the standard Gibbs energy of formation of  $PbI_2(s)$  is  $-173.64 \text{ kJ mol}^{-1}$ . Calculate the standard Gibbs energy of formation of  $PbI_2(aq)$ .

**6.20(a)** Write the cell reaction and electrode half-reactions and calculate the standard potential of each of the following cells:

- (a)  $Zn|ZnSO_4(aq)||AgNO_3(aq)|Ag$
- (b)  $Cd|CdCl_2(aq)||HNO_3(aq)|H_2(g)|Pt$
- (c)  $Pt|K_3[Fe(CN)_6](aq), K_4[Fe(CN)_6](aq)||CrCl_3(aq)|Cr$

**6.20(b)** Write the cell reaction and electrode half-reactions and calculate the standard potential of each of the following cells:

- (a)  $Pt|Cl_2(g)|HCl(aq)||K_2CrO_4(aq)|Ag_2CrO_4(s)|Ag$
- (b)  $Pt|Fe^{3+}(aq), Fe^{2+}(aq)||Sn^{4+}(aq), Sn^{2+}(aq)|Pt$
- (c)  $Cu|Cu^{2+}(aq)||Mn^{2+}(aq), H^+(aq)|MnO_2(s)|Pt$

**6.21(a)** Devise cells in which the following are the reactions and calculate the standard cell potential in each case:

- (a)  $Zn(s) + CuSO_4(aq) \rightarrow ZnSO_4(aq) + Cu(s)$
- (b)  $2 AgCl(s) + H_2(g) \rightarrow 2 HCl(aq) + 2 Ag(s)$
- (c)  $2 H_2(g) + O_2(g) \rightarrow 2 H_2O(l)$

**6.21(b)** Devise cells in which the following are the reactions and calculate the standard cell potential in each case:

- (a)  $2 Na(s) + 2 H_2O(l) \rightarrow 2 NaOH(aq) + H_2(g)$
- (b)  $H_2(g) + I_2(s) \rightarrow 2 HI(aq)$
- (c)  $H_3O^+(aq) + OH^-(aq) \rightarrow 2 H_2O(l)$

**6.22(a)** Use the Debye–Hückel limiting law and the Nernst equation to estimate the potential of the cell  $Ag|AgBr(s)|KBr(aq, 0.050 \text{ mol kg}^{-1})||Cd(NO_3)_2(aq, 0.010 \text{ mol kg}^{-1})|Cd$  at  $25^\circ\text{C}$ .

**6.22(b)** Consider the cell  $Pt|H_2(g, p^\circ)|HCl(aq)|AgCl(s)|Ag$ , for which the cell reaction is  $2 AgCl(s) + H_2(g) \rightarrow 2 Ag(s) + 2 HCl(aq)$ . At  $25^\circ\text{C}$  and a molality of HCl of  $0.010 \text{ mol kg}^{-1}$ ,  $E_{\text{cell}} = +0.4658 \text{ V}$ . (a) Write the Nernst equation for the cell reaction. (b) Calculate  $\Delta_r G$  for the cell reaction. (c) Assuming that the Debye–Hückel limiting law holds at this concentration, calculate  $E^\circ(Cl^-, AgCl, Ag)$ .

**6.23(a)** Calculate the equilibrium constants of the following reactions at  $25^\circ\text{C}$  from standard potential data:

- (a)  $Sn(s) + Sn^{4+}(aq) \rightleftharpoons 2 Sn^{2+}(aq)$
- (b)  $Sn(s) + 2 AgCl(s) \rightleftharpoons SnCl_2(aq) + 2 Ag(s)$

**6.23(b)** Calculate the equilibrium constants of the following reactions at  $25^\circ\text{C}$  from standard potential data:

- (a)  $Sn(s) + CuSO_4(aq) \rightleftharpoons Cu(s) + SnSO_4(aq)$
- (b)  $Cu^{2+}(aq) + Cu(s) \rightleftharpoons 2 Cu^+(aq)$

**6.24(a)** The potential of the cell  $Ag|AgI(s)|AgI(aq)|Ag$  is  $+0.9509 \text{ V}$  at  $25^\circ\text{C}$ . Calculate (a) the solubility product of AgI and (b) its solubility.

**6.24(b)** The potential of the cell  $Bi|Bi_2S_3(s)|Bi_2S_3(aq)|Bi$  is  $0.96 \text{ V}$  at  $25^\circ\text{C}$ . Calculate (a) the solubility product of  $Bi_2S_3$  and (b) its solubility.

## Problems\*

## Numerical problems

**6.1** The equilibrium constant for the reaction,  $\text{I}_2(\text{s}) + \text{Br}_2(\text{g}) \rightleftharpoons 2 \text{IBr}(\text{g})$  is 0.164 at 25°C. (a) Calculate  $\Delta_r G^\circ$  for this reaction. (b) Bromine gas is introduced into a container with excess solid iodine. The pressure and temperature are held at 0.164 atm and 25°C, respectively. Find the partial pressure of  $\text{IBr}(\text{g})$  at equilibrium. Assume that all the bromine is in the liquid form and that the vapour pressure of iodine is negligible. (c) In fact, solid iodine has a measurable vapour pressure at 25°C. In this case, how would the calculation have to be modified?

**6.2** Consider the dissociation of methane,  $\text{CH}_4(\text{g})$ , into the elements  $\text{H}_2(\text{g})$  and  $\text{C}(\text{s, graphite})$ . (a) Given that  $\Delta_f H^\circ(\text{CH}_4, \text{g}) = -74.85 \text{ kJ mol}^{-1}$  and that  $\Delta_f S^\circ(\text{CH}_4, \text{g}) = -80.67 \text{ J K}^{-1} \text{ mol}^{-1}$  at 298 K, calculate the value of the equilibrium constant at 298 K. (b) Assuming that  $\Delta_f H^\circ$  is independent of temperature, calculate  $K$  at 50°C. (c) Calculate the degree of dissociation,  $\alpha$ , of methane at 25°C and a total pressure of 0.010 bar. (d) Without doing any numerical calculations, explain how the degree of dissociation for this reaction will change as the pressure and temperature are varied.

**6.3** The equilibrium pressure of  $\text{H}_2$  over  $\text{U}(\text{s})$  and  $\text{UH}_3(\text{s})$  between 450 K and 715 K fits the expression  $\ln(p/\text{Pa}) = A + B/T + C \ln(T/\text{K})$ , with  $A = 69.32$ ,  $B = -1.464 \times 10^4 \text{ K}$ , and  $C = -5.65$ . Find an expression for the standard enthalpy of formation of  $\text{UH}_3(\text{s})$  and from it calculate  $\Delta_f C_p^\circ$ .

**6.4** The degree of dissociation,  $\alpha$ , of  $\text{CO}_2(\text{g})$  into  $\text{CO}(\text{g})$  and  $\text{O}_2(\text{g})$  at high temperatures was found to vary with temperature as follows:

|                  |      |      |      |
|------------------|------|------|------|
| $T/\text{K}$     | 1395 | 1443 | 1498 |
| $\alpha/10^{-4}$ | 1.44 | 2.50 | 4.71 |

Assuming  $\Delta_f H^\circ$  to be constant over this temperature range, calculate  $K$ ,  $\Delta_r G^\circ$ ,  $\Delta_r H^\circ$ , and  $\Delta_r S^\circ$ . Make any justifiable approximations.

**6.5** The standard reaction enthalpy for the decomposition of  $\text{CaCl}_2 \cdot \text{NH}_3(\text{s})$  into  $\text{CaCl}_2(\text{s})$  and  $\text{NH}_3(\text{g})$  is nearly constant at  $+78 \text{ kJ mol}^{-1}$  between 350 K and 470 K. The equilibrium pressure of  $\text{NH}_3$  in the presence of  $\text{CaCl}_2 \cdot \text{NH}_3$  is 1.71 kPa at 400 K. Find an expression for the temperature dependence of  $\Delta_r G^\circ$  in the same range.

**6.6** Calculate the equilibrium constant of the reaction  $\text{CO}(\text{g}) + \text{H}_2(\text{g}) \rightleftharpoons \text{H}_2\text{CO}(\text{g})$  given that, for the production of liquid formaldehyde,  $\Delta_r G^\circ = +28.95 \text{ kJ mol}^{-1}$  at 298 K and that the vapour pressure of formaldehyde is 1500 Torr at that temperature.

**6.7** Acetic acid was evaporated in a container of volume  $21.45 \text{ cm}^3$  at 437 K and at an external pressure of 101.9 kPa, and the container was then sealed. The combined mass of acid monomer and dimer in the sealed container was 0.0463 g. The experiment was repeated with the same container but at 471 K, and the combined mass of acid monomer and dimer was found to be 0.0380 g. Calculate the equilibrium constant for the dimerization of the acid in the vapour and the enthalpy of dimerization.

**6.8** A sealed container was filled with 0.300 mol  $\text{H}_2(\text{g})$ , 0.400 mol  $\text{I}_2(\text{g})$ , and 0.200 mol  $\text{HI}(\text{g})$  at 870 K and total pressure 1.00 bar. Calculate the amounts of the components in the mixture at equilibrium given that  $K = 870$  for the reaction  $\text{H}_2(\text{g}) + \text{I}_2(\text{g}) \rightleftharpoons 2 \text{HI}(\text{g})$ .

**6.9** The dissociation of  $\text{I}_2$  can be monitored by measuring the total pressure, and three sets of results are as follows:

|                   |        |        |        |
|-------------------|--------|--------|--------|
| $T/\text{K}$      | 973    | 1073   | 1173   |
| $100p/\text{atm}$ | 6.244  | 7.500  | 9.181  |
| $10^4 n_1$        | 2.4709 | 2.4555 | 2.4366 |

where  $n_1$  is the amount of I atoms per mole of  $\text{I}_2$  molecules in the mixture, which occupied  $342.68 \text{ cm}^3$ . Calculate the equilibrium constants of the dissociation and the standard enthalpy of dissociation at the mean temperature.

**6.10†** Thorn *et al.* (*J. Phys. Chem.* **100**, 14178 (1996)) carried out a study of  $\text{Cl}_2\text{O}(\text{g})$  by photoelectron ionization. From their measurements, they report  $\Delta_f H^\circ(\text{Cl}_2\text{O}) = +77.2 \text{ kJ mol}^{-1}$ . They combined this measurement with literature data on the reaction  $\text{Cl}_2\text{O}(\text{g}) + \text{H}_2\text{O}(\text{g}) \rightarrow 2 \text{HOCl}(\text{g})$ , for which  $K = 8.2 \times 10^{-2}$  and  $\Delta_r S^\circ = +16.38 \text{ J K}^{-1} \text{ mol}^{-1}$ , and with readily available thermodynamic data on water vapour to report a value for  $\Delta_f H^\circ(\text{HOCl})$ . Calculate that value. All quantities refer to 298 K.

**6.11†** The 1980s saw reports of  $\Delta_f H^\circ(\text{SiH}_2)$  ranging from 243 to 289  $\text{kJ mol}^{-1}$ . If the standard enthalpy of formation is uncertain by this amount, by what factor is the equilibrium constant for the formation of  $\text{SiH}_2$  from its elements uncertain at (a) 298 K, (b) 700 K?

**6.12** Fuel cells provide electrical power for spacecraft (as in the NASA space shuttles) and also show promise as power sources for automobiles. Hydrogen and carbon monoxide have been investigated for use in fuel cells, so their solubilities in molten salts are of interest. Their solubilities in a molten  $\text{NaNO}_3/\text{KNO}_3$  mixture were found to fit the following expressions:

$$\log s_{\text{H}_2} = -5.39 - \frac{768}{T/\text{K}} \quad \log s_{\text{CO}} = -5.98 - \frac{980}{T/\text{K}}$$

where  $s$  is the solubility in  $\text{mol cm}^{-3} \text{ bar}^{-1}$ . Calculate the standard molar enthalpies of solution of the two gases at 570 K.

**6.13** Given that  $\Delta_r G^\circ = -212.7 \text{ kJ mol}^{-1}$  for the reaction in the Daniell cell at 25°C, and  $b(\text{CuSO}_4) = 1.0 \times 10^{-3} \text{ mol kg}^{-1}$  and  $b(\text{ZnSO}_4) = 3.0 \times 10^{-3} \text{ mol kg}^{-1}$ , calculate (a) the ionic strengths of the solutions, (b) the mean ionic activity coefficients in the compartments, (c) the reaction quotient, (d) the standard cell potential, and (e) the cell potential. (Take  $\gamma_+ = \gamma_- = \gamma_\pm$  in the respective compartments.)

**6.14** A fuel cell develops an electric potential from the chemical reaction between reagents supplied from an outside source. What is the cell potential of a cell fuelled by (a) hydrogen and oxygen, (b) the combustion of butane at 1.0 bar and 298 K?

**6.15** Although the hydrogen electrode may be conceptually the simplest electrode and is the basis for our reference state of electrical potential in electrochemical systems, it is cumbersome to use. Therefore, several substitutes for it have been devised. One of these alternatives is the quinhydrone electrode (quinhydrone,  $\text{Q-QH}_2$ , is a complex of quinone,  $\text{C}_6\text{H}_4\text{O}_2 = \text{Q}$ , and hydroquinone,  $\text{C}_6\text{H}_4\text{O}_2\text{H}_2 = \text{QH}_2$ ). The electrode half-reaction is  $\text{Q}(\text{aq}) + 2 \text{H}^+(\text{aq}) + 2 \text{e}^- \rightarrow \text{QH}_2(\text{aq})$ ,  $E^\circ = +0.6994 \text{ V}$ . If the cell  $\text{Hg}|\text{Hg}_2\text{Cl}_2(\text{s})|\text{HCl}(\text{aq})|\text{Q-QH}_2|\text{Au}$  is prepared, and the measured cell potential is  $+0.190 \text{ V}$ , what is the pH of the  $\text{HCl}$  solution? Assume that the Debye–Hückel limiting law is applicable.

**6.16** Consider the cell,  $\text{Zn}(\text{s})|\text{ZnCl}_2(0.0050 \text{ mol kg}^{-1})|\text{Hg}_2\text{Cl}_2(\text{s})|\text{Hg}(\text{l})$ , for which the cell reaction is  $\text{Hg}_2\text{Cl}_2(\text{s}) + \text{Zn}(\text{s}) \rightarrow 2 \text{Hg}(\text{l}) + 2 \text{Cl}^-(\text{aq}) + \text{Zn}^{2+}(\text{aq})$ . Given that  $E^\circ(\text{Zn}^{2+}, \text{Zn}) = -0.7628 \text{ V}$ ,  $E^\circ(\text{Hg}_2\text{Cl}_2, \text{Hg}) = +0.2676 \text{ V}$ , and that the cell potential is  $+1.2272 \text{ V}$ , (a) write the Nernst equation for the cell. Determine (b) the standard cell potential, (c)  $\Delta_r G$ ,  $\Delta_r G^\circ$ , and  $K$  for the cell reaction, (d) the mean ionic activity and activity coefficient of  $\text{ZnCl}_2$  from the measured cell potential, and (e) the mean ionic activity coefficient of  $\text{ZnCl}_2$  from the Debye–Hückel limiting law. (f) Given that  $(\partial E_{\text{cell}}/\partial T)_p = -4.52 \times 10^{-4} \text{ V K}^{-1}$ , calculate  $\Delta_r S$  and  $\Delta_r H$ .

\* Problems denoted with the symbol † were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

**6.17** The potential of the cell  $\text{Pt}|\text{H}_2(\text{g}, p^\circ)|\text{HCl}(\text{aq}, b)|\text{Hg}_2\text{Cl}_2(\text{s})|\text{Hg}(\text{l})$  has been measured with high precision with the following results at 25°C:

|                           |         |         |         |         |         |
|---------------------------|---------|---------|---------|---------|---------|
| $b/(\text{mmol kg}^{-1})$ | 1.6077  | 3.0769  | 5.0403  | 7.6938  | 10.9474 |
| $E/\text{V}$              | 0.60080 | 0.56825 | 0.54366 | 0.52267 | 0.50532 |

Determine the standard cell potential and the mean activity coefficient of HCl at these molalities. (Make a least-squares fit of the data to the best straight line.)

**6.18** Careful measurements of the potential of the cell  $\text{Pt}|\text{H}_2(\text{g}, p^\circ)|\text{NaOH}(\text{aq}, 0.0100 \text{ mol kg}^{-1}), \text{NaCl}(\text{aq}, 0.0125 \text{ mol kg}^{-1})|\text{AgCl}(\text{s})|\text{Ag}$  have been reported. Among the data is the following information:

|                            |         |         |         |
|----------------------------|---------|---------|---------|
| $\theta/^\circ\text{C}$    | 20.0    | 25.0    | 30.0    |
| $E_{\text{cell}}/\text{V}$ | 1.04774 | 1.04864 | 1.04942 |

Calculate  $\text{p}K_w$  at these temperatures and the standard enthalpy and entropy of the autoprotolysis of water at 25.0°C.

**6.19** Measurements of the potential of cells of the type  $\text{Ag}|\text{AgX}(\text{s})|\text{MX}(b_1)|\text{M}_x\text{Hg}|\text{MX}(b_2)|\text{AgX}(\text{s})|\text{Ag}$ , where  $\text{M}_x\text{Hg}$  denotes an amalgam and the electrolyte is LiCl in ethylene glycol, are given below. Estimate the activity coefficient at the concentration marked \* and then use this value to calculate activity coefficients from the measured cell potential at the other concentrations. Base your answer on the following version of the extended Debye–Hückel law:

$$\log \gamma_{\pm} = -\frac{AI^{1/2}}{1 + BI^{1/2}} + CI$$

with  $A = 1.461$ ,  $B = 1.70$ ,  $C = 0.20$ , and  $I = b/b^\circ$ . For  $b_2 = 0.09141 \text{ mol kg}^{-1}$ :

|                            |         |          |        |        |        |        |

### Theoretical problems

**6.22** Express the equilibrium constant of a gas-phase reaction  $\text{A} + 3 \text{B} \rightleftharpoons 2 \text{C}$  in terms of the equilibrium value of the extent of reaction,  $\xi$ , given that

initially A and B were present in stoichiometric proportions. Find an expression for  $\xi$  as a function of the total pressure,  $p$ , of the reaction mixture and sketch a graph of the expression obtained.

**6.23** Find an expression for the standard reaction Gibbs energy at a temperature  $T'$  in terms of its value at another temperature  $T$  and the coefficients  $a$ ,  $b$ , and  $c$  in the expression for the molar heat capacity listed in Table 2.2. Evaluate the standard Gibbs energy of formation of  $\text{H}_2\text{O}(\text{l})$  at 372 K from its value at 298 K.

**6.24** Derive an expression for the temperature dependence of  $K_c$  for a gas-phase reaction.

### Applications: to biology, environmental science, and chemical engineering

**6.25** Here we investigate the molecular basis for the observation that the hydrolysis of ATP is exergonic at  $\text{pH} = 7.0$  and 310 K. (a) It is thought that the exergonicity of ATP hydrolysis is due in part to the fact that the standard entropies of hydrolysis of polyphosphates are positive. Why would an increase in entropy accompany the hydrolysis of a triphosphate group into a diphosphate and a phosphate group? (b) Under identical conditions, the Gibbs energies of hydrolysis of  $\text{H}_4\text{ATP}$  and  $\text{MgATP}^{2-}$ , a complex between the  $\text{Mg}^{2+}$  ion and  $\text{ATP}^{4-}$ , are less negative than the Gibbs energy of hydrolysis of  $\text{ATP}^{4-}$ . This observation has been used to support the hypothesis that electrostatic repulsion between adjacent phosphate groups is a factor that controls the exergonicity of ATP hydrolysis. Provide a rationale for the hypothesis and discuss how the experimental evidence supports it. Do these electrostatic effects contribute to the  $\Delta_r H$  or  $\Delta_r S$  terms that determine the exergonicity of the reaction? *Hint.* In the  $\text{MgATP}^{2-}$  complex, the  $\text{Mg}^{2+}$  ion and  $\text{ATP}^{4-}$  anion form two bonds: one that involves a negatively charged oxygen belonging to the terminal phosphate group of  $\text{ATP}^{4-}$  and another that involves a negatively charged oxygen belonging to the phosphate group adjacent to the terminal phosphate group of  $\text{ATP}^{4-}$ .

**6.26** To get a sense of the effect of cellular conditions on the ability of ATP to drive biochemical processes, compare the standard Gibbs energy of hydrolysis of ATP to ADP with the reaction Gibbs energy in an environment at 37°C in which  $\text{pH} = 7.0$  and the ATP, ADP, and  $\text{P}_i^-$  concentrations are all  $1.0 \mu\text{mol dm}^{-3}$ .

**6.27** Under biochemical standard conditions, aerobic respiration produces approximately 38 molecules of ATP per molecule of glucose that is completely oxidized. (a) What is the percentage efficiency of aerobic respiration under biochemical standard conditions? (b) The following conditions are more likely to be observed in a living cell:  $p_{\text{CO}_2} = 5.3 \times 10^{-2} \text{ atm}$ ,  $p_{\text{O}_2} = 0.132 \text{ atm}$ ,  $[\text{glucose}] = 5.6 \times 10^{-2} \text{ mol dm}^{-3}$ ,  $[\text{ATP}] = [\text{ADP}] = [\text{P}_i] = 1.0 \times 10^{-4} \text{ mol dm}^{-3}$ ,  $\text{pH} = 7.4$ ,  $T = 310 \text{ K}$ . Assuming that activities can be replaced by the numerical values of molar concentrations, calculate the efficiency of aerobic respiration under these physiological conditions. (c) A typical diesel engine operates between  $T_c = 873 \text{ K}$  and  $T_h = 1923 \text{ K}$  with an efficiency that is approximately 75 per cent of the theoretical limit of  $(1 - T_c/T_h)$  (see Section 3.2). Compare the efficiency of a typical diesel engine with that of aerobic respiration under typical physiological conditions (see part b). Why is biological energy conversion more or less efficient than energy conversion in a diesel engine?

**6.28** In anaerobic bacteria, the source of carbon may be a molecule other than glucose and the final electron acceptor is some molecule other than  $\text{O}_2$ . Could a bacterium evolve to use the ethanol/nitrate pair instead of the glucose/ $\text{O}_2$  pair as a source of metabolic energy?

**6.29** The standard potentials of proteins are not commonly measured by the methods described in this chapter because proteins often lose their native structure and function when they react on the surfaces of electrodes. In an alternative method, the oxidized protein is allowed to react with an

appropriate electron donor in solution. The standard potential of the protein is then determined from the Nernst equation, the equilibrium concentrations of all species in solution, and the known standard potential of the electron donor. We illustrate this method with the protein cytochrome *c*. The one-electron reaction between cytochrome *c*, cyt, and 2,6-dichloroindophenol, D, can be followed spectrophotometrically because each of the four species in solution has a distinct absorption spectrum. We write the reaction as  $\text{cyt}_{\text{ox}} + \text{D}_{\text{red}} \rightleftharpoons \text{cyt}_{\text{red}} + \text{D}_{\text{ox}}$ , where the subscripts 'ox' and 'red' refer to oxidized and reduced states, respectively. (a) Consider  $E_{\text{cyt}}^{\circ}$  and  $E_{\text{D}}^{\circ}$  to be the standard potentials of cytochrome *c* and D, respectively. Show that, at equilibrium, a plot of  $\ln([\text{D}_{\text{ox}}]_{\text{eq}}/[\text{D}_{\text{red}}]_{\text{eq}})$  versus  $\ln([\text{cyt}_{\text{ox}}]_{\text{eq}}/[\text{cyt}_{\text{red}}]_{\text{eq}})$  is linear with slope of 1 and  $y$ -intercept  $F(E_{\text{cyt}}^{\circ} - E_{\text{D}}^{\circ})/RT$ , where equilibrium activities are replaced by the numerical values of equilibrium molar concentrations. (b) The following data were obtained for the reaction between oxidized cytochrome *c* and reduced D in a pH 6.5 buffer at 298 K. The ratios  $[\text{D}_{\text{ox}}]_{\text{eq}}/[\text{D}_{\text{red}}]_{\text{eq}}$  and  $[\text{cyt}_{\text{ox}}]_{\text{eq}}/[\text{cyt}_{\text{red}}]_{\text{eq}}$  were adjusted by titrating a solution containing oxidized cytochrome *c* and reduced D with a solution of sodium ascorbate, which is a strong reductant. From the data and the standard potential of D of 0.237 V, determine the standard potential cytochrome *c* at pH 6.5 and 298K.

|--------------|--------------------|--------------------|--------------------|--------------------|--------------------|--------------------|
| $T/\text{K}$ | 233                | 248                | 258                | 268                | 273                | 280                |
| $K$          | $4.13 \times 10^8$ | $5.00 \times 10^7$ | $1.45 \times 10^7$ | $5.37 \times 10^6$ | $3.20 \times 10^6$ | $9.62 \times 10^5$ |

|              |                    |                    |                    |
|--------------|--------------------|--------------------|--------------------|
| $T/\text{K}$ | 288                | 295                | 303                |
| $K$          | $4.28 \times 10^5$ | $1.67 \times 10^5$ | $6.02 \times 10^4$ |

(a) Derive the values of  $\Delta_r H^{\circ}$  and  $\Delta_r S^{\circ}$  for this reaction. (b) Compute the standard enthalpy of formation and the standard molar entropy of  $(\text{ClO})_2$  given  $\Delta_f H^{\circ}(\text{ClO}) = +101.8 \text{ kJ mol}^{-1}$  and  $S_m^{\circ}(\text{ClO}) = 266.6 \text{ J K}^{-1} \text{ mol}^{-1}$ .

**6.31†** Nitric acid hydrates have received much attention as possible catalysts for heterogeneous reactions that bring about the Antarctic ozone hole. Standard reaction Gibbs energies are as follows:

- (i)  $\text{H}_2\text{O}(\text{g}) \rightarrow \text{H}_2\text{O}(\text{s})$   $\Delta_r G^{\circ} = -23.6 \text{ kJ mol}^{-1}$
- (ii)  $\text{H}_2\text{O}(\text{g}) + \text{HNO}_3(\text{g}) \rightarrow \text{HNO}_3 \cdot \text{H}_2\text{O}(\text{s})$   $\Delta_r G^{\circ} = -57.2 \text{ kJ mol}^{-1}$
- (iii)  $2 \text{H}_2\text{O}(\text{g}) + \text{HNO}_3(\text{g}) \rightarrow \text{HNO}_3 \cdot 2\text{H}_2\text{O}(\text{s})$   $\Delta_r G^{\circ} = -85.6 \text{ kJ mol}^{-1}$
- (iv)  $3 \text{H}_2\text{O}(\text{g}) + \text{HNO}_3(\text{g}) \rightarrow \text{HNO}_3 \cdot 3\text{H}_2\text{O}(\text{s})$   $\Delta_r G^{\circ} = -112.8 \text{ kJ mol}^{-1}$

Which solid is thermodynamically most stable at 190 K if  $p_{\text{H}_2\text{O}} = 1.3 \times 10^{-7} \text{ bar}$  and  $p_{\text{HNO}_3} = 4.1 \times 10^{-10} \text{ bar}$ ? *Hint.* Try computing  $\Delta_r G$  for each reaction under the prevailing conditions; if more than one solid forms spontaneously, examine  $\Delta_r G$  for the conversion of one solid to another.

**6.32†** Suppose that an iron catalyst at a particular manufacturing plant produces ammonia in the most cost-effective manner at 450°C when the pressure is such that  $\Delta_r G$  for the reaction  $\frac{1}{2}\text{N}_2(\text{g}) + \frac{3}{2}\text{H}_2(\text{g}) \rightarrow \text{NH}_3(\text{g})$  is equal to  $-500 \text{ J mol}^{-1}$ . (a) What pressure is needed? (b) Now suppose that a new catalyst is developed that is most cost-effective at 400°C when the pressure gives the same value of  $\Delta_r G$ . What pressure is needed when the new catalyst is used? What are the advantages of the new catalyst? Assume that (i) all gases are perfect gases or that (ii) all gases are van der Waals gases. Isotherms of  $\Delta_r G(T, p)$  in the pressure range  $100 \text{ atm} \leq p \leq 400 \text{ atm}$  are needed to derive the answer. (c) Do the isotherms you plotted confirm Le Chatelier's principle concerning the response of equilibrium changes in temperature and pressure?

# Quantum theory: introduction and principles

This chapter introduces some of the basic principles of quantum mechanics. First, it reviews the experimental results that overthrew the concepts of classical physics. These experiments led to the conclusion that particles may not have an arbitrary energy and that the classical concepts of ‘particle’ and ‘wave’ blend together. The overthrow of classical mechanics inspired the formulation of a new set of concepts and led to the formulation of quantum mechanics. In quantum mechanics, all the properties of a system are expressed in terms of a wavefunction that is obtained by solving the Schrödinger equation. We see how to interpret wavefunctions. Finally, we introduce some of the techniques of quantum mechanics in terms of operators, and see that they lead to the uncertainty principle, one of the most profound departures from classical mechanics.

It was once thought that the motion of atoms and subatomic particles could be expressed using **classical mechanics**, the laws of motion introduced in the seventeenth century by Isaac Newton, for these laws were very successful at explaining the motion of everyday objects and planets. However, towards the end of the nineteenth century, experimental evidence accumulated showing that classical mechanics failed when it was applied to particles as small as electrons, and it took until the 1920s to discover the appropriate concepts and equations for describing them. We describe the concepts of this new mechanics, which is called **quantum mechanics**, in this chapter, and apply them throughout the remainder of the text.

## The origins of quantum mechanics

The basic principles of classical mechanics are reviewed in *Further information 7.1*. In brief, they show that classical physics (1) predicts a precise trajectory for particles, with precisely specified locations and momenta at each instant, and (2) allows the translational, rotational, and vibrational modes of motion to be excited to any energy simply by controlling the forces that are applied. These conclusions agree with everyday experience. Everyday experience, however, does not extend to individual atoms, and careful experiments of the type described below have shown that classical mechanics fails when applied to the transfers of very small energies and to objects of very small mass.

We shall also investigate the properties of light. In classical physics, light is described as electromagnetic radiation, which is understood in terms of the **electromagnetic field**, an oscillating electric and magnetic disturbance that spreads as a harmonic wave, wave displacements that can be expressed as sine or cosine functions (see *Fundamentals F.6*), through empty space, the vacuum. Such waves are generated by

Problems

**Fig. 7.1** The wavelength,  $\lambda$ , of a wave is the peak-to-peak distance. (b) The wave is shown travelling to the right at a speed  $c$ . At a given location, the instantaneous amplitude of the wave changes through a complete cycle (the five dots show half a cycle). The frequency,  $\nu$ , is the number of cycles per second that occur at a given point.

the acceleration of electric charge, as in the oscillating motion of electrons in the antenna of a radio transmitter. The wave travels at a constant speed called the *speed of light*,  $c$ , which is about  $3 \times 10^8 \text{ m s}^{-1}$ . As its name suggests, an electromagnetic field has two components, an **electric field** that acts on charged particles (whether stationary or moving) and a **magnetic field** that acts only on moving charged particles. The electromagnetic field is characterized by a **wavelength**,  $\lambda$  (lambda), the distance between the neighbouring peaks of the wave, and its **frequency**,  $\nu$  (nu), the number of times per second at which its displacement at a fixed point returns to its original value (Fig. 7.1). The frequency is measured in *hertz*, where  $1 \text{ Hz} = 1 \text{ s}^{-1}$ . The wavelength and frequency of an electromagnetic wave are related by

$$\lambda \nu = c \quad (7.1)$$

Therefore, the shorter the wavelength, the higher the frequency. The characteristics of the wave are also reported by giving the **wavenumber**,  $\tilde{\nu}$  (nu tilde), of the radiation, where

$$\tilde{\nu} = \frac{\nu}{c} = \frac{1}{\lambda} \quad [7.2]$$

Wavenumbers are normally reported in reciprocal centimetres ( $\text{cm}^{-1}$ ).

Figure 7.2 summarizes the **electromagnetic spectrum**, the description and classification of the electromagnetic field according to its frequency and wavelength. ‘Light’ is electromagnetic radiation that falls in the visible region of the spectrum. White light is a mixture of electromagnetic radiation with wavelengths ranging from about 400 nm to about 700 nm ( $1 \text{ nm} = 10^{-9} \text{ m}$ ). Our eyes perceive different wavelengths of radiation in this range as different colours, so it can be said that white light is a mixture of light of all different colours.

## 7.1 Energy quantization

**Key points** (a) The classical approach to the description of black-body radiation results in the ultraviolet catastrophe. (b) To avoid this catastrophe, Planck proposed that the electromagnetic field could take up energy only in discrete amounts. (c) The thermal properties of solids, specifically their heat capacities, also provide evidence that the vibrations of atoms can take up energy only in discrete amounts. (d) Atomic and molecular spectra show that atoms and molecules can take up energy only in discrete amounts.

**Fig. 7.2** The electromagnetic spectrum and the classification of the spectral regions.

The overthrow of classical mechanics and its replacement by quantum mechanics was driven, as always in science, by noticing that experimental observations conflicted with the predictions of accepted theory. Here we outline three examples of experiment overthrowing current theory, which came to light at the end of the nineteenth century and which drove scientists to the view that energy can be transferred only in discrete amounts.

### (a) Black-body radiation

A hot object emits electromagnetic radiation. At high temperatures, an appreciable proportion of the radiation is in the visible region of the spectrum, and a higher proportion of short-wavelength blue light is generated as the temperature is raised. This behaviour is seen when a heated metal bar glowing red hot becomes white hot when heated further. The dependence is illustrated in Fig. 7.3, which shows how the energy output varies with wavelength at several temperatures. The curves are those of an ideal emitter called a **black body**, which is an object capable of emitting and absorbing all wavelengths of radiation uniformly. A good approximation to a black body is a pinhole in an empty container maintained at a constant temperature, because any radiation leaking out of the hole has been absorbed and re-emitted inside so many times as it reflected around inside the container that it has come to thermal equilibrium with the walls (Fig. 7.4).

The approach adopted by nineteenth-century scientists to explain black-body radiation was to calculate the **energy density**,  $d\mathcal{E}$ , the total energy in a region of the electromagnetic field divided by the volume of the region (units: joules per metre-cubed,  $\text{J m}^{-3}$ ), due to all the oscillators corresponding to wavelengths between  $\lambda$  and  $\lambda + d\lambda$ . This energy density is proportional to the width,  $d\lambda$ , of this range, and is written

$$d\mathcal{E}(\lambda, T) = \rho(\lambda, T) d\lambda \quad (7.3)$$

where  $\rho$  (rho), the constant of proportionality between  $d\mathcal{E}$  and  $d\lambda$ , is called the **density of states** (units: joules per metre<sup>4</sup>,  $\text{J m}^{-4}$ ). A high density of states at the wavelength  $\lambda$  and temperature  $T$  simply means that there is a lot of energy associated with wavelengths lying between  $\lambda$  and  $\lambda + d\lambda$  at that temperature. The total energy density in a region is the integral over all wavelengths:

$$\mathcal{E}(T) = \int_0^\infty \rho(\lambda, T) d\lambda \quad (7.4)$$

and depends on the temperature: the higher the temperature, the greater the energy density. Just as the mass of an object is its mass density multiplied by its volume, the total energy within a region of volume  $V$  is this energy density multiplied by the volume:

$$E(T) = V\mathcal{E}(T) \quad (7.5)$$

The physicist Lord Rayleigh thought of the electromagnetic field as a collection of oscillators of all possible frequencies. He regarded the presence of radiation of frequency  $\nu$  (and therefore of wavelength  $\lambda = c/\nu$ ) as signifying that the electromagnetic oscillator of that frequency had been excited (Fig. 7.5). Rayleigh knew that according to the classical equipartition principle (*Fundamentals* F.5b), the average energy of each oscillator, regardless of its frequency, is  $kT$ . On that basis, with minor help from James Jeans, he arrived at the **Rayleigh–Jeans law** for the density of states:

$$\rho(\lambda, T) = \frac{8\pi kT}{\lambda^4} \quad \text{Rayleigh–Jeans law} \quad (7.6)$$

where  $k$  is Boltzmann's constant ( $k = 1.381 \times 10^{-23} \text{ J K}^{-1}$ ).

**Fig. 7.3** The energy distribution in a black-body cavity at several temperatures. Note how the energy density increases in the region of shorter wavelengths as the temperature is raised, and how the peak shifts to shorter wavelengths. The total energy density (the area under the curve) increases as the temperature is increased (as  $T^4$ ).

**Fig. 7.4** An experimental representation of a black body is a pinhole in an otherwise closed container. The radiation is reflected many times within the container and comes to thermal equilibrium with the walls at a temperature  $T$ . Radiation leaking out through the pinhole is characteristic of the radiation within the container.

**Fig. 7.5** The electromagnetic vacuum can be regarded as able to support oscillations of the electromagnetic field. When a high frequency, short wavelength oscillator (a) is excited, that frequency of radiation is present. The presence of low frequency, long wavelength radiation (b) signifies that an oscillator of the corresponding frequency has been excited.

**Fig. 7.6** The Rayleigh–Jeans law (eqn 7.6) predicts an infinite energy density at short wavelengths. This approach to infinity is called the *ultraviolet catastrophe*.

#### A brief comment

The series expansion of an exponential function is  $e^x = 1 + x + \frac{1}{2}x^2 + \dots$ . If  $x \ll 1$ , a good approximation is  $e^x \approx 1 + x$ . For example,  $e^{0.01} = 1.010\,050\dots \approx 1 + 0.01$ .

Although the Rayleigh–Jeans law is quite successful at long wavelengths (low frequencies), it fails badly at short wavelengths (high frequencies). Thus, as  $\lambda$  decreases,  $\rho$  increases without going through a maximum (Fig. 7.6). The equation therefore predicts that oscillators of very short wavelength (corresponding to ultraviolet radiation, X-rays, and even  $\gamma$ -rays) are strongly excited even at room temperature. The total energy density in a region, the integral in eqn 7.4, is also predicted to be infinite at all temperatures above zero. This absurd result, which implies that a large amount of energy is radiated in the high-frequency region of the electromagnetic spectrum, is called the **ultraviolet catastrophe**. According to classical physics, even cool objects should radiate in the visible and ultraviolet regions, so objects should glow in the dark; there should in fact be no darkness.

In 1900, the German physicist Max Planck found that he could account for the experimental observations by proposing that the energy of each electromagnetic oscillator is limited to discrete values and cannot be varied arbitrarily. This proposal is contrary to the viewpoint of classical physics in which all possible energies are allowed and every oscillator has a mean energy  $kT$ . The limitation of energies to discrete values is called the **quantization of energy**. In particular, Planck found that he could account for the observed distribution of energy if he supposed that the permitted energies of an electromagnetic oscillator of frequency  $\nu$  are integer multiples of  $h\nu$ :

$$E = nh\nu \quad n = 0, 1, 2, \dots \quad (7.7)$$

where  $h$  is a fundamental constant now known as **Planck's constant**. On the basis of this assumption, Planck was able to derive the **Planck distribution**:

$$\rho(\lambda, T) = \frac{8\pi hc}{\lambda^5 (e^{hc/\lambda kT} - 1)} \quad \text{Planck distribution} \quad (7.8)$$

This expression fits the experimental curve very well at all wavelengths (Fig. 7.7), and the value of  $h$ , which is an undetermined parameter in the theory, may be obtained by varying its value until a best fit is obtained. The currently accepted value for  $h$  is  $6.626 \times 10^{-34} \text{ J s}$ .

As usual, it is a good idea to ‘read’ the content of an equation:

1. The Planck distribution resembles the Rayleigh–Jeans law (eqn 7.6) apart from the all-important exponential factor in the denominator. For short wavelengths,  $hc/\lambda kT \gg 1$  and  $e^{hc/\lambda kT} \rightarrow \infty$  faster than  $\lambda^5 \rightarrow 0$ ; therefore  $\rho \rightarrow 0$  as  $\lambda \rightarrow 0$  or  $\nu \rightarrow \infty$ . Hence, the energy density approaches zero at high frequencies, in agreement with observation.
2. For long wavelengths,  $hc/\lambda kT \ll 1$ , and the denominator in the Planck distribution can be replaced by

$$e^{hc/\lambda kT} - 1 = \left( 1 + \frac{hc}{\lambda kT} + \dots \right) - 1 \approx \frac{hc}{\lambda kT}$$

When this approximation is substituted into eqn 7.8, we find that the Planck distribution reduces to the Rayleigh–Jeans law.

3. As we should infer from the graph in Fig. 7.7, the total energy density (the integral in eqn 7.4 and therefore the area under the curve) is no longer infinite, and in fact

$$\mathcal{E}(T) = \int_0^\infty \frac{8\pi hc}{\lambda^5 (e^{hc/\lambda kT} - 1)} d\lambda = aT^4 \quad \text{with} \quad a = \frac{8\pi^5 k^4}{15(hc)^3} \quad (7.9)$$

That is, the energy density increases as the fourth power of the temperature.

### • A brief illustration

We can now see why an incandescent lamp is so effective. Before it is switched on, the energy density inside the glass envelope corresponds to about 20°C (293 K). When it is switched on, the temperature of the filament rises to about 2000 K. The energy density increases by a factor of  $(2000 \text{ K}/293 \text{ K})^4 \approx 2000$ , and it generates nearly white light. •

It is easy to see why Planck's approach was successful while Rayleigh's was not. The thermal motion of the atoms in the walls of the black body excites the oscillators of the electromagnetic field. According to classical mechanics, all the oscillators of the field share equally in the energy supplied by the walls, so even the highest frequencies are excited. The excitation of very high frequency oscillators results in the ultraviolet catastrophe. According to Planck's hypothesis, however, oscillators are excited only if they can acquire an energy of at least  $h\nu$ . This energy is too large for the walls to supply in the case of the very high frequency oscillators, so the latter remain unexcited. The effect of quantization is to reduce the contribution from the high frequency oscillators, for they cannot be significantly excited with the energy available.

### (b) Heat capacities

In the early nineteenth century, the French scientists Pierre-Louis Dulong and Alexis-Thérèse Petit determined the heat capacities,  $C_V = (\partial U/\partial T)_V$  (Section 2.4), of a number of monatomic solids. On the basis of some somewhat slender experimental evidence, they proposed that the molar heat capacities of all monatomic solids are the same and (in modern units) close to  $25 \text{ J K}^{-1} \text{ mol}^{-1}$ .

Dulong and Petit's law is easy to justify in terms of classical physics in much the same way as Rayleigh attempted to explain black-body radiation. If classical physics were valid, the equipartition principle could be used to infer that the mean energy of an atom as it oscillates about its mean position in a solid is  $kT$  for each direction of displacement. As each atom can oscillate in three dimensions, the average energy of each atom is  $3kT$ ; for  $N$  atoms the total energy is  $3NkT$ . The contribution of this motion to the molar internal energy is therefore

$$U_m = 3N_A kT = 3RT \quad (7.10a)$$

because  $N_A k = R$ , the gas constant. The molar constant volume heat capacity is then predicted to be

$$C_{V,m} = \left( \frac{\partial U_m}{\partial T} \right)_V = 3R \quad (7.10b)$$

This result, with  $3R = 24.9 \text{ J K}^{-1} \text{ mol}^{-1}$ , is in striking accord with Dulong and Petit's value.

Unfortunately, significant deviations from their law were observed when advances in refrigeration techniques made it possible to measure heat capacities at low temperatures. It was found that the molar heat capacities of all monatomic solids are lower than  $3R$  at low temperatures, and that the values approach zero as  $T \rightarrow 0$ . To account for these observations, Einstein (in 1905) assumed that each atom oscillated about its equilibrium position with a single frequency  $\nu$ . He then invoked Planck's hypothesis to assert that the energy of oscillation is confined to discrete values, and specifically to  $n h \nu$ , where  $n$  is an integer. Einstein discarded the equipartition result, calculated the vibrational contribution of the atoms to the total molar internal energy of the solid (by a method described in Section 16.4), and obtained the expression known as the **Einstein formula**:

**Fig. 7.7** The Planck distribution (eqn 7.8) accounts very well for the experimentally determined distribution of black-body radiation. Planck's quantization hypothesis essentially quenches the contributions of high frequency, short wavelength oscillators. The distribution coincides with the Rayleigh–Jeans distribution at long wavelengths.

 **InterActivity** Plot the Planck distribution at several temperatures and confirm that eqn 7.8 predicts the behaviour summarized by Fig. 7.3.

$$C_{V,m}(T) = 3Rf_E(T) \quad f_E(T) = \left(\frac{\theta_E}{T}\right)^2 \left(\frac{e^{\theta_E/2T}}{e^{\theta_E/T} - 1}\right)^2 \quad \text{Einstein formula} \quad (7.11)$$

The **Einstein temperature**,  $\theta_E = h\nu/k$ , is a way of expressing the frequency of oscillation of the atoms as a temperature: a high frequency corresponds to a high Einstein temperature.

As before, we now ‘read’ this expression:

1. At high temperatures (when  $T \gg \theta_E$ ) the exponentials in  $f_E$  can be expanded as  $1 + \theta_E/T + \dots$  and higher terms ignored. The result is

$$f_E(T) = \left(\frac{\theta_E}{T}\right)^2 \left\{ \frac{1 + \theta_E/2T + \dots}{(1 + \theta_E/T + \dots) - 1} \right\}^2 \approx 1 \quad (7.12a)$$

Consequently, the classical result ( $C_{V,m} = 3R$ ) is obtained at high temperatures.

2. At low temperatures, when  $T \ll \theta_E$ ,

$$f_E(T) \approx \left(\frac{\theta_E}{T}\right)^2 \left(\frac{e^{\theta_E/2T}}{e^{\theta_E/T}}\right)^2 = \left(\frac{\theta_E}{T}\right)^2 e^{-\theta_E/T} \quad (7.12b)$$

The strongly decaying exponential function goes to zero more rapidly than  $1/T$  goes to infinity; so  $f_E \rightarrow 0$  as  $T \rightarrow 0$ , and the heat capacity therefore approaches zero too.

We see that Einstein’s formula accounts for the decrease of heat capacity at low temperatures. The physical reason for this success is that at low temperatures only a few oscillators possess enough energy to oscillate significantly so the solid behaves as though it contains far fewer atoms than is actually the case. At higher temperatures, there is enough energy available for all the oscillators to become active: all  $3N$  oscillators contribute, many of their energy levels are accessible, and the heat capacity approaches its classical value.

Figure 7.8 shows the temperature dependence of the heat capacity predicted by the Einstein formula. The general shape of the curve is satisfactory, but the numerical agreement is in fact quite poor. The poor fit arises from Einstein’s assumption that all the atoms oscillate with the same frequency, whereas in fact they oscillate over a range of frequencies from zero up to a maximum value,  $\nu_D$ . This complication is taken into account by averaging over all the frequencies present, the final result being the **Debye formula**:

$$C_{V,m} = 3Rf_D(T) \quad f_D(T) = 3 \left(\frac{T}{\theta_D}\right)^3 \int_0^{\theta_D/T} \frac{x^4 e^x}{(e^x - 1)^2} dx \quad \text{Debye formula} \quad (7.13)$$

where  $\theta_D = h\nu_D/k$  is the Debye temperature. The integral in eqn 7.13 has to be evaluated numerically, but that is simple with mathematical software. The details of this modification, which, as Fig. 7.9 shows, gives improved agreement with experiment, need not distract us at this stage from the main conclusion, which is that quantization must be introduced in order to explain the thermal properties of solids.

#### • A brief illustration

The Debye temperature for lead is 105 K, corresponding to a vibrational frequency of  $2.2 \times 10^{12}$  Hz, whereas that for diamond and its much lighter, more rigidly bonded atoms, is 2230 K, corresponding to  $4.6 \times 10^{13}$  Hz. As we see from Fig. 7.9,  $f \approx 1$  for  $T > \theta_D$  and the heat capacity is almost classical. For lead at 25°C, corresponding to  $T/\theta_D = 2.8$ ,  $f = 0.99$  and the heat capacity has almost its classical value. For diamond at the same temperature,  $T/\theta_D = 0.13$ , corresponding to  $f = 0.15$ , and the heat capacity is only 15 per cent of its classical value. •

**Fig. 7.8** Experimental low-temperature molar heat capacities and the temperature dependence predicted on the basis of Einstein’s theory. His equation (eqn 7.11) accounts for the dependence fairly well, but is everywhere too low.

**interActivity** Using eqn 7.11, plot  $C_{V,m}$  against  $T$  for several values of the Einstein temperature  $\theta_E$ . At low temperature, does an increase in  $\theta_E$  result in an increase or decrease of  $C_{V,m}$ ? Estimate the temperature at which the value of  $C_{V,m}$  reaches the classical value given by eqn 7.10.

### (c) Atomic and molecular spectra

The most compelling and direct evidence for the quantization of energy comes from **spectroscopy**, the detection and analysis of the electromagnetic radiation absorbed, emitted, or scattered by a substance. The record of light intensity transmitted or scattered by a molecule as a function of frequency ( $\nu$ ), wavelength ( $\lambda$ ), or wavenumber ( $\tilde{\nu} = \nu/c$ ) is called its **spectrum** (from the Latin word for appearance).

A typical atomic spectrum is shown in Fig. 7.10, and a typical molecular spectrum is shown in Fig. 7.11. The obvious feature of both is that radiation is emitted or absorbed at a series of discrete frequencies. This observation can be understood if the energy of the atoms or molecules is also confined to discrete values, for then energy can be discarded or absorbed only in discrete amounts (Fig. 7.12). Then, if the energy of an atom decreases by  $\Delta E$ , the energy is carried away as radiation of frequency  $\nu$ , and an emission ‘line’, a sharply defined peak, appears in the spectrum. We say that a molecule undergoes a **spectroscopic transition**, a change of state, when the **Bohr frequency condition**

$$\Delta E = h\nu \quad \text{Bohr frequency condition} \quad (7.14)$$

is fulfilled. We develop the principles and applications of atomic spectroscopy in Chapter 9 and of molecular spectroscopy in Chapters 12–14.

## 7.2 Wave–particle duality

**Key points** (a) The photoelectric effect establishes the view that electromagnetic radiation, regarded in classical physics as wave-like, consists of particles (photons). (b) The diffraction of electrons establishes the view that electrons, regarded in classical physics as particles, are wave-like with a wavelength given by the de Broglie relation.

**Fig. 7.10** A region of the spectrum of radiation emitted by excited iron atoms consists of radiation at a series of discrete wavelengths (or frequencies).

**Fig. 7.11** When a molecule changes its state, it does so by absorbing radiation at definite frequencies. This spectrum is part of that due to the electronic, vibrational, and rotational excitation of sulfur dioxide ( $\text{SO}_2$ ) molecules. This observation suggests that molecules can possess only discrete energies, not an arbitrary energy.

**Fig. 7.9** Debye’s modification of Einstein’s calculation (eqn 7.13) gives very good agreement with experiment. For copper,  $T/\theta_D = 2$  corresponds to about 170 K, so the detection of deviations from Dulong and Petit’s law had to await advances in low-temperature physics.

**interActivity** Starting with the Debye formula (eqn 7.13), plot  $dC_{v,m}/dT$ , the temperature coefficient of  $C_{v,m}$ , against  $T$  for  $\theta_D = 400$  K. At what temperature is  $C_{v,m}$  most sensitive to temperature?

**Fig. 7.12** Spectroscopic transitions, such as those shown above, can be accounted for if we assume that a molecule emits a photon as it changes between discrete energy levels. Note that high-frequency radiation is emitted when the energy change is large.

At this stage we have established that the energies of the electromagnetic field and of oscillating atoms are quantized. In this section we shall see the experimental evidence that led to the revision of two other basic concepts concerning natural phenomena. One experiment shows that electromagnetic radiation—which classical physics treats as wave-like—actually also displays the characteristics of particles. Another experiment shows that electrons—which classical physics treats as particles—also display the characteristics of waves.

### (a) The particle character of electromagnetic radiation

The observation that electromagnetic radiation of frequency  $\nu$  can possess only the energies  $0, h\nu, 2h\nu, \dots$  suggests (and at this stage it is only a suggestion) that it can be thought of as consisting of  $0, 1, 2, \dots$  particles, each particle having an energy  $h\nu$ . Then, if one of these particles is present, the energy is  $h\nu$ , if two are present the energy is  $2h\nu$ , and so on. These particles of electromagnetic radiation are now called **photons**. The observation of discrete spectra from atoms and molecules can be pictured as the atom or molecule generating a photon of energy  $h\nu$  when it discards an energy of magnitude  $\Delta E$ , with  $\Delta E = h\nu$ .

#### Example 7.1 Calculating the number of photons

Calculate the number of photons emitted by a 100 W yellow lamp in 1.0 s. Take the wavelength of yellow light as 560 nm and assume 100 per cent efficiency.

**Method** Each photon has an energy  $h\nu$ , so the total number of photons needed to produce an energy  $E$  is  $E/h\nu$ . To use this equation, we need to know the frequency of the radiation (from  $\nu = c/\lambda$ ) and the total energy emitted by the lamp. The latter is given by the product of the power ( $P$ , in watts) and the time interval for which the lamp is turned on ( $E = P\Delta t$ ).

**Answer** The number of photons is

$$N = \frac{E}{h\nu} = \frac{P\Delta t}{h(c/\lambda)} = \frac{\lambda P\Delta t}{hc}$$

Substitution of the data gives

$$N = \frac{(5.60 \times 10^{-7} \text{ m}) \times (100 \text{ J s}^{-1}) \times (1.0 \text{ s})}{(6.626 \times 10^{-34} \text{ J s}) \times (2.998 \times 10^8 \text{ m s}^{-1})} = 2.8 \times 10^{20}$$

Note that it would take the lamp nearly 40 min to produce 1 mol of these photons.

**Self-test 7.1** How many photons does a monochromatic (single frequency) infrared rangefinder of power 1 mW and wavelength 1000 nm emit in 0.1 s?  
[ $5 \times 10^{14}$ ]

**A note on good practice** To avoid rounding and other numerical errors, it is best to carry out algebraic calculations first, and to substitute numerical values into a single, final formula. Moreover, an analytical result may be used for other data without having to repeat the entire calculation.

So far, the existence of photons is only a suggestion. Experimental evidence for their existence comes from the measurement of the energies of electrons produced in the **photoelectric effect**. This effect is the ejection of electrons from metals when they are exposed to ultraviolet radiation. The experimental characteristics of the photoelectric effect are as follows.

1. No electrons are ejected, regardless of the intensity of the radiation, unless its frequency exceeds a threshold value characteristic of the metal.

- The kinetic energy of the ejected electrons increases linearly with the frequency of the incident radiation but is independent of the intensity of the radiation.
- Even at low light intensities, electrons are ejected immediately if the frequency is above the threshold.

Figure 7.13 illustrates the first and second characteristics.

These observations strongly suggest that the photoelectric effect depends on the ejection of an electron when it is involved in a collision with a particle-like projectile that carries enough energy to eject the electron from the metal. If we suppose that the projectile is a photon of energy  $h\nu$ , where  $\nu$  is the frequency of the radiation, then the conservation of energy requires that the kinetic energy of the ejected electron ( $\frac{1}{2}m_e v^2$ ) should obey

$$\frac{1}{2}m_e v^2 = h\nu - \Phi \quad (7.15)$$

In this expression  $\Phi$  (upper-case phi) is a characteristic of the metal called its **work function**, the energy required to remove an electron from the metal to infinity (Fig. 7.14), the analogue of the ionization energy of an individual atom or molecule. We can now see that the existence of photons accounts for the three observations we have summarized:

- Photoejection cannot occur if  $h\nu < \Phi$  because the photon brings insufficient energy.
- Equation 7.15 predicts that the kinetic energy of an ejected electron should increase linearly with frequency.

**Fig. 7.13** In the photoelectric effect, it is found that no electrons are ejected when the incident radiation has a frequency below a value characteristic of the metal and, above that value, the kinetic energy of the photoelectrons varies linearly with the frequency of the incident radiation.

**InterActivity** Calculate the value of Planck's constant given that the following kinetic energies were observed for photoejected electrons irradiated by radiation of the wavelengths noted.

|                       |      |      |       |       |       |
|-----------------------|------|------|-------|-------|-------|
| $\lambda_i/\text{nm}$ | 320  | 330  | 345   | 360   | 385   |
| $E_k/\text{eV}$       | 1.17 | 1.05 | 0.885 | 0.735 | 0.511 |

**Fig. 7.14** The photoelectric effect can be explained if it is supposed that the incident radiation is composed of photons that have energy proportional to the frequency of the radiation. (a) The energy of the photon is insufficient to drive an electron out of the metal. (b) The energy of the photon is more than enough to eject an electron, and the excess energy is carried away as the kinetic energy of the photoelectron (the ejected electron).

**Fig. 7.15** The Davisson–Germer experiment. The scattering of an electron beam from a nickel crystal shows a variation of intensity characteristic of a diffraction experiment in which waves interfere constructively and destructively in different directions.

3. When a photon collides with an electron, it gives up all its energy, so we should expect electrons to appear as soon as the collisions begin, provided the photons have sufficient energy.

A practical application of eqn 7.15 is that it provides a technique for the determination of Planck’s constant, for the slopes of the lines in Fig. 7.13 are all equal to  $h$ .

### (b) The wave character of particles

Although contrary to the long-established wave theory of light, the view that light consists of particles had been held before, but discarded. No significant scientist, however, had taken the view that matter is wave-like. Nevertheless, experiments carried out in 1925 forced people to consider that possibility. The crucial experiment was performed by the American physicists Clinton Davisson and Lester Germer, who observed the diffraction of electrons by a crystal (Fig. 7.15). Diffraction is the interference caused by an object in the path of waves. Depending on whether the interference is constructive or destructive, the result is a region of enhanced or diminished intensity of the wave. Davisson and Germer’s success was a lucky accident, because a chance rise of temperature caused their polycrystalline sample to anneal, and the ordered planes of atoms then acted as a diffraction grating. At almost the same time, G.P. Thomson, working in Scotland, showed that a beam of electrons was diffracted when passed through a thin gold foil.

The Davisson–Germer experiment, which has since been repeated with other particles (including  $\alpha$  particles and molecular hydrogen), shows clearly that particles have wave-like properties, and the diffraction of neutrons is a well-established technique for investigating the structures and dynamics of condensed phases (see Chapter 19). We have also seen that waves of electromagnetic radiation have particle-like properties. Thus we are brought to the heart of modern physics. When examined on an atomic scale, the classical concepts of particle and wave melt together, particles taking on the characteristics of waves, and waves the characteristics of particles.

Some progress towards coordinating these properties had already been made by the French physicist Louis de Broglie when, in 1924, he suggested that any particle, not only photons, travelling with a linear momentum  $p = mv$  (with  $m$  the mass and  $v$  the speed of the particle) should have in some sense a wavelength given by the **de Broglie relation**:

$$\lambda = \frac{h}{p} \quad \text{de Broglie relation} \quad (7.16)$$

**Fig. 7.16** An illustration of the de Broglie relation between momentum and wavelength. The wave is associated with a particle (shortly this wave will be seen to be the wavefunction of the particle). A particle with high momentum has a wavefunction with a short wavelength, and vice versa.

That is, a particle with a high linear momentum has a short wavelength (Fig. 7.16). Macroscopic bodies have such high momenta (because their mass is so great), even when they are moving slowly, that their wavelengths are undetectably small, and the wave-like properties cannot be observed. This undetectability is why, in spite of its deficiencies, classical mechanics can be used to explain the behaviour of macroscopic bodies. It is necessary to invoke quantum mechanics only for microscopic systems, such as atoms and molecules, in which masses are small.

#### Example 7.2 Estimating the de Broglie wavelength

Estimate the wavelength of electrons that have been accelerated from rest through a potential difference of 40 kV.

**Method** To use the de Broglie relation, we need to know the linear momentum,  $p$ , of the electrons. To calculate the linear momentum, we note that the energy acquired by an electron accelerated through a potential difference  $\Delta\phi$  is  $e\Delta\phi$ , where

$e$  is the magnitude of its charge. At the end of the period of acceleration, all the acquired energy is in the form of kinetic energy,  $E_k = \frac{1}{2}m_e v^2 = p^2/2m_e$ , so we can determine  $p$  by setting  $p^2/2m_e$  equal to  $e\Delta\phi$ . As before, carry through the calculation algebraically before substituting the data.

**Answer** The expression  $p^2/2m_e = e\Delta\phi$  solves to  $p = (2m_e e\Delta\phi)^{1/2}$ ; then, from the de Broglie relation  $\lambda = h/p$ ,

$$\lambda = \frac{h}{(2m_e e\Delta\phi)^{1/2}}$$

Substitution of the data and the fundamental constants (from inside the front cover) gives

$$\begin{aligned}\lambda &= \frac{6.626 \times 10^{-34} \text{ J s}}{\{2 \times (9.109 \times 10^{-31} \text{ kg}) \times (1.602 \times 10^{-19} \text{ C}) \times (4.0 \times 10^4 \text{ V})\}^{1/2}} \\ &= 6.1 \times 10^{-12} \text{ m}\end{aligned}$$

where we have used  $1 \text{ V C} = 1 \text{ J}$  and  $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$ . The wavelength of 6.1 pm is shorter than typical bond lengths in molecules (about 100 pm). Electrons accelerated in this way are used in the technique of electron diffraction for the determination of the structures of solid surfaces (Section 23.3).

**Self-test 7.2** Calculate the wavelength of (a) a neutron with a translational kinetic energy equal to  $kT$  at 300 K, (b) a tennis ball of mass 57 g travelling at 80 km h<sup>-1</sup>.  
[(a) 178 pm, (b)  $5.2 \times 10^{-34}$  m]

We now have to conclude that, not only has electromagnetic radiation the character classically ascribed to particles, but electrons (and all other particles) have the characteristics classically ascribed to waves. This joint particle and wave character of matter and radiation is called **wave–particle duality**. Duality strikes at the heart of classical physics, where particles and waves are treated as entirely distinct entities. We have also seen that the energies of electromagnetic radiation and of matter cannot be varied continuously, and that for small objects the discreteness of energy is highly significant. In classical mechanics, in contrast, energies could be varied continuously. Such total failure of classical physics for small objects implied that its basic concepts were false. A new mechanics had to be devised to take its place.

## IMPACT ON BIOLOGY

### 17.1 Electron microscopy

The basic approach of illuminating a small area of a sample and collecting light with a microscope has been used for many years to image small specimens. However, the *resolution* of a microscope, the minimum distance between two objects that leads to two distinct images, is on the order of the wavelength of light used as a probe. Therefore, conventional microscopes employing visible light have resolutions in the micrometre range and are blind to features on a scale of nanometres.

There is great interest in the development of new experimental probes of very small specimens that cannot be studied by traditional light microscopy. For example, our understanding of biochemical processes, such as enzymatic catalysis, protein folding, and the insertion of DNA into the cell's nucleus, will be enhanced if it becomes possible to image individual biopolymers—with dimensions much smaller than visible wavelengths—at work. One technique that is often used to image nanometre-sized

**Fig. 7.17** A TEM image of a cross-section of a plant cell showing chloroplasts, organelles responsible for the reactions of photosynthesis (Chapter 21). Chloroplasts are typically  $5\text{ }\mu\text{m}$  long. (Image supplied by Brian Bowes.)

objects is *electron microscopy*, in which a beam of electrons with a well-defined de Broglie wavelength replaces the lamp found in traditional light microscopes. Instead of glass or quartz lenses, magnetic fields are used to focus the beam. In *transmission electron microscopy* (TEM), the electron beam passes through the specimen and the image is collected on a screen. In *scanning electron microscopy* (SEM), electrons scattered back from a small irradiated area of the sample are detected and the electrical signal is sent to a video screen. An image of the surface is then obtained by scanning the electron beam across the sample.

As in traditional light microscopy, the wavelength of and the ability to focus the incident beam—in this case a beam of electrons—govern the resolution. Electron wavelengths in typical electron microscopes can be as short as  $10\text{ pm}$ , but it is not possible to focus electrons well with magnetic lenses so, in the end, typical resolutions of TEM and SEM instruments are about  $2\text{ nm}$  and  $50\text{ nm}$ , respectively. It follows that electron microscopes cannot resolve individual atoms (which have diameters of about  $0.2\text{ nm}$ ). Furthermore, only certain samples can be observed under certain conditions. The measurements must be conducted under high vacuum. For TEM observations, the samples must be very thin cross-sections of a specimen and SEM observations must be made on dry samples. A consequence of these requirements is that neither technique can be used to study living cells. In spite of these limitations, electron microscopy is very useful in studies of the internal structure of cells (Fig. 7.17).

## The dynamics of microscopic systems

At this point we have to construct a new mechanics from the ashes of classical physics. **Quantum mechanics** acknowledges the wave–particle duality of matter and the existence of quantization by supposing that, rather than travelling along a definite path, a particle is distributed through space like a wave. This remark may seem mysterious: it will be interpreted more fully shortly. The mathematical representation of the wave that in quantum mechanics replaces the classical concept of trajectory is called a **wave-function**,  $\psi$  (psi).

### 7.3 The Schrödinger equation

**Key point** The Schrödinger equation is a second-order differential equation used to calculate the wavefunction of a system.

In 1926, the Austrian physicist Erwin Schrödinger proposed an equation for finding the wavefunction of any system. The **time-independent Schrödinger equation** for a particle of mass  $m$  moving in one dimension with energy  $E$  in a system that does not change with time (for instance, its volume remains constant) is

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + V(x)\psi = E\psi \quad \text{Time-independent Schrödinger equation} \quad (7.17)$$

The factor  $V(x)$  is the potential energy of the particle at the point  $x$ ; because the total energy  $E$  is the sum of potential and kinetic energies, the first term must be related (in a manner we explore later) to the kinetic energy of the particle;  $\hbar = h/2\pi$  (which is read *h-cross* or *h-bar*) is a convenient modification of Planck's constant with the value  $1.055 \times 10^{-34}\text{ J s}$ .

The following *Justification* shows that the Schrödinger equation is plausible and the discussions later in the chapter will help to overcome its apparent arbitrariness. For

**Table 7.1** The Schrödinger equation

For one-dimensional systems

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + V(x)\psi = E\psi$$

Where  $V(x)$  is the potential energy of the particle and  $E$  is its total energy. For three-dimensional systems

$$-\frac{\hbar^2}{2m} \nabla^2\psi + V\psi = E\psi$$

where  $V$  may depend on position and  $\nabla^2$  ('del squared') is

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$$

In systems with spherical symmetry three equivalent forms are

$$\begin{aligned}\nabla^2 &= \frac{1}{r} \frac{\partial^2}{\partial r^2} + \frac{1}{r^2} \Lambda^2 \\ &= \frac{1}{r^2} \frac{\partial}{\partial r} r^2 \frac{\partial}{\partial r} + \frac{1}{r^2} \Lambda^2 \\ &= \frac{\partial^2}{\partial r^2} + \frac{2}{r} \frac{\partial}{\partial r} + \frac{1}{r^2} \Lambda^2\end{aligned}$$

where

$$\Lambda^2 = \frac{1}{\sin^2\theta} \frac{\partial^2}{\partial \phi^2} + \frac{1}{\sin\theta} \frac{\partial}{\partial \theta} \sin\theta \frac{\partial}{\partial \theta}$$

In the general case the Schrodinger equation is written

$$\hat{H}\psi = E\psi$$

where  $\hat{H}$  is the hamiltonian operator for the system:

$$\hat{H} = -\frac{\hbar^2}{2m} \nabla^2 + V$$

For the evolution of a system with time, it is necessary to solve the time-dependent Schrödinger equation:

$$\hat{H}\Psi = i\hbar \frac{\partial \Psi}{\partial t}$$

the present, we shall treat the equation simply as a quantum-mechanical postulate that replaces Newton's postulate of his apparently equally arbitrary equation of motion (that force = mass  $\times$  acceleration). Various ways of expressing the Schrödinger equation, of incorporating the time dependence of the wavefunction, and of extending it to more dimensions are collected in Table 7.1. In Chapter 8 we shall solve the equation for a number of important cases; in this chapter we are mainly concerned with its significance, the interpretation of its solutions, and seeing how it implies that energy is quantized.

**Justification 7.1** *Using the Schrödinger equation to develop the de Broglie relation*

The Schrödinger equation can be seen to be plausible by noting that it implies the de Broglie relation for a freely moving particle in a region where its potential energy  $V$  is constant. After writing  $V(x) = V$ , we can rearrange eqn 7.17 into

$$\frac{d^2\psi}{dx^2} = -\frac{2m}{\hbar^2} (E - V) \psi$$

General strategies for solving differential equations of this and other types that occur frequently in physical chemistry are treated in *Mathematical background 4* following Chapter 8. In this case a solution is

$$\psi = \cos kx \quad k = \left\{ \frac{2m(E - V)}{\hbar^2} \right\}^{1/2}$$

We now recognize that  $\cos kx$  is a wave of wavelength  $\lambda = 2\pi/k$ , as can be seen by comparing  $\cos kx$  with the standard form of a harmonic wave,  $\cos(2\pi x/\lambda)$ . The quantity  $E - V$  is equal to the kinetic energy of the particle,  $E_k$ , so  $k = (2mE_k/\hbar^2)^{1/2}$ , which implies that  $E_k = k^2\hbar^2/2m$ . Because  $E_k = p^2/2m$ , it follows that  $p = \hbar k$ . Therefore, the linear momentum is related to the wavelength of the wavefunction by

$$p = \frac{2\pi}{\lambda} \times \frac{h}{2\pi} = \frac{h}{\lambda}$$

which is the de Broglie relation.

**Fig. 7.18** The wavefunction  $\psi$  is a probability amplitude in the sense that its square modulus ( $\psi^*\psi$  or  $|\psi|^2$ ) is a probability density. The probability of finding a particle in the region  $dx$  located at  $x$  is proportional to  $|\psi|^2 dx$ . We represent the probability density by the density of shading in the superimposed band.

**Fig. 7.19** The Born interpretation of the wavefunction in three-dimensional space implies that the probability of finding the particle in the volume element  $d\tau = dxdydz$  at some location  $r$  is proportional to the product of  $d\tau$  and the value of  $|\psi|^2$  at that location.

## 7.4 The Born interpretation of the wavefunction

**Key points** According to the Born interpretation, the probability density is proportional to the square of the wavefunction. (a) A wavefunction is normalized if the integral of its square is equal to 1. (b) The quantization of energy stems from the constraints that an acceptable wavefunction must satisfy.

A central principle of quantum mechanics is that *the wavefunction contains all the dynamical information about the system it describes*. Here we concentrate on the information it carries about the location of the particle.

The interpretation of the wavefunction in terms of the location of the particle is based on a suggestion made by Max Born. He made use of an analogy with the wave theory of light, in which the square of the amplitude of an electromagnetic wave in a region is interpreted as its intensity and therefore (in quantum terms) as a measure of the probability of finding a photon present in the region. The **Born interpretation** of the wavefunction focuses on the square of the wavefunction (or the square modulus,  $|\psi|^2 = \psi^*\psi$ , if  $\psi$  is complex; see *Mathematical background 3*). For a one-dimensional system (Fig. 7.18):

If the wavefunction of a particle has the value  $\psi$  at some point  $x$ , then the probability of finding the particle between  $x$  and  $x + dx$  is proportional to  $|\psi|^2 dx$ .

Born  
interpretation

Thus,  $|\psi|^2$  is the **probability density**, and to obtain the probability it must be multiplied by the length of the infinitesimal region  $dx$ . The wavefunction  $\psi$  itself is called the **probability amplitude**. For a particle free to move in three dimensions (for example, an electron near a nucleus in an atom), the wavefunction depends on the point  $r$  with coordinates  $x$ ,  $y$ , and  $z$ , and the interpretation of  $\psi(r)$  is as follows (Fig. 7.19):

If the wavefunction of a particle has the value  $\psi$  at some point  $r$ , then the probability of finding the particle in an infinitesimal volume  $d\tau = dxdydz$  at that point is proportional to  $|\psi|^2 d\tau$ .

The Born interpretation does away with any worry about the significance of a negative (and, in general, complex) value of  $\psi$  because  $|\psi|^2$  is real and never negative. There is no *direct* significance in the negative (or complex) value of a wavefunction:

only the square modulus, a positive quantity, is directly physically significant, and both negative and positive regions of a wavefunction may correspond to a high probability of finding a particle in a region (Fig. 7.20). However, later we shall see that the presence of positive and negative regions of a wavefunction is of great *indirect* significance, because it gives rise to the possibility of constructive and destructive interference between different wavefunctions.

### Example 7.3 Interpreting a wavefunction

We shall see in Chapter 9 that the wavefunction of an electron in the lowest energy state of a hydrogen atom is proportional to  $e^{-r/a_0}$ , with  $a_0$  a constant and  $r$  the distance from the nucleus. Calculate the relative probabilities of finding the electron inside a region of volume  $\delta V = 1.0 \text{ pm}^3$ , which is small even on the scale of the atom, located at (a) the nucleus, (b) a distance  $a_0$  from the nucleus.

**Method** The region of interest is so small on the scale of the atom that we can ignore the variation of  $\psi$  within it and write the probability,  $P$ , as proportional to the probability density ( $\psi^2$ ; note that  $\psi$  is real) evaluated at the point of interest multiplied by the volume of interest,  $\delta V$ . That is,  $P \propto \psi^2 \delta V$ , with  $\psi^2 \propto e^{-2r/a_0}$ .

**Answer** In each case  $\delta V = 1.0 \text{ pm}^3$ . (a) At the nucleus,  $r = 0$ , so

$$P \propto e^0 \times (1.0 \text{ pm}^3) = (1.0) \times (1.0 \text{ pm}^3)$$

(b) At a distance  $r = a_0$  in an arbitrary direction,

$$P \propto e^{-2} \times (1.0 \text{ pm}^3) = (0.14) \times (1.0 \text{ pm}^3)$$

Therefore, the ratio of probabilities is  $1.0/0.14 = 7.1$ . Note that it is more probable (by a factor of 7) that the electron will be found at the nucleus than in a volume element of the same size located at a distance  $a_0$  from the nucleus. The negatively charged electron is attracted to the positively charged nucleus, and is likely to be found close to it.

**Self-test 7.3** The wavefunction for the electron in its lowest energy state in the ion  $\text{He}^+$  is proportional to  $e^{-2r/a_0}$ . Repeat the calculation for this ion. Any comment? [55; more compact wavefunction]

**Fig. 7.20** The sign of a wavefunction has no direct physical significance: the positive and negative regions of this wavefunction both correspond to the same probability distribution (as given by the square modulus of  $\psi$  and depicted by the density of shading).

**A note on good practice** The square of a wavefunction is a probability density, and (in three dimensions) has the dimensions of  $1/\text{length}^3$ . It becomes a (unitless) probability when multiplied by a volume. In general, we have to take into account the variation of the amplitude of the wavefunction over the volume of interest, but here we are supposing that the volume is so small that the variation of  $\psi$  in the region can be ignored.

### (a) Normalization

A mathematical feature of the Schrödinger equation is that, if  $\psi$  is a solution, then so is  $N\psi$ , where  $N$  is any constant. This feature is confirmed by noting that  $\psi$  occurs in every term in eqn 7.17, so any constant factor can be cancelled. This freedom to vary the wavefunction by a constant factor means that it is always possible to find a **normalization constant**,  $N$ , such that the proportionality of the Born interpretation becomes an equality.

We find the normalization constant by noting that, for a normalized wavefunction  $N\psi$ , the probability that a particle is in the region  $dx$  is equal to  $(N\psi^*)(N\psi)dx$  (we are taking  $N$  to be real). Furthermore, the sum over all space of these individual probabilities must be 1 (the probability of the particle being somewhere is 1). Expressed mathematically, the latter requirement is

$$N^2 \int_{-\infty}^{\infty} \psi^* \psi dx = 1 \quad (7.18)$$

**Fig. 7.21** The spherical polar coordinates used for discussing systems with spherical symmetry.

Wavefunctions for which the integral in eqn 7.18 exists (in the sense of having a finite value) are said to be ‘square-integrable’. It follows that

$$N = \frac{1}{\left( \int_{-\infty}^{\infty} \psi^* \psi dx \right)^{1/2}} \quad (7.19)$$

Therefore, by evaluating the integral, we can find the value of  $N$  and hence ‘normalize’ the wavefunction. From now on, unless we state otherwise, we always use wavefunctions that have been normalized to 1; that is, from now on we assume that  $\psi$  already includes a factor that ensures that (in one dimension)

$$\int_{-\infty}^{\infty} \psi^* \psi dx = 1 \quad (7.20a)$$

In three dimensions, the wavefunction is normalized if

$$\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \psi^* \psi dx dy dz = 1 \quad (7.20b)$$

or, more succinctly, if

$$\int \psi^* \psi d\tau = 1 \quad \text{Normalization integral} \quad (7.20c)$$

where  $d\tau = dx dy dz$  and the limits of this definite integral are not written explicitly: in all such integrals, the integration is over all the space accessible to the particle. For systems with spherical symmetry it is best to work in **spherical polar coordinates**  $r$ ,  $\theta$ , and  $\phi$  (Fig. 7.21):

$$x = r \sin \theta \cos \phi, y = r \sin \theta \sin \phi, z = r \cos \theta$$

Spherical polar coordinates

$r$ , the radius, ranges from 0 to  $\infty$

$\theta$ , the colatitude, ranges from 0 to  $\pi$

$\phi$ , the azimuth, ranges from 0 to  $2\pi$

That these ranges cover space is illustrated in Fig. 7.22. Standard manipulations then yield

$$d\tau = r^2 \sin \theta dr d\theta d\phi$$

In these coordinates, the explicit form of eqn 7.20c is

$$\int_0^{\infty} \int_0^{\pi} \int_0^{2\pi} \psi^* \psi r^2 dr \sin \theta d\theta d\phi = 1 \quad (7.20d)$$

The limits on the first integral sign refer to  $r$ , those on the second to  $\theta$ , and those on the third to  $\phi$ .

**Fig. 7.22** The surface of a sphere is covered by allowing  $\theta$  to range from 0 to  $\pi$ , and then sweeping that arc around a complete circle by allowing  $\phi$  to range from 0 to  $2\pi$ .

#### Example 7.4 Normalizing a wavefunction

Normalize the wavefunction used for the hydrogen atom in Example 7.3.

**Method** We need to find the factor  $N$  that guarantees that the integral in eqn 7.20c is equal to 1. Because the system is spherical, it is most convenient to use spherical coordinates and to carry out the integrations specified in eqn 7.20d. A useful integral for calculations on atomic wavefunctions is

$$\int_0^{\infty} x^n e^{-ax} dx = \frac{n!}{a^{n+1}}$$

where  $n!$  denotes a factorial:  $n! = n(n-1)(n-2) \dots 1$ , and  $0! = 1$  by definition.

**Answer** The integration required is the product of three factors:

$$\int \psi^* \psi d\tau = N^2 \overbrace{\int_0^{\infty} r^2 e^{-2r/a_0} dr}^{\frac{1}{4}a_0^3} \overbrace{\int_0^{\pi} \sin \theta d\theta}^2 \overbrace{\int_0^{2\pi} d\phi}^{2\pi} = \pi a_0^3 N^2$$

Therefore, for this integral to equal 1, we must set

$$N = \left( \frac{1}{\pi a_0^3} \right)^{1/2}$$

and the normalized wavefunction is

$$\psi = \left( \frac{1}{\pi a_0^3} \right)^{1/2} e^{-r/a_0}$$

Note that, because  $a_0$  is a length, the dimensions of  $\psi$  are  $1/\text{length}^{3/2}$  and therefore those of  $\psi^2$  are  $1/\text{length}^3$  (for instance,  $1/\text{m}^3$ ) as is appropriate for a probability density (in the sense that a probability density times a volume is a probability).

If Example 7.3 is now repeated, we can obtain the actual probabilities of finding the electron in the volume element at each location, not just their relative values. Given (from inside the front cover) that  $a_0 = 52.9$  pm, the results are (a)  $2.2 \times 10^{-6}$ , corresponding to 1 chance in about 500 000 inspections of finding the electron in the test volume, and (b)  $2.9 \times 10^{-7}$ , corresponding to 1 chance in 3.4 million.

**Self-test 7.4** Normalize the wavefunction given in Self-test 7.3. [ $N = (8/\pi a_0^3)^{1/2}$ ]

### (b) Quantization

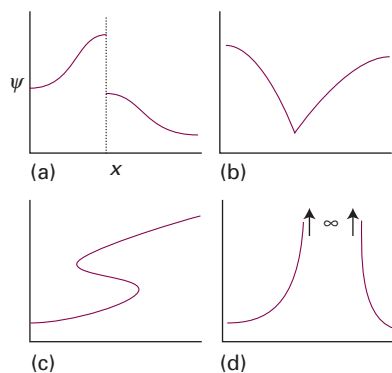

The Born interpretation puts severe restrictions on the acceptability of wavefunctions. The principal constraint is that  $\psi$  must not be infinite anywhere. If it were, the integral in eqn 7.20 would be infinite (in other words,  $\psi$  would not be square-integrable) and the normalization constant would be zero. The normalized function would then be zero everywhere, except where it is infinite, which would be unacceptable. The requirement that  $\psi$  is finite everywhere rules out many possible solutions of the Schrödinger equation, because many mathematically acceptable solutions rise to infinity and are therefore physically unacceptable. We shall meet several examples shortly.

The requirement that  $\psi$  is finite everywhere is not the only restriction implied by the Born interpretation. We could imagine (and in Section 8.6a will meet) a solution of the Schrödinger equation that gives rise to more than one value of  $|\psi|^2$  at a single point. The Born interpretation implies that such solutions are unacceptable, because it would be absurd to have more than one probability that a particle is at the same point. This restriction is expressed by saying that the wavefunction must be *single-valued*; that is, have only one value at each point of space.

The Schrödinger equation itself also implies some mathematical restrictions on the type of functions that will occur. Because it is a second-order differential equation, the second derivative of  $\psi$  must be well-defined if the equation is to be applicable everywhere. We can take the second derivative of a function only if it is continuous

### A brief comment

Infinitely sharp spikes are acceptable provided they have zero width, so it is more appropriate to state that the wavefunction must not be infinite over any finite region. In elementary quantum mechanics the simpler restriction, to finite  $\psi$ , is sufficient.

**Fig. 7.23** The wavefunction must satisfy stringent conditions for it to be acceptable. (a) Unacceptable because it is not continuous; (b) unacceptable because its slope is discontinuous; (c) unacceptable because it is not single-valued; (d) unacceptable because it is infinite over a finite region.

#### A brief comment

There are cases, and we shall meet them, where acceptable wavefunctions have kinks. These cases arise when the potential energy has peculiar properties, such as rising abruptly to infinity. When the potential energy is smoothly well-behaved and finite, the slope of the wavefunction must be continuous; if the potential energy becomes infinite, then the slope of the wavefunction need not be continuous. There are only two cases of this behaviour in elementary quantum mechanics, and the peculiarity will be mentioned when we meet them.

(so there are no sharp steps in it, Fig. 7.23) and if its first derivative, its slope, is continuous (so there are no kinks).

At this stage we see that  $\psi$  must be:

- continuous
- have a continuous slope
- be single-valued
- be square-integrable

Conditions on the wavefunction

An acceptable wavefunction cannot be zero everywhere, because the particle it describes must be somewhere. These are such severe restrictions that acceptable solutions of the Schrödinger equation do not in general exist for arbitrary values of the energy  $E$ . In other words, a particle may possess only certain energies, for otherwise its wavefunction would be physically unacceptable. That is, *as a consequence of the restriction on its wavefunction, the energy of a particle is quantized*. We can find the acceptable energies by solving the Schrödinger equation for motion of various kinds, and selecting the solutions that conform to the restrictions listed above. That is the task of the next chapter.

## Quantum mechanical principles

We have claimed that a wavefunction contains all the information it is possible to obtain about the dynamical properties of the particle (for example, its location and momentum). We have seen that the Born interpretation tells us as much as we can know about location, but how do we find any additional dynamical information?

### 7.5 The information in a wavefunction

**Key points** (a) The wavefunction of a free particle with a specific linear momentum corresponds to a uniform probability density. (b) The Schrödinger equation is an eigenvalue equation in which the wavefunction is an eigenfunction of the Hamiltonian operator. (c) Observables are represented by operators; the value of an observable is an eigenvalue of the corresponding operator constructed from the operators for position and linear momentum. (d) All operators that correspond to observables are hermitian; their eigenvalues are real and their eigenfunctions are mutually orthogonal. Sets of functions that are normalized and mutually orthogonal are called orthonormal. (e) When the system is not described by an eigenfunction of an operator, it may be expressed as a superposition of such eigenfunctions. The mean value of a series of observations is given by the expectation value of the corresponding operator.

The Schrödinger equation for a particle of mass  $m$  free to move parallel to the  $x$ -axis with zero potential energy is obtained from eqn 7.17 by setting  $V = 0$ , and is

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} = E\psi \quad (7.21)$$

The solutions of this equation have the form

$$\psi = Ae^{ikx} + Be^{-ikx} \quad E = \frac{k^2\hbar^2}{2m} \quad (7.22)$$

where  $A$  and  $B$  are constants. (See *Mathematical background 3* following this chapter for more on complex numbers.) To verify that  $\psi$  is a solution of eqn 7.21, we simply substitute it into the left-hand side of the equation and confirm that we obtain  $E\psi$ .

$$\begin{aligned}
 -\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} &= -\frac{\hbar^2}{2m} \frac{d^2}{dx^2} (Ae^{ikx} + Be^{-ikx}) \\
 &= -\frac{\hbar^2}{2m} \{A(ik)^2 e^{ikx} + B(-ik)^2 e^{-ikx}\} \\
 &= \frac{\hbar^2 k^2}{2m} (Ae^{ikx} + Be^{-ikx}) = E\psi
 \end{aligned}$$

### (a) The probability density

We shall see later what determines the values of  $A$  and  $B$ ; for the time being we can treat them as arbitrary constants that we can vary at will. Suppose that  $B = 0$  in eqn 7.22, then the wavefunction is simply

$$\psi = Ae^{ikx} \quad (7.23)$$

Where is the particle? To find out, we calculate the probability density:

$$|\psi|^2 = (Ae^{ikx})^* (Ae^{ikx}) = (A^* e^{-ikx}) (Ae^{ikx}) = |A|^2 \quad (7.24)$$

This probability density is independent of  $x$  so, wherever we look along the  $x$ -axis, there is an equal probability of finding the particle (Fig. 7.24a). In other words, if the wavefunction of the particle is given by eqn 7.23, then we cannot predict where we will find it. The same would be true if the wavefunction in eqn 7.22 had  $A = 0$ ; then the probability density would be  $|B|^2$ , a constant.

Now suppose that in the wavefunction  $A = B$ . Then eqn 7.22 becomes

$$\psi = A(e^{ikx} + e^{-ikx}) = 2A \cos kx \quad (7.25)$$

The probability density now has the form

$$|\psi|^2 = (2A \cos kx)^* (2A \cos kx) = 4|A|^2 \cos^2 kx \quad (7.26)$$

This function is illustrated in Fig. 7.24b. As we see, the probability density periodically varies between 0 and  $4|A|^2$ . The locations where the probability density is zero correspond to *nodes* in the wavefunction. Specifically, a **node** is a point where a wavefunction passes *through* zero. The location where a wavefunction approaches zero without actually passing through zero is not a node.

### (b) Operators, eigenvalues, and eigenfunctions

To formulate a systematic way of extracting information from the wavefunction, we first note that any Schrödinger equation (such as those in eqns 7.17 and 7.21) may be written in the succinct form

$$\hat{H}\psi = E\psi \quad \text{Operator form of Schrödinger equation} \quad (7.27a)$$

with (in one dimension)

$$\hat{H} = -\frac{\hbar^2}{2m} \frac{d^2}{dx^2} + V(x) \quad \text{Hamiltonian operator} \quad (7.27b)$$

The quantity  $\hat{H}$  (commonly read aitch-hat) is an **operator**, something that carries out a mathematical operation on the function  $\psi$ . In this case, the operation is to take the second derivative of  $\psi$  and (after multiplication by  $-\hbar^2/2m$ ) to add the result to the outcome of multiplying  $\psi$  by  $V$ . The operator  $\hat{H}$  plays a special role in quantum mechanics, and is called the **hamiltonian operator** after the nineteenth century

**Fig. 7.24** (a) The square modulus of a wavefunction corresponding to a definite state of linear momentum is a constant; so it corresponds to a uniform probability of finding the particle anywhere. (b) The probability distribution corresponding to the superposition of states of equal magnitude of linear momentum but opposite direction of travel.

#### A brief comment

If the probability density of a particle is a constant, then it follows that, with  $x$  ranging from  $-\infty$  to  $+\infty$ , the normalization constants,  $A$  or  $B$ , are 0. To avoid this embarrassing problem,  $x$  is allowed to range from  $-L$  to  $+L$ , and  $L$  is allowed to go to infinity at the end of any subsequent calculation. We ignore this complication here.

mathematician William Hamilton, who developed a form of classical mechanics that, it subsequently turned out, is well suited to the formulation of quantum mechanics. The hamiltonian operator is the operator corresponding to the total energy of the system, the sum of the kinetic and potential energies. Consequently, we can infer that the first term in eqn 7.27b (the term proportional to the second derivative) must be the operator for the kinetic energy.

When the Schrödinger equation is written as in eqn 7.27a, it is seen to be an **eigenvalue equation**, an equation of the form

$$(\text{Operator})(\text{function}) = (\text{constant factor}) \times (\text{same function}) \quad (7.28a)$$

If we denote a general operator by  $\hat{\Omega}$  (where  $\Omega$  is upper-case omega) and a constant factor by  $\omega$  (lower-case omega), then an eigenvalue equation has the form

$$\hat{\Omega}\psi = \omega\psi \quad \text{Eigenvalue equation} \quad (7.28b)$$

The factor  $\omega$  is called the **eigenvalue** of the operator. The eigenvalue in eqn 7.27a is the energy. The function  $\psi$  in an equation of this kind is called an **eigenfunction** of the operator  $\hat{\Omega}$  and is different for each eigenvalue. So, in this technical language, we would write eqn 7.28a as

$$(\text{Operator})(\text{eigenfunction}) = (\text{eigenvalue}) \times (\text{eigenfunction}) \quad (7.28c)$$

The eigenfunction in eqn 7.27a is the wavefunction corresponding to the energy  $E$ . It follows that another way of saying ‘solve the Schrödinger equation’ is to say ‘find the eigenvalues and eigenfunctions of the hamiltonian operator for the system’.

#### Example 7.5 Identifying an eigenfunction

Show that  $e^{ax}$  is an eigenfunction of the operator  $d/dx$ , and find the corresponding eigenvalue. Show that  $e^{ax^2}$  is not an eigenfunction of  $d/dx$ .

**Method** We need to operate on the function with the operator and check whether the result is a constant factor times the original function.

**Answer** For  $\hat{\Omega} = d/dx$  (the operation ‘differentiate with respect to  $x$ ’) and  $\psi = e^{ax}$ :

$$\hat{\Omega}\psi = \frac{d}{dx}e^{ax} = ae^{ax} = a\psi$$

Therefore  $e^{ax}$  is indeed an eigenfunction of  $d/dx$ , and its eigenvalue is  $a$ . For  $\psi = e^{ax^2}$ ,

$$\hat{\Omega}\psi = \frac{d}{dx}e^{ax^2} = 2axe^{ax^2} = 2ax \times \psi$$

which is not an eigenvalue equation of  $\hat{\Omega}$  even though the same function  $\psi$  occurs on the right, because  $\psi$  is now multiplied by a variable factor ( $2ax$ ), not a constant factor. Alternatively, if the right-hand side is written  $2a(xe^{ax^2})$ , we see that it is a constant ( $2a$ ) times a *different* function.

**Self-test 7.5** Is the function  $\cos ax$  an eigenfunction of (a)  $d/dx$ , (b)  $d^2/dx^2$ ?

[(a) No, (b) yes]

#### (c) The construction of operators

The importance of eigenvalue equations is that the pattern

$$(\text{Energy operator})\psi = (\text{energy}) \times \psi$$

exemplified by the Schrödinger equation is repeated for other **observables**, or measurable properties of a system, such as the momentum or the electric dipole moment. Thus, it is often the case that we can write

$$(\text{Operator corresponding to an observable})\psi = (\text{value of observable}) \times \psi$$

The symbol  $\hat{\Omega}$  in eqn 7.28b is then interpreted as an operator (for example, the hamiltonian operator) corresponding to an observable (for example, the energy), and the eigenvalue  $\omega$  is the value of that observable (for example, the value of the energy,  $E$ ). Therefore, if we know both the wavefunction  $\psi$  and the operator  $\hat{\Omega}$  corresponding to the observable  $\Omega$  of interest, and the wavefunction is an eigenfunction of the operator  $\hat{\Omega}$ , then we can predict the outcome of an observation of the property  $\Omega$  (for example, an atom's energy) by picking out the factor  $\omega$  in the eigenvalue equation, eqn 7.28b.

A basic postulate of quantum mechanics tells us how to set up the operator corresponding to a given observable:

Observables,  $\Omega$ , are represented by operators,  $\hat{\Omega}$ , built from the following position and momentum operators:

$$\hat{x} = x \times \quad \hat{p}_x = \frac{\hbar}{i} \frac{d}{dx} \quad \text{Specification of operators} \quad [7.29]$$

That is, the operator for location along the  $x$ -axis is multiplication (of the wavefunction) by  $x$  and the operator for linear momentum parallel to the  $x$ -axis is proportional to taking the derivative (of the wavefunction) with respect to  $x$ .

#### A brief comment

The rules summarized by eqn 7.29 apply to observables that depend on spatial variables; intrinsic properties such as spin (Section 8.8) are treated differently.

#### Example 7.6 Determining the value of an observable

What is the linear momentum of a particle described by the wavefunction in eqn 7.22 with (a)  $B = 0$ , (b)  $A = 0$ ?

**Method** We operate on  $\psi$  with the operator corresponding to linear momentum (eqn 7.29), and inspect the result. If the outcome is the original wavefunction multiplied by a constant (that is, we generate an eigenvalue equation), then the constant is identified with the value of the observable.

**Answer** (a) With the wavefunction given in eqn 7.22 with  $B = 0$

$$\hat{p}_x \psi = \frac{\hbar}{i} \frac{d\psi}{dx} = \frac{\hbar}{i} A \frac{de^{ikx}}{dx} = \frac{\hbar}{i} A \times ike^{ikx} = k\hbar A e^{ikx} = k\hbar \psi$$

This is an eigenvalue equation, and by comparing it with eqn 7.28b we find that  $p_x = +k\hbar$ . (b) For the wavefunction with  $A = 0$

$$\hat{p}_x \psi = \frac{\hbar}{i} \frac{d\psi}{dx} = \frac{\hbar}{i} B \frac{de^{-ikx}}{dx} = \frac{\hbar}{i} B \times (-ik)e^{-ikx} = -k\hbar \psi$$

The magnitude of the linear momentum is the same in each case ( $k\hbar$ ), but the signs are different: in (a) the particle is travelling to the right (positive  $x$ ) but in (b) it is travelling to the left (negative  $x$ ).

**Self-test 7.6** The operator for the angular momentum of a particle travelling in a circle in the  $xy$ -plane is  $\hat{L}_z = (\hbar/i)d/d\phi$ , where  $\phi$  is its angular position. What is the angular momentum of a particle described by the wavefunction  $e^{-2i\phi}$ ? [ $L_z = -2\hbar$ ]

We use the definitions in eqn 7.29 to construct operators for other spatial observables. For example, suppose we wanted the operator for a potential energy of the form

**Fig. 7.25** Even if a wavefunction does not have the form of a periodic wave, it is still possible to infer from it the average kinetic energy of a particle by noting its average curvature. This illustration shows two wavefunctions: the sharply curved function corresponds to a higher kinetic energy than the less sharply curved function.

**Fig. 7.26** The observed kinetic energy of a particle is an average of contributions from the entire space covered by the wavefunction. Sharply curved regions contribute a high kinetic energy to the average; slightly curved regions contribute only a small kinetic energy.

#### A brief comment

We are using the term ‘curvature’ informally: the precise technical definition of the curvature of a function  $f$  is  $(d^2f/dx^2)/\{1 + (df/dx)^2\}^{3/2}$ .

$V(x) = \frac{1}{2}kx^2$ , with  $k$  a constant (later, we shall see that this potential energy describes the vibrations of atoms in molecules). Then it follows from eqn 7.29 that the operator corresponding to  $V(x)$  is multiplication by  $x^2$ :

$$\hat{V} = \frac{1}{2}kx^2 \times \quad (7.30)$$

In normal practice, the multiplication sign is omitted. To construct the operator for kinetic energy, we make use of the classical relation between kinetic energy and linear momentum, which in one dimension is  $E_k = p_x^2/2m$ . Then, by using the operator for  $p_x$  in eqn 7.29 we find:

$$\hat{E}_k = \frac{1}{2m} \left( \frac{\hbar}{i} \frac{d}{dx} \right) \left( \frac{\hbar}{i} \frac{d}{dx} \right) = -\frac{\hbar^2}{2m} \frac{d^2}{dx^2} \quad (7.31)$$

It follows that the operator for the total energy, the hamiltonian operator, is

$$\hat{H} = \hat{E}_k + \hat{V} = -\frac{\hbar^2}{2m} \frac{d^2}{dx^2} + \hat{V} \quad \text{Hamiltonian operator} \quad (7.32)$$

with  $\hat{V}(x)$  the multiplicative operator in eqn 7.30 (or some other appropriate expression for the potential energy).

The expression for the kinetic energy operator, eqn 7.31, enables us to develop the point made earlier concerning the interpretation of the Schrödinger equation. In mathematics, the second derivative of a function is a measure of its curvature: a large second derivative indicates a sharply curved function (Fig. 7.25). It follows that a sharply curved wavefunction is associated with a high kinetic energy, and one with a low curvature is associated with a low kinetic energy. This interpretation is consistent with the de Broglie relation, which predicts a short wavelength (a sharply curved wavefunction) when the linear momentum (and hence the kinetic energy) is high. However, it extends the interpretation to wavefunctions that do not spread through space and resemble those shown in Fig. 7.25. The curvature of a wavefunction in general varies from place to place. Wherever a wavefunction is sharply curved, its contribution to the total kinetic energy is large (Fig. 7.26). Wherever the wavefunction is not sharply curved, its contribution to the overall kinetic energy is low. As we shall shortly see, the observed kinetic energy of the particle is an integral of all the contributions of the kinetic energy from each region. Hence, we can expect a particle to have a high kinetic energy if the average curvature of its wavefunction is high. Locally there can be both positive and negative contributions to the kinetic energy (because the curvature can be either positive,  $\cup$ , or negative,  $\cap$ ), but the average is always positive (see Problem 7.26).

The association of high curvature with high kinetic energy will turn out to be a valuable guide to the interpretation of wavefunctions and the prediction of their shapes. For example, suppose we need to know the wavefunction of a particle with a given total energy and a potential energy that decreases with increasing  $x$  (Fig. 7.27). Because the difference  $E - V = E_k$  increases from left to right, the wavefunction must become more sharply curved as  $x$  increases: its wavelength decreases as the local contributions to its kinetic energy increase. We can therefore guess that the wavefunction will look like the function sketched in the illustration, and more detailed calculation confirms this to be so.

#### (d) Hermitian operators

All the quantum mechanical operators that correspond to observables have a very special mathematical property: they are ‘hermitian’. A **hermitian operator** is one for which the following relation is true:

$$\text{Hermiticity: } \int \psi_i^* \hat{Q} \psi_j d\tau = \left\{ \int \psi_j^* \hat{Q} \psi_i d\tau \right\}^* \quad \boxed{\text{Definition of hermiticity}} \quad [7.33]$$

That is, the same result is obtained by letting the operator act on  $\psi_j$  and then integrating or by letting it act on  $\psi_i$  instead, integrating, and then taking the complex conjugate of the result. One trivial consequence of hermiticity is that it reduces the number of integrals we need to evaluate. However, as we shall see, hermiticity has much more profound implications.

It is easy to confirm that the position operator ( $x \times$ ) is hermitian because we are free to change the order of the factors in the integrand:

$$\int_{-\infty}^{\infty} \psi_i^* x \psi_j d\tau = \int_{-\infty}^{\infty} \psi_j x \psi_i^* d\tau = \left\{ \int_{-\infty}^{\infty} \psi_j^* x \psi_i d\tau \right\}^*$$

The demonstration that the linear momentum operator is hermitian is more involved because we cannot just alter the order of functions we differentiate; but it is hermitian, as we show in the following *Justification*.

**Justification 7.2** *The hermiticity of the linear momentum operator*

Our task is to show that

$$\int_{-\infty}^{\infty} \psi_i^* \hat{p}_x \psi_j dx = \left\{ \int_{-\infty}^{\infty} \psi_j^* \hat{p}_x \psi_i dx \right\}^*$$

with  $\hat{p}_x$  given in eqn 7.29. To do so, we use ‘integration by parts’ (see *Mathematical background 1*), the relation

$$\int f \frac{dg}{dx} dx = fg - \int g \frac{df}{dx} dx$$

In the present case we write

$$\begin{aligned} \int_{-\infty}^{\infty} \psi_i^* \hat{p}_x \psi_j dx &= \frac{\hbar}{i} \int_{-\infty}^{\infty} \psi_i^* \frac{d\psi_j}{dx} dx \\ &= \frac{\hbar}{i} \psi_i^* \psi_j \Big|_{-\infty}^{\infty} - \frac{\hbar}{i} \int_{-\infty}^{\infty} \psi_j \frac{d\psi_i^*}{dx} dx \end{aligned}$$

The first term on the right of the second equality is zero, because all wavefunctions are zero at infinity in either direction, so we are left with

$$\begin{aligned} \int_{-\infty}^{\infty} \psi_i^* \hat{p}_x \psi_j dx &= -\frac{\hbar}{i} \int_{-\infty}^{\infty} \psi_j \frac{d\psi_i^*}{dx} dx = \left\{ \frac{\hbar}{i} \int_{-\infty}^{\infty} \psi_j^* \frac{d\psi_i}{dx} dx \right\}^* \\ &= \left\{ \int_{-\infty}^{\infty} \psi_j^* \hat{p}_x \psi_i dx \right\}^* \end{aligned}$$

as we set out to prove. In the final line we have used  $(\psi^*)^* = \psi$ .

**Fig. 7.27** The wavefunction of a particle in a potential decreasing towards the right and hence subjected to a constant force to the right. Only the real part of the wavefunction is shown, the imaginary part is similar, but displaced to the right.

**Self-test 7.7** Confirm that the operator  $d^2/dx^2$  is hermitian.

Hermitian operators are enormously important by virtue of two properties: their eigenvalues are real (as we prove in the following *Justification*), and their eigenfunctions are ‘orthogonal’. All observables have real values (in the mathematical sense, such as  $x = 2$  m and  $E = 10$  J), so all observables are represented by hermitian operators.

---

**Justification 7.3** *The reality of eigenvalues*

For a wavefunction  $\psi$  that is normalized and is an eigenfunction of a hermitian operator  $\hat{Q}$  with eigenvalue  $\omega$ , we can write

$$\int \psi^* \hat{Q} \psi d\tau = \int \psi^* \omega \psi d\tau = \omega \int \psi^* \psi d\tau = \omega$$

However, by taking the complex conjugate we can write

$$\omega^* = \left\{ \int \psi^* \hat{Q} \psi d\tau \right\}^* \overset{\text{hermiticity}}{=} \int \psi^* \hat{Q} \psi d\tau = \omega$$

The conclusion that  $\omega^* = \omega$  confirms that  $\omega$  is real.

---

To say that two different functions  $\psi_i$  and  $\psi_j$  are **orthogonal** means that the integral (over all space) of their product is zero:

$$\int \psi_i^* \psi_j d\tau = 0 \quad \text{for} \quad i \neq j \quad \boxed{\text{Definition of orthogonality}} \quad (7.34)$$

A general feature of quantum mechanics, which we prove in the following *Justification*, is that *wavefunctions corresponding to different eigenvalues of an hermitian operator are orthogonal*. For example, the hamiltonian operator is hermitian (it corresponds to an observable, the energy). Therefore, if  $\psi_1$  corresponds to one energy, and  $\psi_2$  corresponds to a different energy, then we know at once that the two functions are orthogonal and that the integral of their product is zero.

---

**Justification 7.4** *The orthogonality of wavefunctions*

Suppose we have two wavefunctions  $\psi_n$  and  $\psi_m$  corresponding to two different energies  $E_n$  and  $E_m$ , respectively. Then we can write

$$\hat{H}\psi_n = E_n\psi_n \quad \hat{H}\psi_m = E_m\psi_m$$

Now multiply the first of these two Schrödinger equations by  $\psi_m^*$  and the second by  $\psi_n^*$  and integrate over all space:

$$\int \psi_m^* \hat{H} \psi_n d\tau = E_n \int \psi_m^* \psi_n d\tau \quad \int \psi_n^* \hat{H} \psi_m d\tau = E_m \int \psi_n^* \psi_m d\tau$$

Next, noting that the energies themselves are real, form the complex conjugate of the second expression (for the state  $m$ ) and subtract it from the first expression (for the state  $n$ ):

$$\int \psi_m^* \hat{H} \psi_n d\tau - \left( \int \psi_n^* \hat{H} \psi_m d\tau \right)^* = E_n \int \psi_m^* \psi_n d\tau - E_m \int \psi_n^* \psi_m^* d\tau$$

By the hermiticity of the hamiltonian, the two terms on the left are equal, so they cancel and we are left with

$$0 = (E_n - E_m) \int \psi_m^* \psi_n d\tau$$

However, the two energies are different; therefore the integral on the right must be zero, which confirms that two wavefunctions belonging to different energies are orthogonal. The same argument applies to eigenfunctions of any Hermitian operator.

The property of orthogonality is of great importance in quantum mechanics because it enables us to eliminate a large number of integrals from calculations. Orthogonality plays a central role in the theory of chemical bonding (Chapter 10) and spectroscopy (Chapters 12–14). Sets of functions that are normalized and mutually orthogonal are called **orthonormal**.

#### • A brief illustration

The wavefunctions  $\sin x$  and  $\sin 2x$  are eigenfunctions of the hermitian operator  $d^2/dx^2$ , with eigenvalues  $-1$  and  $-4$ , respectively. To verify that the two wavefunctions are mutually orthogonal, we integrate the product  $(\sin x)(\sin 2x)$  over all space, which we may take to span from  $x = 0$  to  $x = 2\pi$ , because both functions repeat themselves outside that range. Hence proving that the integral of their product is zero within that range implies that the integral over the whole of space is also zero (Fig. 7.28). A useful integral for this calculation when  $a^2 \neq b^2$  is

$$\int \sin ax \sin bx dx = \frac{\sin(a-b)x}{2(a-b)} - \frac{\sin(a+b)x}{2(a+b)} + \text{constant}$$

It follows that, for  $a = 1$  and  $b = 2$ , and the fact that  $\sin 0 = 0$ ,  $\sin 2\pi = 0$ , and  $\sin 6\pi = 0$ , that

$$\int_0^{2\pi} \sin x \sin 2x dx = 0$$

and the two functions are mutually orthogonal. •

**Fig. 7.28** The integral of the function  $f(x) = \sin x \sin 2x$  is equal to the area (tinted) below the green curve, and is zero, as can be inferred by symmetry. The function—and the value of the integral—repeats itself for all replications of the section between 0 and  $2\pi$ , so the integral from  $-\infty$  to  $\infty$  is zero.

**Self-test 7.8** Confirm that the functions  $\sin x$  and  $\sin 3x$  are mutually orthogonal.

$$\left[ \int_0^{2\pi} \sin x \sin 3x dx = 0 \right]$$

#### (e) Superpositions and expectation values

Suppose now that the wavefunction is the one given in eqn 7.22 (with  $A = B$ ). What is the linear momentum of the particle it describes? We quickly run into trouble if we use the operator technique. When we operate with  $\hat{p}_x$ , we find

$$\hat{p}_x \psi = \frac{\hbar}{i} \frac{d\psi}{dx} = \frac{2\hbar}{i} A \frac{d \cos kx}{dx} = -\frac{2k\hbar}{i} A \sin kx \quad (7.35)$$

This expression is not an eigenvalue equation, because the function on the right ( $\sin kx$ ) is different from that on the left ( $\cos kx$ ).

When the wavefunction of a particle is not an eigenfunction of an operator, the property to which the operator corresponds does not have a definite value. However, in the current example the momentum is not completely indefinite because the cosine wavefunction is a **linear combination**, or sum, of  $e^{ikx}$  and  $e^{-ikx}$ , and these two functions, as we have seen, individually correspond to definite momentum states. We say that

**A brief comment**

In general, a linear combination of two functions  $f$  and  $g$  is  $c_1f + c_2g$ , where  $c_1$  and  $c_2$  are numerical coefficients, so a linear combination is a more general term than 'sum'. In a sum,  $c_1 = c_2 = 1$ . A linear combination might have the form  $0.567f + 1.234g$ , for instance, so it is more general than the simple sum  $f + g$ .

the total wavefunction is a **superposition** of more than one wavefunction. Symbolically we can write the superposition as

$$\psi = \underbrace{\psi_{\rightarrow}}_{\substack{\text{Particle with} \\ \text{linear} \\ \text{momentum} \\ +\hbar k}} + \underbrace{\psi_{\leftarrow}}_{\substack{\text{Particle with} \\ \text{linear} \\ \text{momentum} \\ -\hbar k}}$$

The interpretation of this composite wavefunction is that, if the momentum of the particle is repeatedly measured in a long series of observations, then its magnitude will found to be  $\hbar k$  in all the measurements (because that is the value for each component of the wavefunction). However, because the two component wavefunctions occur equally in the superposition, half the measurements will show that the particle is moving to the right ( $p_x = +\hbar k$ ), and half the measurements will show that it is moving to the left ( $p_x = -\hbar k$ ). According to quantum mechanics, we cannot predict in which direction the particle will in fact be found to be travelling; all we can say is that, in a long series of observations, if the particle is described by this wavefunction, then there are equal probabilities of finding the particle travelling to the right and to the left.

The same interpretation applies to any wavefunction written as a linear combination of eigenfunctions of an operator. Thus, suppose the wavefunction is known to be a superposition of many different linear momentum eigenfunctions and written as the linear combination

$$\psi = c_1\psi_1 + c_2\psi_2 + \cdots = \sum_k c_k\psi_k \quad \text{Linear combination of basis functions} \quad (7.36)$$

where the  $c_k$  are numerical (possibly complex) coefficients and the  $\psi_k$  correspond to different momentum states. The functions  $\psi_k$  are said to form a **complete set** in the sense that any arbitrary function can be expressed as a linear combination of them. Then according to quantum mechanics:

1. When the momentum is measured, in a single observation one of the eigenvalues corresponding to the  $\psi_k$  that contribute to the superposition will be found.
2. The probability of measuring a particular eigenvalue in a series of observations is proportional to the square modulus ( $|c_k|^2$ ) of the corresponding coefficient in the linear combination.
3. The average value of a large number of observations is given by the expectation value,  $\langle \Omega \rangle$ , of the operator corresponding to the observable of interest.

The **expectation value** of an operator  $\hat{\Omega}$  is defined as

$$\langle \Omega \rangle = \int \psi^* \hat{\Omega} \psi d\tau \quad \text{Definition of expectation value} \quad [7.37]$$

This formula is valid only for normalized wavefunctions. As we see in the following *Justification*, an expectation value is the weighted average of a large number of observations of a property.

**Justification 7.5** *The expectation value of an operator*

If  $\psi$  is an eigenfunction of  $\hat{\Omega}$  with eigenvalue  $\omega$ , the expectation value of  $\hat{\Omega}$  is

$$\langle \Omega \rangle = \int \psi^* \overbrace{\hat{\Omega} \psi}^{\omega \psi} d\tau = \int \psi^* \omega \psi d\tau = \omega \int \psi^* \psi d\tau = \omega$$

because  $\omega$  is a constant and may be taken outside the integral, and the resulting integral is equal to 1 for a normalized wavefunction. The interpretation of this expression is that, because every observation of the property  $\Omega$  results in the value  $\omega$  (because the wavefunction is an eigenfunction of  $\hat{\Omega}$ ), the mean value of all the observations is also  $\omega$ .

A wavefunction that is not an eigenfunction of the operator of interest can be written as a linear combination of eigenfunctions. For simplicity, suppose the wavefunction is the sum of two eigenfunctions (the general case, eqn 7.36, can easily be developed). Then

$$\begin{aligned}\langle\Omega\rangle &= \int (c_1\psi_1 + c_2\psi_2)^* \hat{\Omega} (c_1\psi_1 + c_2\psi_2) d\tau \\ &= \int (c_1\psi_1 + c_2\psi_2)^* (c_1\hat{\Omega}\psi_1 + c_2\hat{\Omega}\psi_2) d\tau \\ &= \int (c_1\psi_1 + c_2\psi_2)^* (c_1\omega_1\psi_1 + c_2\omega_2\psi_2) d\tau \\ &= c_1^*c_1\omega_1 \overbrace{\int \psi_1^*\psi_1 d\tau}^1 + c_2^*c_2\omega_2 \overbrace{\int \psi_2^*\psi_2 d\tau}^1 \\ &\quad + c_2^*c_1\omega_1 \overbrace{\int \psi_2^*\psi_1 d\tau}^0 + c_1^*c_2\omega_2 \overbrace{\int \psi_1^*\psi_2 d\tau}^0\end{aligned}$$

The first two integrals on the right are both equal to 1 because the wavefunctions are individually normalized. Because  $\psi_1$  and  $\psi_2$  correspond to different eigenvalues of an hermitian operator, they are orthogonal, so the third and fourth integrals on the right are zero. We can conclude that

$$\langle\Omega\rangle = |c_1|^2\omega_1 + |c_2|^2\omega_2$$

This expression shows that the expectation value is the sum of the two eigenvalues weighted by the probabilities that each one will be found in a series of measurements. Hence, the expectation value is the weighted mean of a series of observations.

### Example 7.7 Calculating an expectation value

Calculate the average value of the distance of an electron from the nucleus in the hydrogen atom in its state of lowest energy.

**Method** The average radius is the expectation value of the operator corresponding to the distance from the nucleus, which is multiplication by  $r$ . To evaluate  $\langle r \rangle$ , we need to know the normalized wavefunction (from Example 7.4) and then evaluate the integral in eqn 7.37.

**Answer** The average value is given by the expectation value

$$\langle r \rangle = \int \psi^* r \psi d\tau = \int r |\psi|^2 d\tau$$

which we evaluate by using spherical polar coordinates and the appropriate expression for the volume element,  $d\tau = r^2 dr \sin \theta d\theta d\phi$ . Using the normalized function in Example 7.4, gives

$$\langle r \rangle = \frac{1}{\pi a_0^3} \int_0^\infty \overbrace{r^3}^{3a_0^4/2^3} e^{-2r/a_0} dr \int_0^\pi \overbrace{\sin \theta}^2 d\theta \int_0^{2\pi} \overbrace{d\phi}^{2\pi} = \frac{3}{2} a_0$$

Because  $a_0 = 52.9$  pm (see inside the front cover),  $\langle r \rangle = 79.4$  pm. This result means that, if a very large number of measurements of the distance of the electron from the nucleus are made, then their mean value will be 79.4 pm. However, each different observation will give a different and unpredictable individual result because the wavefunction is not an eigenfunction of the operator corresponding to  $r$ .

**Self-test 7.9** Evaluate the root mean square distance,  $\langle r^2 \rangle^{1/2}$ , of the electron from the nucleus in the hydrogen atom.  $[3^{1/2} a_0 = 91.6 \text{ pm}]$

The mean kinetic energy of a particle in one dimension is the expectation value of the operator given in eqn 7.31. Therefore, we can write

$$\langle E_k \rangle = \int \psi^* \hat{E}_k \psi dx = -\frac{\hbar^2}{2m} \int \psi^* \frac{d^2 \psi}{dx^2} dx \quad (7.38)$$

This conclusion confirms the previous assertion that the kinetic energy is a kind of average over the curvature of the wavefunction: we get a large contribution to the observed value from regions where the wavefunction is sharply curved (so  $d^2 \psi / dx^2$  is large) and the wavefunction itself is large (so that  $\psi^*$  is large too).

## 7.6 The uncertainty principle

**Key points** The uncertainty principle restricts the precision with which complementary observables may be specified and measured. Complementary observables are observables for which the corresponding operators do not commute.

We have seen that, if the wavefunction is  $Ae^{ikx}$ , then the particle it describes has a definite state of linear momentum, namely travelling to the right with momentum  $p_x = +k\hbar$ . However, we have also seen that the position of the particle described by this wavefunction is completely unpredictable. In other words, if the momentum is specified precisely, it is impossible to predict the location of the particle. This statement is one-half of a special case of the **Heisenberg uncertainty principle**, one of the most celebrated results of quantum mechanics:

It is impossible to specify simultaneously, with arbitrary precision, both the momentum and the position of a particle.

Heisenberg  
uncertainty principle

Before discussing the principle further, we must establish its other half: that, if we know the position of a particle exactly, then we can say nothing about its momentum. The argument draws on the idea of regarding a wavefunction as a superposition of eigenfunctions, and runs as follows.

If we know that the particle is at a definite location, its wavefunction must be large there and zero everywhere else (Fig. 7.29). Such a wavefunction can be created by superimposing a large number of harmonic (sine and cosine) functions, or, equivalently, a number of  $e^{ikx}$  functions. In other words, we can create a sharply localized wavefunction, called a **wave packet**, by forming a linear combination of wavefunctions that correspond to many different linear momenta. The superposition of a few harmonic functions gives a wavefunction that spreads over a range of locations

**Fig. 7.29** The wavefunction for a particle at a well-defined location is a sharply spiked function that has zero amplitude everywhere except at the particle's position.

(Fig. 7.30). However, as the number of wavefunctions in the superposition increases, the wave packet becomes sharper on account of the more complete interference between the positive and negative regions of the individual waves. When an infinite number of components are used, the wave packet is a sharp, infinitely narrow spike, which corresponds to perfect localization of the particle. Now the particle is perfectly localized. However, we have lost all information about its momentum because, as we saw above, a measurement of the momentum will give a result corresponding to any one of the infinite number of waves in the superposition, and which one it will give is unpredictable. Hence, if we know the location of the particle precisely (implying that its wavefunction is a superposition of an infinite number of momentum eigenfunctions), then its momentum is completely unpredictable.

A quantitative version of this result is

$$\Delta p \Delta q \geq \frac{1}{2} \hbar$$

Heisenberg  
uncertainty principle

(7.39a)

In this expression  $\Delta p$  is the ‘uncertainty’ in the linear momentum parallel to the axis  $q$ , and  $\Delta q$  is the uncertainty in position along that axis. These ‘uncertainties’ are precisely defined, for they are the root mean square deviations of the properties from their mean values:

$$\Delta p = \{\langle p^2 \rangle - \langle p \rangle^2\}^{1/2} \quad \Delta q = \{\langle q^2 \rangle - \langle q \rangle^2\}^{1/2} \quad (7.39b)$$

If there is complete certainty about the position of the particle ( $\Delta q = 0$ ), then the only way that eqn 7.39a can be satisfied is for  $\Delta p = \infty$ , which implies complete uncertainty about the momentum. Conversely, if the momentum parallel to an axis is known exactly ( $\Delta p = 0$ ), then the position along that axis must be completely uncertain ( $\Delta q = \infty$ ).

The  $p$  and  $q$  that appear in eqn 7.39 refer to the same direction in space. Therefore, whereas simultaneous specifications of the position on the  $x$ -axis and momentum parallel to the  $x$ -axis are restricted by the uncertainty relation, simultaneous locations of position on  $x$  and motion parallel to  $y$  or  $z$  are not restricted. The restrictions that the uncertainty principle implies are summarized in Table 7.2.

### Example 7.8 Using the uncertainty principle

Suppose the speed of a projectile of mass 1.0 g is known to within  $1 \mu\text{m s}^{-1}$ . Calculate the minimum uncertainty in its position.

**Method** Estimate  $\Delta p$  from  $m\Delta v$ , where  $\Delta v$  is the uncertainty in the speed; then use eqn 7.39a to estimate the minimum uncertainty in position,  $\Delta q$ .

**Answer** The minimum uncertainty in position is

$$\begin{aligned} \Delta q &= \frac{\hbar}{2m\Delta v} \\ &= \frac{1.055 \times 10^{-34} \text{ J s}}{2 \times (1.0 \times 10^{-3} \text{ kg}) \times (1 \times 10^{-6} \text{ m s}^{-1})} = 5 \times 10^{-26} \text{ m} \end{aligned}$$

where we have used  $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$ . The uncertainty is completely negligible for all practical purposes concerning macroscopic objects. However, if the mass is that of an electron, then the same uncertainty in speed implies an uncertainty in position far larger than the diameter of an atom (the analogous calculation gives  $\Delta q = 60 \text{ m}$ ); so the concept of a trajectory, the simultaneous possession of a precise position and momentum, is untenable.

**Fig. 7.30** The wavefunction for a particle with an ill-defined location can be regarded as the superposition of several wavefunctions of definite wavelength that interfere constructively in one place but destructively elsewhere. As more waves are used in the superposition (as given by the numbers attached to the curves), the location becomes more precise at the expense of uncertainty in the particle's momentum. An infinite number of waves is needed to construct the wavefunction of a perfectly localized particle.

 **interActivity** Use mathematical software or an electronic spreadsheet to construct superpositions of cosine functions as  $\psi(x) = \sum_{k=1}^N (1/N) \cos(k\pi x)$ , where the constant  $1/N$  is introduced to keep the superpositions with the same overall magnitude. Explore how the probability density  $\psi^2(x)$  changes with the value of  $N$ .

**Table 7.2\*** Constraints of the uncertainty principle

| Variable 2 | Variable 1 |     |     |       |       |       |
|------------|------------|-----|-----|-------|-------|-------|
|            | $x$        | $y$ | $z$ | $p_x$ | $p_y$ | $p_z$ |

\* Pairs of observables that cannot be determined simultaneously with arbitrary precision are marked with a black rectangle; all others are unrestricted.

**Self-test 7.10** Estimate the minimum uncertainty in the speed of an electron in a one-dimensional region of length  $2a_0$ . [547 km s<sup>-1</sup>]

The Heisenberg uncertainty principle is more general than eqn 7.39 suggests. It applies to any pair of observables called **complementary observables**, which are defined in terms of the properties of their operators. Specifically, two observables  $\hat{\Omega}_1$  and  $\hat{\Omega}_2$  are complementary if

$$\hat{\Omega}_1(\hat{\Omega}_2\psi) \neq \hat{\Omega}_2(\hat{\Omega}_1\psi) \quad (7.40)$$

where the term on the left implies that  $\hat{\Omega}_2$  acts first, then  $\hat{\Omega}_1$  acts on the result, and the term on the right implies that the operations are performed in the opposite order. When the effect of two operators applied in succession depends on their order (as this equation implies), we say that they do not **commute**. The different outcomes of the effect of applying  $\hat{\Omega}_1$  and  $\hat{\Omega}_2$  in a different order are expressed by introducing the **commutator** of the two operators, which is defined as

$$[\hat{\Omega}_1, \hat{\Omega}_2] = \hat{\Omega}_1\hat{\Omega}_2 - \hat{\Omega}_2\hat{\Omega}_1 \quad (7.41)$$

Definition of commutator

We show in the following *Justification* that the commutator of the operators for position and linear momentum is

$$[\hat{x}, \hat{p}_x] = i\hbar \quad (7.42)$$

**Justification 7.6** *The commutator of position and momentum*

To show that the operators for position and momentum do not commute (and hence are complementary observables) we consider the effect of  $\hat{x}\hat{p}_x$  (that is, the effect of  $\hat{p}_x$  followed by the effect on the outcome of multiplication by  $x$ ) on a wavefunction  $\psi$ :

$$\hat{x}\hat{p}_x\psi = x \times \frac{\hbar}{i} \frac{d\psi}{dx}$$

Next, we consider the effect of  $\hat{p}_x\hat{x}$  on the same function (that is, the effect of multiplication by  $x$  followed by the effect of  $\hat{p}_x$  on the outcome):

$$\hat{p}_x\hat{x}\psi = \frac{\hbar}{i} \frac{d(x\psi)}{dx} = \frac{\hbar}{i} \left( \psi + x \frac{d\psi}{dx} \right)$$

For this step we have used the standard rule about differentiating a product of functions ( $d(fg)/dx = fdg/dx + gdf/dx$ ). The second expression is clearly different from the first, so the two operators do not commute. Their commutator can be inferred from the difference of the two expressions:

$$\hat{x}\hat{p}_x\psi - \hat{p}_x\hat{x}\psi = -\frac{\hbar}{i} \psi = i\hbar\psi$$

This relation is true for any wavefunction  $\psi$ , so the operator relation in eqn 7.42 follows immediately.

The commutator in eqn 7.42 is of such vital significance in quantum mechanics that it is taken as a fundamental distinction between classical mechanics and quantum mechanics. In fact, this commutator may be taken as a postulate of quantum mechanics, and is used to justify the choice of the operators for position and linear momentum given in eqn 7.29.

With the concept of commutator established, the Heisenberg uncertainty principle can be given its most general form. For *any* two pairs of observables,  $\Omega_1$  and  $\Omega_2$ , the uncertainties (to be precise, the root mean square deviations of their values from the mean) in simultaneous determinations are related by

$$\Delta\Omega_1\Delta\Omega_2 \geq \frac{1}{2} |\langle [\hat{\Omega}_1, \hat{\Omega}_2] \rangle| \quad (7.43)$$

We obtain the special case of eqn 7.39 when we identify the observables with  $x$  and  $p_x$  and use eqn 7.42 for their commutator. (See *Mathematical background 3* for the meaning of the  $|\dots|$  notation.)

Complementary observables are observables with non-commuting operators. With the discovery that some pairs of observables are complementary (we meet more examples in the next chapter), we are at the heart of the difference between classical and quantum mechanics. Classical mechanics supposed, falsely as we now know, that the position and momentum of a particle could be specified simultaneously with arbitrary precision. However, quantum mechanics shows that position and momentum are complementary, and that we have to make a choice: we can specify position at the expense of momentum, or momentum at the expense of position.

The realization that some observables are complementary allows us to make considerable progress with the calculation of atomic and molecular properties; but it does away with some of the most cherished concepts of classical physics.

## 7.7 The postulates of quantum mechanics

For convenience, we collect here the postulates on which quantum mechanics is based and which have been introduced in the course of this chapter.

*The wavefunction.* All dynamical information is contained in the wavefunction  $\psi$  for the system, which is a mathematical function found by solving the Schrödinger equation for the system. In one dimension:

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + V(x)\psi = E\psi$$

*The Born interpretation.* If the wavefunction of a particle has the value  $\psi$  at some point  $r$ , then the probability of finding the particle in an infinitesimal volume  $d\tau = dx dy dz$  at that point is proportional to  $|\psi|^2 d\tau$ .

*Acceptable wavefunctions.* An acceptable wavefunction must be continuous, have a continuous first derivative, be single-valued, and be square-integrable.

*Observables.* Observables,  $\Omega$ , are represented by operators,  $\hat{\Omega}$ , built from the following position and momentum operators:

$$\hat{x} = x \times \quad \hat{p}_x = \frac{\hbar}{i} \frac{d}{dx}$$

or, more generally, from operators that satisfy the commutation relation  $[\hat{x}, \hat{p}_x] = i\hbar$ .

*The Heisenberg uncertainty relation.* It is impossible to specify simultaneously, with arbitrary precision, both the momentum and the position of a particle and, more generally, any pair of observables with operators that do not commute.

Checklist of key equations

| Property                                                   | Equation                                                                                                                                                          | Comment                                                          |

Further information

Further information 7.1 *Classical mechanics*

Classical mechanics describes the behaviour of objects in terms of two equations. One expresses the fact that the total energy is constant in the absence of external forces; the other expresses the response of particles to the forces acting on them.

(a) The trajectory in terms of the energy

The velocity,  $v$ , of a particle is the rate of change of its position:

$$v = \frac{dr}{dt}$$

Definition of velocity

(7.44)

The velocity is a vector, with both direction and magnitude. (Vectors are discussed in *Mathematical background 5*.) The magnitude of the velocity is the **speed**,  $v$ . The **linear momentum**,  $p$ , of a particle of mass  $m$  is related to its velocity,  $v$ , by

$$p = mv$$

Definition of linear momentum

(7.45)

Like the velocity vector, the linear momentum vector points in the direction of travel of the particle (Fig. 7.31). In terms of the linear

Fig. 7.31 The linear momentum of a particle is a vector property and points in the direction of motion.

momentum, the total energy—the sum of the kinetic and potential energy—of a particle is

$$E = E_k + V(x) = \frac{p^2}{2m} + V(x)$$

(7.46)

This equation can be used to show that a particle will have a definite **trajectory**, or definite position and momentum at each instant. For example, consider a particle free to move in one direction (along the  $x$ -axis) in a region where  $V=0$  (so the energy is independent of position). From the definition of the kinetic energy,  $E_k = \frac{1}{2}mv^2$ , and  $v = dx/dt$ , it follows from eqns 7.45 and 7.46 that

$$\frac{dx}{dt} = \left( \frac{2E_k}{m} \right)^{1/2} \quad (7.47)$$

A solution of this differential equation is

$$x(t) = x(0) + \left( \frac{2E_k}{m} \right)^{1/2} t \quad (7.48)$$

The linear momentum is a constant:

$$p(t) = mv(t) = m \frac{dx}{dt} = (2mE_k)^{1/2} \quad (7.49)$$

Hence, if we know the initial position and momentum, we can predict all later positions and momenta exactly.

### (b) Newton's second law

The **force**,  $F$ , experienced by a particle free to move in one dimension is related to its potential energy,  $V$ , by

$$F = -\frac{dV}{dx} \quad (7.50a)$$

This relation implies that the direction of the force is towards decreasing potential energy (Fig. 7.32). In three dimensions

**Fig. 7.32** The force acting on a particle is determined by the slope of the potential energy at each point. The force points in the direction of lower potential energy.

$$F = -\nabla V \quad \nabla = i \frac{\partial}{\partial x} + j \frac{\partial}{\partial y} + k \frac{\partial}{\partial z} \quad (7.50b)$$

**Newton's second law of motion** states that *the rate of change of momentum is equal to the force acting on the particle*. In one dimension:

$$\frac{dp}{dt} = F \quad \text{Newton's second law of motion} \quad (7.51a)$$

Because  $p = m(dx/dt)$  in one dimension, it is sometimes more convenient to write this equation as

$$m \frac{d^2x}{dt^2} = F \quad (7.51b)$$

The second derivative,  $d^2x/dt^2$ , is the **acceleration** of the particle, its rate of change of velocity (in this instance, along the  $x$ -axis). It follows that, if we know the force acting everywhere and at all times, then solving eqn 7.51 will also give the trajectory. This calculation is equivalent to the one based on  $E$ , but is more suitable in some applications. For example, it can be used to show that, if a particle of mass  $m$  is initially stationary and is subjected to a constant force  $F$  for a time  $\tau$ , then its kinetic energy increases from zero to

$$E_k = \frac{F^2 \tau^2}{2m} \quad (7.52)$$

and then remains at that energy after the force ceases to act. Because the applied force,  $F$ , and the time,  $\tau$ , for which it acts may be varied at will, the solution implies that the energy of the particle may be increased to any value.

### (c) Rotational motion

The rotational motion of a particle about a central point is described by its **angular momentum**,  $J$ . The angular momentum is a vector: its magnitude gives the rate at which a particle circulates and its direction indicates the axis of rotation (Fig. 7.33). The magnitude of the angular momentum,  $J$ , is given by the expression

**Fig. 7.33** The angular momentum of a particle is represented by a vector along the axis of rotation and perpendicular to the plane of rotation. The length of the vector denotes the magnitude of the angular momentum. The direction of motion is clockwise to an observer looking in the direction of the vector.

$$J = I\omega \quad \text{Magnitude of the angular momentum} \quad (7.53)$$

where  $\omega$  is the **angular velocity** of the body, its rate of change of angular position (in radians per second), and  $I$  is the **moment of inertia**. The analogous roles of  $m$  and  $I$ , of  $v$  and  $\omega$ , and of  $p$  and  $J$  in the translational and rotational cases, respectively, should be remembered, because they provide a ready way of constructing and recalling equations. For a point particle of mass  $m$  moving in a circle of radius  $r$ , the moment of inertia about the axis of rotation is given by the expression

$$I = mr^2$$

$$\text{Moment of inertia of a point particle moving in a circle} \quad (7.54)$$

To accelerate a rotation it is necessary to apply a **torque**,  $T$ , a twisting force. Newton's equation is then

$$\frac{dJ}{dt} = T \quad \text{Definition of torque} \quad (7.55)$$

If a constant torque is applied for a time  $\tau$ , the rotational energy of an initially stationary body is increased to

$$E_k = \frac{T^2 \tau^2}{2I} \quad (7.56)$$

The implication of this equation is that an appropriate torque and period for which it is applied can excite the rotation to an arbitrary energy.

#### (d) The harmonic oscillator

A **harmonic oscillator** consists of a particle that experiences a restoring force proportional to its displacement from its equilibrium position:

$$F = -kx \quad \text{Restoring force} \quad (7.57)$$

An example is a particle joined to a rigid support by a spring. The constant of proportionality  $k$  is called the **force constant**, and the stiffer the spring the greater the force constant. The negative sign in  $F$  signifies that the direction of the force is opposite to that of the displacement (Fig. 7.34).

**Fig. 7.34** The force acting on a particle that undergoes harmonic motion. The force is directed toward zero displacement and is proportional to the displacement. The corresponding potential energy is parabolic (proportional to  $x^2$ ).

The motion of a particle that undergoes harmonic motion is found by substituting the expression for the force, eqn 7.57, into Newton's equation, eqn 7.51b. The resulting equation is

$$m \frac{d^2x}{dt^2} = -kx$$

A solution is

$$x(t) = A \sin \omega t \quad p(t) = m\omega A \cos \omega t \quad \omega = (k/m)^{1/2} \quad (7.58)$$

These solutions show that the position of the particle varies **harmonically** (that is, as  $\sin \omega t$ ) with a frequency  $\nu = \omega/2\pi$ . They also show that the particle is stationary ( $p = 0$ ) when the displacement,  $x$ , has its maximum value,  $A$ , which is called the **amplitude** of the motion.

The total energy of a classical harmonic oscillator is proportional to the square of the amplitude of its motion. To confirm this remark we note that the kinetic energy is

$$E_k = \frac{p^2}{2m} = \frac{(m\omega A \cos \omega t)^2}{2m} = \frac{1}{2}m\omega^2 A^2 \cos^2 \omega t \quad (7.59)$$

Then, because  $\omega = (k/m)^{1/2}$ , this expression may be written

$$E_k = \frac{1}{2}kA^2 \cos^2 \omega t \quad (7.60)$$

The force on the oscillator is  $F = -kx$ , so it follows from the relation  $F = -dV/dx$  that the potential energy of a harmonic oscillator is

$$V = \frac{1}{2}kx^2 = \frac{1}{2}kA^2 \sin^2 \omega t \quad (7.61)$$

The total energy is therefore

$$E = \frac{1}{2}kA^2 \cos^2 \omega t + \frac{1}{2}kA^2 \sin^2 \omega t = \frac{1}{2}kA^2 \quad (7.62)$$

(We have used  $\cos^2 \omega t + \sin^2 \omega t = 1$ .) That is, the energy of the oscillator is constant and, for a given force constant, is determined by its maximum displacement. It follows that the energy of an oscillating particle can be raised to any value by stretching the spring to any desired amplitude  $A$ . Note that the frequency of the motion depends only on the inherent properties of the oscillator (as represented by  $k$  and  $m$ ) and is independent of the energy; the amplitude governs the energy, through  $E = \frac{1}{2}kA^2$ , and is independent of the frequency. In other words, the particle will oscillate at the same frequency regardless of the amplitude of its motion.

## Discussion questions

- 7.1** Summarize the evidence that led to the introduction of quantum mechanics.
- 7.2** Explain why Planck's introduction of quantization accounted for the properties of black-body radiation.
- 7.3** Explain why Einstein's introduction of quantization accounted for the properties of heat capacities at low temperatures.
- 7.4** Explain the meaning and consequences of wave-particle duality.
- 7.5** Describe how a wavefunction determines the dynamical properties of a system and how those properties may be predicted.
- 7.6** Account for the uncertainty relation between position and linear momentum in terms of the shape of the wavefunction.
- 7.7** Suggest how the general shape of a wavefunction can be predicted without solving the Schrödinger equation explicitly.

## Exercises

- 7.1(a)** To what speed must an electron be accelerated for it to have a wavelength of 3.0 cm?
- 7.1(b)** To what speed must a proton be accelerated for it to have a wavelength of 3.0 cm?
- 7.2(a)** The fine-structure constant,  $\alpha$ , plays a special role in the structure of matter; its approximate value is  $1/137$ . What is the wavelength of an electron travelling at a speed  $\alpha c$ , where  $c$  is the speed of light?
- 7.2(b)** Calculate the linear momentum of photons of wavelength 350 nm. What speed does a hydrogen molecule need to travel to have the same linear momentum?
- 7.3(a)** The speed of a certain proton is  $0.45 \text{ Mm s}^{-1}$ . If the uncertainty in its momentum is to be reduced to 0.0100 per cent, what uncertainty in its location must be tolerated?
- 7.3(b)** The speed of a certain electron is  $995 \text{ km s}^{-1}$ . If the uncertainty in its momentum is to be reduced to 0.0010 per cent, what uncertainty in its location must be tolerated?
- 7.4(a)** Calculate the energy per photon and the energy per mole of photons for radiation of wavelength (a) 600 nm (red), (b) 550 nm (yellow), (c) 400 nm (blue).
- 7.4(b)** Calculate the energy per photon and the energy per mole of photons for radiation of wavelength (a) 200 nm (ultraviolet), (b) 150 pm (X-ray), (c) 1.00 cm (microwave).
- 7.5(a)** Calculate the speed to which a stationary H atom would be accelerated if it absorbed each of the photons used in Exercise 7.4a.
- 7.5(b)** Calculate the speed to which a stationary  $^4\text{He}$  atom (mass  $4.0026m_{\text{u}}$ ) would be accelerated if it absorbed each of the photons used in Exercise 7.4b.
- 7.6(a)** A glow-worm of mass 5.0 g emits red light (650 nm) with a power of 0.10 W entirely in the backward direction. To what speed will it have accelerated after 10 y if released into free space and assumed to live?
- 7.6(b)** A photon-powered spacecraft of mass 10.0 kg emits radiation of wavelength 225 nm with a power of 1.50 kW entirely in the backward direction. To what speed will it have accelerated after 10.0 y if released into free space?
- 7.7(a)** A sodium lamp emits yellow light (550 nm). How many photons does it emit each second if its power is (a) 1.0 W, (b) 100 W?
- 7.7(b)** A laser used to read CDs emits red light of wavelength 700 nm. How many photons does it emit each second if its power is (a) 0.10 W, (b) 1.0 W?
- 7.8(a)** The work function for metallic caesium is 2.14 eV. Calculate the kinetic energy and the speed of the electrons ejected by light of wavelength (a) 700 nm, (b) 300 nm.
- 7.8(b)** The work function for metallic rubidium is 2.09 eV. Calculate the kinetic energy and the speed of the electrons ejected by light of wavelength (a) 650 nm, (b) 195 nm.
- 7.9(a)** Calculate the size of the quantum involved in the excitation of (a) an electronic oscillation of period 1.0 fs, (b) a molecular vibration of period 10 fs, (c) a pendulum of period 1.0 s. Express the results in joules and kilojoules per mole.
- 7.9(b)** Calculate the size of the quantum involved in the excitation of (a) an electronic oscillation of period 2.50 fs, (b) a molecular vibration of period 2.21 fs, (c) a balance wheel of period 1.0 ms. Express the results in joules and kilojoules per mole.
- 7.10(a)** Calculate the de Broglie wavelength of (a) a mass of 1.0 g travelling at  $1.0 \text{ cm s}^{-1}$ , (b) the same, travelling at  $100 \text{ km s}^{-1}$ , (c) an He atom travelling at  $1000 \text{ m s}^{-1}$  (a typical speed at room temperature).
- 7.10(b)** Calculate the de Broglie wavelength of an electron accelerated from rest through a potential difference of (a) 100 V, (b) 1.0 kV, (c) 100 kV.
- 7.11(a)** An unnormalized wavefunction for a light atom rotating around a heavy atom to which it is bonded is  $\psi(\phi) = e^{i\phi}$  with  $0 \leq \phi \leq 2\pi$ . Normalize this wavefunction.
- 7.11(b)** An unnormalized wavefunction for an electron in a carbon nanotube of length  $L$  is  $\sin(2\pi x/L)$ . Normalize this wavefunction.
- 7.12(a)** For the system described in Exercise 7.11a, what is the probability of finding the light atom in the volume element  $d\phi$  at  $\phi = \pi$ ?
- 7.12(b)** For the system described in Exercise 7.11b, what is the probability of finding the electron in the range  $dx$  at  $x = L/2$ ?
- 7.13(a)** For the system described in Exercise 7.11a, what is the probability of finding the light atom between  $\phi = \pi/2$  and  $\phi = 3\pi/2$ ?
- 7.13(b)** For the system described in Exercise 7.11b, what is the probability of finding the electron between  $x = L/4$  and  $x = L/2$ ?
- 7.14(a)** Confirm that the operator  $\hat{L}_z = (\hbar/i)d/d\phi$ , where  $\phi$  is an angle, is hermitian.
- 7.14(b)** Show that the linear combinations  $\hat{A} + i\hat{B}$  and  $\hat{A} - i\hat{B}$  are not hermitian if  $\hat{A}$  and  $\hat{B}$  are hermitian operators.

**7.15(a)** Calculate the minimum uncertainty in the speed of a ball of mass 500 g that is known to be within  $1.0\ \mu\text{m}$  of a certain point on a bat. What is the minimum uncertainty in the position of a bullet of mass 5.0 g that is known to have a speed somewhere between  $350.000\ 01\ \text{m s}^{-1}$  and  $350.000\ 00\ \text{m s}^{-1}$ ?

**7.15(b)** An electron is confined to a linear region with a length of the same order as the diameter of an atom (about  $100\ \text{pm}$ ). Calculate the minimum uncertainties in its position and speed.

**7.16(a)** In an X-ray photoelectron experiment, a photon of wavelength  $150\ \text{pm}$  ejects an electron from the inner shell of an atom and it emerges with a speed of  $21.4\ \text{Mm s}^{-1}$ . Calculate the binding energy of the electron.

**7.16(b)** In an X-ray photoelectron experiment, a photon of wavelength  $121\ \text{pm}$  ejects an electron from the inner shell of an atom and it emerges with a speed of  $56.9\ \text{Mm s}^{-1}$ . Calculate the binding energy of the electron.

**7.17(a)** Determine the commutators of the operators (a)  $d/dx$  and  $1/x$ , (b)  $d/dx$  and  $x^2$ .

**7.17(b)** Determine the commutators of the operators  $a$  and  $a^\dagger$ , where  $a = (\hat{x} + i\hat{p})/2^{1/2}$  and  $a^\dagger = (\hat{x} - i\hat{p})/2^{1/2}$ .

## Problems\*

### Numerical problems

**7.1** The Planck distribution gives the energy in the wavelength range  $d\lambda$  at the wavelength  $\lambda$ . Calculate the energy density in the range  $650\ \text{nm}$  to  $655\ \text{nm}$  inside a cavity of volume  $100\ \text{cm}^3$  when its temperature is (a)  $25^\circ\text{C}$ , (b)  $3000^\circ\text{C}$ .

**7.2** For a black body, the temperature and the wavelength of emission maximum,  $\lambda_{\text{max}}$ , are related by Wien's law,  $\lambda_{\text{max}}T = \frac{1}{5}c_2$ , where  $c_2 = hc/k$  (see Problem 7.12). Values of  $\lambda_{\text{max}}$  from a small pinhole in an electrically heated container were determined at a series of temperatures, and the results are given below. Deduce a value for Planck's constant.

| $\theta/^\circ\text{C}$          | 1000 | 1500 | 2000 | 2500 | 3000 | 3500 |
|----------------------------------|------|------|------|------|------|------|
| $\lambda_{\text{max}}/\text{nm}$ | 2181 | 1600 | 1240 | 1035 | 878  | 763  |

**7.3** The Einstein frequency is often expressed in terms of an equivalent temperature  $\theta_E$ , where  $\theta_E = h\nu/k$ . Confirm that  $\theta_E$  has the dimensions of temperature, and express the criterion for the validity of the high-temperature form of the Einstein equation in terms of it. Evaluate  $\theta_E$  for (a) diamond, for which  $\nu = 46.5\ \text{THz}$  and (b) for copper, for which  $\nu = 7.15\ \text{THz}$ . What fraction of the Dulong and Petit value of the heat capacity does each substance reach at  $25^\circ\text{C}$ ?

**7.4** The ground-state wavefunction for a particle confined to a one-dimensional box of length  $L$  is

$$\psi = \left(\frac{2}{L}\right)^{1/2} \sin\left(\frac{\pi x}{L}\right)$$

Suppose the box is  $10.0\ \text{nm}$  long. Calculate the probability that the particle is (a) between  $x = 4.95\ \text{nm}$  and  $5.05\ \text{nm}$ , (b) between  $x = 1.95\ \text{nm}$  and  $2.05\ \text{nm}$ , (c) between  $x = 9.90\ \text{nm}$  and  $10.00\ \text{nm}$ , (d) in the right half of the box, (e) in the central third of the box.

**7.5** The ground-state wavefunction of a hydrogen atom is

$$\psi = \left(\frac{1}{\pi a_0^3}\right)^{1/2} e^{-r/a_0}$$

where  $a_0 = 53\ \text{pm}$  (the Bohr radius). (a) Calculate the probability that the electron will be found somewhere within a small sphere of radius  $1.0\ \text{pm}$  centred on the nucleus. (b) Now suppose that the same sphere is located at  $r = a_0$ . What is the probability that the electron is inside it?

**7.6** Atoms in a chemical bond vibrate around the equilibrium bond length. An atom undergoing vibrational motion is described by the wavefunction  $\psi(x) = Ne^{-x^2/2a^2}$ , where  $a$  is a constant and  $-\infty < x < \infty$ . (a) Normalize this function. (b) Calculate the probability of finding the particle in the range  $-a \leq x \leq a$ . *Hint.* The integral encountered in part (b) is the error function. It is defined and tabulated in M. Abramowitz and I.A. Stegun, *Handbook of mathematical functions*, Dover (1965) and is provided in most mathematical software packages.

**7.7** Suppose that the state of the vibrating atom in Problem 7.6 is described by the wavefunction  $\psi(x) = Nxe^{-x^2/2a^2}$ . Where is the most probable location of the particle?

**7.8** The normalized wavefunctions for a particle confined to move on a circle are  $\psi(\phi) = (1/2\pi)^{1/2} e^{-im\phi}$ , where  $m = 0, \pm 1, \pm 2, \pm 3, \dots$  and  $0 \leq \phi \leq 2\pi$ . Determine  $\langle \phi \rangle$ .

**7.9** A particle is in a state described by the wavefunction  $\psi(x) = (2a/\pi)^{1/4} e^{-ax^2}$ , where  $a$  is a constant and  $-\infty \leq x \leq \infty$ . Verify that the value of the product  $\Delta p \Delta x$  is consistent with the predictions from the uncertainty principle.

**7.10** A particle is in a state described by the wavefunction  $\psi(x) = (2a)^{1/2} e^{-ax}$ , where  $a$  is a constant and  $0 \leq x \leq \infty$ . Determine the expectation value of the commutator of the position and momentum operators.

### Theoretical problems

**7.11** Demonstrate that the Planck distribution reduces to the Rayleigh–Jeans law at long wavelengths.

**7.12** Derive Wien's law, that  $\lambda_{\text{max}}T$  is a constant, where  $\lambda_{\text{max}}$  is the wavelength corresponding to maximum in the Planck distribution at the temperature  $T$ , and deduce an expression for the constant as a multiple of the second radiation constant,  $c_2 = hc/k$ .

**7.13** Use the Planck distribution to deduce the Stefan–Boltzmann law that the total energy density of black-body radiation is proportional to  $T^4$ , and find the constant of proportionality.

**7.14‡** Prior to Planck's derivation of the distribution law for black-body radiation, Wien found empirically a closely related distribution function that is very nearly but not exactly in agreement with the experimental results, namely  $\rho = (a/\lambda^5) e^{-b/\lambda kT}$ . This formula shows small deviations from Planck's at long wavelengths. (a) By fitting Wien's empirical formula to Planck's at

\* Problems denoted with the symbol ‡ were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

short wavelengths determine the constants  $a$  and  $b$ . (b) Demonstrate that Wien's formula is consistent with Wien's law (Problem 7.12) and with the Stefan–Boltzmann law (Problem 7.13).

**7.15** Normalize the following wavefunctions: (a)  $\sin(n\pi x/L)$  in the range  $0 \leq x \leq L$ , where  $n = 1, 2, 3, \dots$ , (b) a constant in the range  $-L \leq x \leq L$ , (c)  $e^{-r/a}$  in three-dimensional space, (d)  $re^{-r/2a}$  in three-dimensional space. *Hint.* The volume element in three dimensions is  $d\tau = r^2 dr \sin \theta d\theta d\phi$ , with  $0 \leq r < \infty$ ,  $0 \leq \theta \leq \pi$ ,  $0 \leq \phi \leq 2\pi$ . Use the integral in Example 7.4.

**7.16** (a) Two (unnormalized) excited state wavefunctions of the H atom are

$$(i) \psi = \left(2 - \frac{r}{a_0}\right) e^{-r/a_0} \quad (ii) \psi = r \sin \theta \cos \phi e^{-r/2a_0}$$

Normalize both functions to 1. (b) Confirm that these two functions are mutually orthogonal.

**7.17** Identify which of the following functions are eigenfunctions of the operator  $d/dx$ : (a)  $e^{ikx}$ , (b)  $\cos kx$ , (c)  $k$ , (d)  $kx$ , (e)  $e^{-ax^2}$ . Give the corresponding eigenvalue where appropriate.

**7.18** Determine which of the following functions are eigenfunctions of the inversion operator  $i$  (which has the effect of making the replacement  $x \rightarrow -x$ ): (a)  $x^3 - kx$ , (b)  $\cos kx$ , (c)  $x^2 + 3x - 1$ . State the eigenvalue of  $i$  when relevant.

**7.19** Which of the functions in Problem 7.17 are (a) also eigenfunctions of  $d^2/dx^2$  and (b) only eigenfunctions of  $d^2/dx^2$ ? Give the eigenvalues where appropriate.

**7.20** Construct quantum mechanical operators for the following observables: (a) kinetic energy in one and in three dimensions, (b) the inverse separation,  $1/x$ , (c) electric dipole moment in one dimension, (d) the mean square deviations of the position and momentum of a particle in one dimension from the mean values.

**7.21** Write the time-independent Schrödinger equations for (a) an electron moving in one dimension about a stationary proton and subjected to a Coulombic potential, (b) a free particle, (c) a particle subjected to a constant, uniform force.

**7.22** A particle is in a state described by the wavefunction  $\psi = (\cos \chi)e^{ikx} + (\sin \chi)e^{-ikx}$ , where  $\chi$  (chi) is a parameter. What is the probability that the particle will be found with a linear momentum (a)  $+k\hbar$ , (b)  $-k\hbar$ ? What form would the wavefunction have if it were 90 per cent certain that the particle had linear momentum  $+k\hbar$ ?

**7.23** Evaluate the kinetic energy of the particle with wavefunction given in Problem 7.22.

**7.24** Calculate the average linear momentum of a particle described by the following wavefunctions: (a)  $e^{ikx}$ , (b)  $\cos kx$ , (c)  $e^{-ax^2}$ , where in each one  $x$  ranges from  $-\infty$  to  $+\infty$ .

**7.25** Evaluate the expectation values of  $r$  and  $r^2$  for a hydrogen atom with wavefunctions given in Problem 7.16.

**7.26** Calculate (a) the mean potential energy and (b) the mean kinetic energy of an electron in the ground state of a hydrogenic atom.

**7.27** Use mathematical software to construct superpositions of cosine functions and determine the probability that a given momentum will be observed. If you plot the superposition (which you should), set  $x = 0$  at the centre of the screen and build the superposition there. Evaluate the root mean square location of the packet,  $\langle x^2 \rangle^{1/2}$ .

**7.28** Show that the expectation value of an operator that can be written as the square of an hermitian operator is positive.

**7.29** (a) Given that any operators used to represent observables must satisfy the commutation relation in eqn 7.41, what would be the operator for position if the choice had been made to represent linear momentum parallel to the  $x$ -axis by multiplication by the linear momentum. These different choices are all valid 'representations' of quantum mechanics. (b) With the identification of  $\hat{x}$  in this representation, what would be the operator for  $1/x$ ? *Hint.* Think of  $1/x$  as  $x^{-1}$ .

## Applications: to nanoscience, environmental science, and astrophysics

**7.30†** The temperature of the Sun's surface is approximately 5800 K. On the assumption that the human eye evolved to be most sensitive at the wavelength of light corresponding to the maximum in the Sun's radiant energy distribution, determine the colour of light to which the eye is the most sensitive.

**7.31** We saw in *Impact 17.1* that electron microscopes can obtain images with several hundredfold higher resolution than optical microscopes because of the short wavelength obtainable from a beam of electrons. For electrons moving at speeds close to  $c$ , the speed of light, the expression for the de Broglie wavelength (eqn 7.16) needs to be corrected for relativistic effects:

$$\lambda = \frac{h}{\left\{2m_e e \Delta \phi \left(1 + \frac{e \Delta \phi}{2m_e c^2}\right)\right\}^{1/2}}$$

where  $c$  is the speed of light in vacuum and  $\Delta \phi$  is the potential difference through which the electrons are accelerated. (a) Use the expression above to calculate the de Broglie wavelength of electrons accelerated through 50 kV. (b) Is the relativistic correction important?

**7.32†** Solar energy strikes the top of the Earth's atmosphere at a rate of  $343 \text{ W m}^{-2}$ . About 30 per cent of this energy is reflected directly back into space by the Earth or the atmosphere. The Earth–atmosphere system absorbs the remaining energy and re-radiates it into space as black-body radiation. What is the average black-body temperature of the Earth? What is the wavelength of the most plentiful of the Earth's black-body radiation? *Hint.* Use Wien's law, Problem 7.12.

**7.33†** A star too small and cold to shine has been found by S. Kulkarni *et al.* (*Science* 270, 1478 (1995)). The spectrum of the object shows the presence of methane, which, according to the authors, would not exist at temperatures much above 1000 K. The mass of the star, as determined from its gravitational effect on a companion star, is roughly 20 times the mass of Jupiter. The star is considered to be a brown dwarf, the coolest ever found. (a) From available thermodynamic data, test the stability of methane at temperatures above 1000 K. (b) What is  $\lambda_{\text{max}}$  for this star? (c) What is the energy density of the star relative to that of the Sun (6000 K)? (d) To determine whether the star will shine, estimate the fraction of the energy density of the star in the visible region of the spectrum.

**7.34** Suppose that the wavefunction of an electron in a carbon nanotube is a linear combination of  $\cos(nx)$  functions. Use mathematical software to construct superpositions of cosine functions and determine the probability that a given momentum will be observed. If you plot the superposition (which you should), set  $x = 0$  at the centre of the screen and build the superposition there. Evaluate the root mean square location of the packet,  $\langle x^2 \rangle^{1/2}$ .

## MATHEMATICAL BACKGROUND 3

## Complex numbers

We describe here general properties of complex numbers and functions, which are mathematical constructs frequently encountered in quantum mechanics.

## MB3.1 Definitions

Complex numbers have the general form

$$z = x + iy \quad \text{General form of a complex number} \quad (\text{MB3.1})$$

where  $i = (-1)^{1/2}$ . The real numbers  $x$  and  $y$  are, respectively, the real and imaginary parts of  $z$ , denoted  $\text{Re}(z)$  and  $\text{Im}(z)$ . When  $y = 0$ ,  $z = x$  is a real number; when  $x = 0$ ,  $z = iy$  is a pure imaginary number. Two complex numbers  $z_1 = x_1 + iy_1$  and  $z_2 = x_2 + iy_2$  are equal when  $x_1 = x_2$  and  $y_1 = y_2$ . Although the general form of the imaginary part of a complex number is written  $iy$ , a specific numerical value is typically written in the reverse order; for instance, as  $3i$ .

The **complex conjugate** of  $z$ , denoted  $z^*$ , is formed by replacing  $i$  by  $-i$

$$z^* = x - iy \quad \text{Definition of the complex conjugate} \quad (\text{MB3.2})$$

The product of  $z^*$  and  $z$  is denoted  $|z|^2$  and is called the **square modulus** of  $z$ . From eqns MB3.1 and MB3.2,

$$|z|^2 = (x + iy)(x - iy) = x^2 + y^2 \quad \text{Square modulus} \quad (\text{MB3.3})$$

since  $i^2 = -1$ . The square modulus is a real number. The **absolute value** or **modulus** is itself denoted  $|z|$  and is given by:

$$|z| = (z^*z)^{1/2} = (x^2 + y^2)^{1/2} \quad \text{Absolute value or modulus} \quad (\text{MB3.4})$$

Since  $z z^* = |z|^2$  it follows that  $z \times (z^*/|z|^2) = 1$ , from which we can identify the (multiplicative) inverse of  $z$  (which exists for all nonzero complex numbers):

$$z^{-1} = \frac{z^*}{|z|^2} \quad \text{Inverse of a complex number} \quad (\text{MB3.5})$$

## • A brief illustration

Consider the complex number  $z = 8 - 3i$ . Its square modulus is

$$|z|^2 = z^*z = (8 + 3i)(8 - 3i) = (8 + 3i)(8 - 3i) = 64 + 9 = 73$$

The modulus is therefore  $|z| = 73^{1/2}$ . From eqn MB3.5, the inverse of  $z$  is

$$z^{-1} = \frac{8 + 3i}{73} = \frac{8}{73} + \frac{3}{73}i$$

## MB3.2 Polar representation

The complex number  $z = x + iy$  can be represented as a point in a plane, the **complex plane**, with  $\text{Re}(z)$  along the  $x$ -axis and  $\text{Im}(z)$  along the  $y$ -axis (Fig. MB3.1). If, as shown in the figure,  $r$  and  $\phi$  denote the polar coordinates of the point, then since  $x = r \cos \phi$  and  $y = r \sin \phi$ , we can express the complex number in **polar form** as

$$z = r (\cos \phi + i \sin \phi) \quad \text{Polar form of a complex number} \quad (\text{MB3.6})$$

The angle  $\phi$ , called the **argument** of  $z$ , is the angle that  $z$  makes with the  $x$ -axis. Because  $y/x = \tan \phi$ , it follows that the polar form can be constructed from

$$r = (x^2 + y^2)^{1/2} = |z| \quad \phi = \arctan \frac{y}{x} \quad (\text{MB3.7a})$$

To convert from polar to Cartesian form, use

$$x = r \cos \phi \text{ and } y = r \sin \phi \text{ to form } z = x + iy \quad (\text{MB3.7b})$$

One of the most useful relations involving complex numbers is **Euler's formula**:

$$e^{i\phi} = \cos \phi + i \sin \phi \quad \text{Euler's formula} \quad (\text{MB3.8a})$$

The simplest proof of this relation is to expand the exponential function as a power series and to collect real and imaginary terms. It follows that

$$\cos \phi = \frac{1}{2}(e^{i\phi} + e^{-i\phi}) \quad \sin \phi = -\frac{1}{2}i(e^{i\phi} - e^{-i\phi}) \quad (\text{MB3.8b})$$

The polar form in eqn MB3.6 then becomes

$$z = re^{i\phi} \quad (\text{MB3.7})$$

### • A brief illustration

Consider the complex number  $z = 8 - 3i$ . From the previous *brief illustration*,  $r = |z| = 73^{1/2}$ . The argument of  $z$  is

$$\phi = \arctan \frac{-3}{8} = -0.359 \text{ rad} \quad \text{or} \quad -20.6^\circ$$

The polar form of the number is therefore

$$z = 73^{1/2} e^{-0.359i}$$

## MB3.3 Operations

The following rules apply for arithmetic operations for the complex numbers  $z_1 = x_1 + iy_1$  and  $z_2 = x_2 + iy_2$ .

$$1. \text{ Addition: } z_1 + z_2 = (x_1 + x_2) + i(y_1 + y_2) \quad (\text{MB3.10a})$$

$$2. \text{ Subtraction: } z_1 - z_2 = (x_1 - x_2) + i(y_1 - y_2) \quad (\text{MB3.10b})$$

$$3. \text{ Multiplication: } z_1 z_2 = (x_1 + iy_1)(x_2 + iy_2) = (x_1 x_2 - y_1 y_2) + i(x_1 y_2 + y_1 x_2) \quad (\text{MB3.10c})$$

4. Division: We interpret  $z_1/z_2$  as  $z_1 z_2^{-1}$  and use eqn MB3.5 for the inverse:

$$\frac{z_1}{z_2} = z_1 z_2^{-1} = \frac{z_1 z_2^*}{|z_2|^2} \quad (\text{MB3.10d})$$

### • A brief illustration

Consider the complex numbers  $z_1 = 6 + 2i$  and  $z_2 = -4 - 3i$ . Then

$$z_1 + z_2 = (6 - 4) + (2 - 3)i = 2 - i$$

$$z_1 - z_2 = 10 + 5i$$

$$z_1 z_2 = \{6(-4) - 2(-3)\} + \{6(-3) + 2(-4)\}i = -18 - 26i$$

$$\frac{z_1}{z_2} = (6 + 2i) \left( \frac{-4 + 3i}{25} \right) = -\frac{6}{5} + \frac{2}{5}i$$

The polar form of a complex number is commonly used to perform arithmetical operations. For instance, the product of two complex numbers in polar form is

$$z_1 z_2 = (r_1 e^{i\phi_1})(r_2 e^{i\phi_2}) = r_1 r_2 e^{i(\phi_1 + \phi_2)} \quad (\text{MB3.11})$$

This multiplication is depicted in the complex plane as shown in Fig. MB3.2. The  $n$ th power and the  $n$ th root of a complex number are

$$z^n = (re^{i\phi})^n = r^n e^{in\phi} \quad z^{1/n} = (re^{i\phi})^{1/n} = r^{1/n} e^{i\phi/n} \quad (\text{MB3.12})$$

The depictions in the complex plane are shown in Fig. MB3.3.

Fig. MB3.2 The multiplication of two complex numbers depicted in the complex plane.

Fig. MB3.3 (a) The  $n$ th powers and (b) the  $n$ th roots ( $n = 1, 2, 3, 4$ ) of a complex number depicted in the complex plane.

### • A brief illustration

To determine the 5th root of  $z = 8 - 3i$ , we note that from the second *brief illustration* its polar form is

$$z = 73^{1/2} e^{-0.359i} = 8.544 e^{-0.359i}$$

The 5th root is therefore

$$z^{1/5} = (8.544 e^{-0.359i})^{1/5} = 8.544^{1/5} e^{-0.359i/5} = 1.536 e^{-0.0718i}$$

It follows that  $x = 1.536 \cos(-0.0718) = 1.532$  and  $y = 1.536 \sin(-0.0718) = -0.110$  (note that we work in radians), so

$$(8 - 3i)^{1/5} = 1.532 - 0.110i$$

Problems

To calculate the properties of systems according to quantum mechanics we need to solve the appropriate Schrödinger equation. This chapter presents the essentials of the solutions for three basic types of motion: translation, vibration, and rotation. We shall see that only certain wavefunctions and their corresponding energies are acceptable. Hence, quantization emerges as a natural consequence of the equation and the conditions imposed on it. The solutions bring to light a number of nonclassical features of particles, especially their ability to tunnel into and through regions where classical physics would forbid them to be found. We also encounter a property of the electron, its spin, that has no classical counterpart.

The three basic modes of motion—translation (motion through space), vibration, and rotation—all play an important role in chemistry because they are ways in which molecules store energy. Gas-phase molecules, for instance, undergo translational motion and their kinetic energy is a contribution to the total internal energy of a sample. Molecules can also store energy as rotational kinetic energy and transitions between their rotational energy states can be observed spectroscopically. Energy is also stored as molecular vibration, and transitions between vibrational states are responsible for the appearance of infrared and Raman spectra.

## Translational motion

Section 7.5 introduced the quantum mechanical description of free motion in one dimension. We saw there that the Schrödinger equation is

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} = E\psi \quad (8.1a)$$

or more succinctly

$$\hat{H}\psi = E\psi \quad \hat{H} = -\frac{\hbar^2}{2m} \frac{d^2}{dx^2} \quad (8.1b)$$

The general solutions of eqn 8.1 are (see *Mathematical background 4* following this chapter):

$$\psi_k = Ae^{ikx} + Be^{-ikx} \quad E_k = \frac{k^2\hbar^2}{2m} \quad (8.2)$$

Wavefunctions and  
energies of a free particle

Note that we are now labelling both the wavefunctions and the energies (that is, the eigenfunctions and eigenvalues of  $\hat{H}$ , with the index  $k$ ). We can verify that these functions

are solutions by substituting  $\psi_k$  into the left-hand side of eqn 8.1a and showing that the result is equal to  $E_k\psi_k$ . In this case, all values of  $k$ , and therefore all values of the energy, are permitted. It follows that the translational energy of a free particle is not quantized.

We saw in Section 7.5c that a wavefunction of the form  $e^{ikx}$  describes a particle with linear momentum  $p_x = +k\hbar$ , corresponding to motion towards positive  $x$  (to the right), and that a wavefunction of the form  $e^{-ikx}$  describes a particle with the same magnitude of linear momentum but travelling towards negative  $x$  (to the left). That is,  $e^{ikx}$  is an eigenfunction of the operator  $\hat{p}_x$  with eigenvalue  $+k\hbar$ , and  $e^{-ikx}$  is an eigenfunction with eigenvalue  $-k\hbar$ . In either state,  $|\psi|^2$  is independent of  $x$ , which implies that the position of the particle is completely unpredictable. This conclusion is consistent with the uncertainty principle, because, if the momentum is certain, then the position cannot be specified (the operators for  $x$  and  $p_x$  do not commute, Section 7.6).

## 8.1 A particle in a box

**Key points** (a) The energies of a particle constrained to move in a finite region of space are quantized. (b) The energies and wavefunctions for a particle moving in a box are labelled by quantum numbers. The wavefunctions of a particle constrained to move in a one-dimensional box are mutually orthogonal sine functions with the same amplitude but different wavelengths. The zero point energy is the lowest, irremovable energy of a particle in a box. The correspondence principle states that classical mechanics emerges from quantum mechanics as high quantum numbers are reached.

In this section, we consider a **particle in a box**, in which a particle of mass  $m$  is confined between two walls at  $x = 0$  and  $x = L$ : the potential energy is zero inside the box but rises abruptly to infinity at the walls (Fig. 8.1). This model is an idealization of the potential energy of a gas-phase molecule that is free to move in a one-dimensional container or a bead confined to a wire. However, it is also the basis of the treatment of the electronic structure of metals (Chapter 19) and of a primitive treatment of conjugated molecules. The particle in a box is also used in statistical thermodynamics in assessing the contribution of the translational motion of molecules to their thermodynamic properties (Chapter 16).

### (a) The acceptable solutions

The Schrödinger equation for the region between the walls (where  $V = 0$ ) is the same as for a free particle (eqn 8.1), so the general solutions given in eqn 8.2 are also the same. However, it will turn out to be an advantage to use the relation  $e^{\pm ix} = \cos x \pm i \sin x$  to write

$$\begin{aligned}\psi_k &= Ae^{ikx} + Be^{-ikx} = A(\cos kx + i \sin kx) + B(\cos kx - i \sin kx) \\ &= (A + B)\cos kx + (A - B)i \sin kx\end{aligned}$$

If we absorb all numerical factors into two new coefficients  $C$  and  $D$ , the general solutions take the form

$$\psi_k(x) = C \sin kx + D \cos kx \quad E_k = \frac{k^2 \hbar^2}{2m} \quad (8.3)$$

For a free particle, any value of  $E_k$  corresponds to an acceptable solution. However, when the particle is confined within a region, the acceptable wavefunctions must satisfy certain **boundary conditions**, or constraints on the function at certain locations. As we shall see when we discuss penetration into barriers, a wavefunction decays

**Fig. 8.1** A particle in a one-dimensional region with impenetrable walls. Its potential energy is zero between  $x = 0$  and  $x = L$ , and rises abruptly to infinity as soon as it touches the walls.

exponentially with distance inside a barrier, such as a wall, and the decay is infinitely fast when the potential energy is infinite. This behaviour is consistent with the fact that it is physically impossible for the particle to be found with an infinite potential energy. We conclude that the wavefunction must be zero where  $V$  is infinite, at  $x < 0$  and  $x > L$ . The continuity of the wavefunction then requires it to vanish just inside the well at  $x = 0$  and  $x = L$ . That is, the boundary conditions are  $\psi_k(0) = 0$  and  $\psi_k(L) = 0$ . These boundary conditions imply energy quantization, as we show in the following *Justification*.

**Justification 8.1** *The energy levels and wavefunctions of a particle in a one-dimensional box*

Consider the wall at  $x = 0$ . According to eqn 8.3,  $\psi(0) = D$  (because  $\sin 0 = 0$  and  $\cos 0 = 1$ ). However, because  $\psi(0) = 0$  we must have  $D = 0$ . It follows that the wavefunction must be of the form  $\psi_k(x) = C \sin kx$ . The value of  $\psi$  at the other wall (at  $x = L$ ) is  $\psi_k(L) = C \sin kL$ , which must also be zero. Taking  $C = 0$  would give  $\psi_k(x) = 0$  for all  $x$ , which would conflict with the Born interpretation (the particle must be somewhere). Therefore,  $kL$  must be chosen so that  $\sin kL = 0$ , which is satisfied by

$$kL = n\pi \quad n = 1, 2, \dots$$

The value  $n = 0$  is ruled out, because it implies  $k = 0$  and  $\psi_k(x) = 0$  everywhere (because  $\sin 0 = 0$ ), which is unacceptable. Negative values of  $n$  merely change the sign of  $\sin kL$  (because  $\sin(-x) = -\sin x$ ) and do not give rise to a new wavefunction. The wavefunctions are therefore

$$\psi_n(x) = C \sin(n\pi x/L) \quad n = 1, 2, \dots$$

(At this point we have started to label the solutions with the index  $n$  instead of  $k$ .) Because  $E_k = k^2 \hbar^2 / 2m$ , and  $k = n\pi/L$ , it follows that the energy of the particle is limited to the values  $n^2 \hbar^2 / 8mL^2$  with  $n = 1, 2, \dots$

We conclude that the energy of the particle in a one-dimensional box is quantized and that this quantization arises from the boundary conditions that  $\psi$  must satisfy if it is to be an acceptable wavefunction. This is a general conclusion: *the need to satisfy boundary conditions implies that only certain wavefunctions are acceptable, and hence restricts observables to discrete values*. So far, only energy has been quantized; shortly we shall see that other physical observables may also be quantized.

**(b) The properties of the solutions**

We complete the derivation of the wavefunctions by finding the normalization constant (here written  $C$  and regarded as real; that is, does not contain  $i = \sqrt{-1}$ ). To do so, we look for the value of  $C$  that ensures that the integral of  $\psi^2$  over all the space available to the particle (that is, from  $x = 0$  to  $x = L$ ) is equal to 1

$$\int_0^L \psi^2 dx = C^2 \int_0^L \sin^2 \frac{n\pi x}{L} dx = C^2 \times \frac{L}{2} = 1, \quad \text{so } C = \left(\frac{2}{L}\right)^{1/2}$$

for all  $n$ . Therefore, the complete solution to the problem is

$$E_n = \frac{n^2 \hbar^2}{8mL^2} \quad n = 1, 2, \dots \quad \boxed{\text{Energies of a particle in a box}} \quad (8.4a)$$

$$\psi_n(x) = \left(\frac{2}{L}\right)^{1/2} \sin\left(\frac{n\pi x}{L}\right) \quad \text{for } 0 \leq x \leq L \quad \boxed{\text{Wavefunctions of a particle in a box}} \quad (8.4b)$$

**Self-test 8.1** Provide the intermediate steps for the determination of the normalization constant  $C$ . *Hint.* Use the standard integral  $\int \sin^2 ax \, dx = \frac{1}{2}x - (1/4a)\sin 2ax + \text{constant}$  and the fact that  $\sin 2m\pi = 0$ , with  $m = 0, 1, 2, \dots$

The energies and wavefunctions are labelled with the ‘quantum number’  $n$ . A **quantum number** is an integer (in some cases, as we shall see, a half-integer; that is, half an odd integer) that labels the state of the system. For a particle in a box there is an infinite number of acceptable solutions, and the quantum number  $n$  specifies the one of interest (Fig. 8.2). As well as acting as a label, a quantum number can often be used to calculate the energy corresponding to the state and to write down the wavefunction explicitly (in the present example, by using eqn 8.4).

Figure 8.3 shows some of the wavefunctions of a particle in a box: they are all sine functions with the same maximum amplitude but different wavelengths. Shortening the wavelength results in a sharper average curvature of the wavefunction and therefore an increase in the kinetic energy of the particle. Note that the number of nodes (points where the wavefunction passes through zero) also increases as  $n$  increases, and that the wavefunction  $\psi_n$  has  $n - 1$  nodes. Increasing the number of nodes between walls of a given separation increases the average curvature of the wavefunction and hence the kinetic energy of the particle.

The linear momentum of a particle in a box is not well-defined because the wavefunction  $\sin kx$  (like  $\cos kx$ ) is not an eigenfunction of the linear momentum operator. However, each wavefunction is a superposition of momentum eigenfunctions:

$$\psi_n = \left(\frac{2}{L}\right)^{1/2} \sin \frac{n\pi x}{L} = \frac{1}{2i} \left(\frac{2}{L}\right)^{1/2} (e^{ikx} - e^{-ikx}) \quad k = \frac{n\pi}{L} \quad (8.5)$$

It follows that measurement of the linear momentum will give the value  $+\hbar k$  for half the measurements of momentum and  $-\hbar k$  for the other half. This detection of opposite directions of travel with equal probability is the quantum mechanical version of the classical picture that a particle in a box rattles from wall to wall, and in any given period spends half its time travelling to the left and half travelling to the right.

**Self-test 8.2** What is (a) the average value of the linear momentum of a particle in a box with quantum number  $n$ , (b) the average value of  $p^2$ ? *Hint.* Compute expectation values.   
 [(a)  $\langle p \rangle = 0$ , (b)  $\langle p^2 \rangle = n^2 \hbar^2 / 4L^2$ ]

Because  $n$  cannot be zero, the lowest energy that the particle may possess is not zero (as would be allowed by classical mechanics, corresponding to a stationary particle) but

$$E_1 = \frac{h^2}{8mL^2} \quad \text{Zero-point energy of a particle in a box} \quad (8.6)$$

This lowest, irremovable energy is called the **zero-point energy**. The physical origin of the zero-point energy can be explained in two ways. First, the uncertainty principle requires a particle to possess kinetic energy if it is confined to a finite region: the location of the particle is not completely indefinite, so its momentum cannot be precisely zero. Hence it has nonzero kinetic energy. Second, if the wavefunction is to be zero at the walls, but smooth, continuous, and not zero everywhere, then it must be curved, and curvature in a wavefunction implies the possession of kinetic energy.

**Fig. 8.2** The allowed energy levels for a particle in a box. Note that the energy levels increase as  $n^2$ , and that their separation increases as the quantum number increases.

#### A brief comment

It is often useful to write  $\cos x = (e^{ix} + e^{-ix})/2$  and  $\sin x = (e^{ix} - e^{-ix})/2i$ .

**Fig. 8.3** The first five normalized wavefunctions of a particle in a box. Each wavefunction is a standing wave, and successive functions possess one more half wave and a correspondingly shorter wavelength.

**InterActivity** Plot the probability density for a particle in a box with  $n = 1, 2, \dots, 5$  and  $n = 50$ . How do your plots illustrate the correspondence principle?

**Fig. 8.4** (a) The first two wavefunctions, (b) the corresponding probability distributions, and (c) a representation of the probability distribution in terms of the darkness of shading.

The separation between adjacent energy levels with quantum numbers  $n$  and  $n + 1$  is

$$E_{n+1} - E_n = \frac{(n+1)^2 h^2}{8mL^2} - \frac{n^2 h^2}{8mL^2} = (2n+1) \frac{h^2}{8mL^2} \quad (8.7)$$

This separation decreases as the length of the container increases, and is very small when the container has macroscopic dimensions. The separation of adjacent levels becomes zero when the walls are infinitely far apart. Atoms and molecules free to move in normal laboratory-sized vessels may therefore be treated as though their translational energy is not quantized. The translational energy of completely free particles (those not confined by walls) is not quantized.

**Self-test 8.3** Estimate a typical nuclear excitation energy in electronvolts (eV) by calculating the first excitation energy of a proton confined to a square well with a length equal to the diameter of a nucleus (approximately 1 fm). [0.6 GeV]

The probability density for a particle in a box is

$$\psi^2(x) = \frac{2}{L} \sin^2 \frac{n\pi x}{L} \quad (8.8)$$

and varies with position. The non-uniformity is pronounced when  $n$  is small (Fig. 8.4), but—provided we take averages over a small region— $\psi^2(x)$  becomes more uniform as  $n$  increases. The distribution at high quantum numbers reflects the classical result that a particle bouncing between the walls spends, on the average, equal times at all points. That the quantum result corresponds to the classical prediction at high quantum numbers is an illustration of the **correspondence principle**, which states that classical mechanics emerges from quantum mechanics as high quantum numbers are reached.

**Example 8.1** Using the particle in a box solutions

What is the probability,  $P$ , of locating a particle between  $x = 0$  (the left-hand end of a box) and  $x = 0.2$  nm in its lowest energy state in a box of length 1.0 nm?

**Method** The value of  $\psi^2 dx$  is the probability of finding the particle in the small region  $dx$  located at  $x$ ; therefore, the total probability of finding the particle in the specified region is the integral of  $\psi^2 dx$  over that region. The wavefunction of the particle is given in eqn 8.4b with  $n = 1$ .

**Answer** The probability of finding the particle in a region between  $x = 0$  and  $x = l$  is

$$P = \int_0^l \psi_n^2 dx = \frac{2}{L} \int_0^l \sin^2 \frac{n\pi x}{L} dx = \frac{l}{L} - \frac{1}{2n\pi} \sin \frac{2n\pi l}{L}$$

We then set  $n = 1$  and  $l = 0.2$  nm, which gives  $P = 0.05$ . The result corresponds to a chance of 1 in 20 of finding the particle in the region. As  $n$  becomes infinite, the sine term, which is multiplied by  $1/n$ , makes no contribution to  $P$  and the classical result,  $P = l/L$ , is obtained.

**Self-test 8.4** Calculate the probability that a particle in the state with  $n = 1$  will be found between  $x = 0.25L$  and  $x = 0.75L$  in a box of length  $L$  (with  $x = 0$  at the left-hand end of the box). [0.82]

## 8.2 Motion in two and more dimensions

**Key points** (a) The separation of variables technique can be used to solve the Schrödinger equation in multiple dimensions. The energies of a particle constrained to move in two or three dimensions are quantized. (b) Degeneracy occurs when different wavefunctions correspond to the same energy. Many of the states of a particle in a square or cubic box are degenerate.

Next, we consider a two-dimensional version of the particle in a box. Now the particle is confined to a rectangular surface of length  $L_1$  in the  $x$ -direction and  $L_2$  in the  $y$ -direction; the potential energy is zero everywhere except at the walls, where it is infinite (Fig. 8.5). The wavefunction is now a function of both  $x$  and  $y$  and the Schrödinger equation is

$$-\frac{\hbar^2}{2m} \left( \frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} \right) = E\psi \quad (8.9)$$

We need to see how to solve this partial differential equation, a differential equation in more than one variable.

### (a) Separation of variables

Some partial differential equations can be simplified by the **separation of variables technique** (*Mathematical background 4* following this chapter), which divides the equation into two or more ordinary differential equations, one for each variable. An important application of this procedure, as we shall see, is the separation of the Schrödinger equation for the hydrogen atom into equations that describe the radial and angular variation of the wavefunction. The technique is particularly simple for a two-dimensional square well, as can be seen by testing whether a solution of eqn 8.9 can be found by writing the wavefunction as a product of functions, one depending only on  $x$  and the other only on  $y$ :

$$\psi(x, y) = X(x)Y(y)$$

Separation  
of variables

With this substitution, we show in the following *Justification* that eqn 8.9 separates into two ordinary differential equations, one for each coordinate:

$$-\frac{\hbar^2}{2m} \frac{d^2 X}{dx^2} = E_X X \quad -\frac{\hbar^2}{2m} \frac{d^2 Y}{dy^2} = E_Y Y \quad E = E_X + E_Y \quad (8.10)$$

The quantity  $E_X$  is the energy associated with the motion of the particle parallel to the  $x$ -axis, and likewise for  $E_Y$  and motion parallel to the  $y$ -axis. Similarly,  $X(x)$  is the wavefunction associated with the particle's freedom to move parallel to the  $x$ -axis and likewise for  $Y(y)$  and motion parallel to the  $y$ -axis.

**Justification 8.2** The separation of variables technique applied to the particle in a two-dimensional box

We follow the procedure in *Mathematical background 4* and apply it to eqn 8.9. The first step in the justification of the separability of the wavefunction into the product of two functions  $X$  and  $Y$  is to note that, because  $X$  is independent of  $y$  and  $Y$  is independent of  $x$ , we can write

$$\frac{\partial^2 \psi}{\partial x^2} = \frac{\partial^2 XY}{\partial x^2} = Y \frac{d^2 X}{dx^2} \quad \frac{\partial^2 \psi}{\partial y^2} = \frac{\partial^2 XY}{\partial y^2} = X \frac{d^2 Y}{dy^2}$$

**Fig. 8.5** A two-dimensional square well. The particle is confined to the plane bounded by impenetrable walls. As soon as it touches the walls, its potential energy rises to infinity.

Then eqn 8.9 becomes

$$-\frac{\hbar^2}{2m} \left( Y \frac{d^2 X}{dx^2} + X \frac{d^2 Y}{dy^2} \right) = EXY$$

When both sides are divided by  $XY$ , we can rearrange the resulting equation into

$$\frac{1}{X} \frac{d^2 X}{dx^2} + \frac{1}{Y} \frac{d^2 Y}{dy^2} = -\frac{2mE}{\hbar^2}$$

The first term on the left is independent of  $y$ , so if  $y$  is varied only the second term can change. However, the sum of these two terms is a constant given by the right-hand side of the equation; therefore, even the second term cannot change when  $y$  is changed. In other words, the second term is a constant. By a similar argument, the first term is a constant when  $x$  changes. If we write these two constants as  $-2mE_X/\hbar^2$  and  $-2mE_Y/\hbar^2$  (because that captures the form of the original equation), we can write

$$\frac{1}{X} \frac{d^2 X}{dx^2} = -\frac{2mE_X}{\hbar^2} \quad \frac{1}{Y} \frac{d^2 Y}{dy^2} = -\frac{2mE_Y}{\hbar^2}$$

Because the sum of the terms on the left of each equation is equal to  $-2mE/\hbar^2$  it follows that  $E_X + E_Y = E$ . These two equations rearrange into the two ordinary (that is, single variable) differential equations in eqn 8.10.

Each of the two ordinary differential equations in eqn 8.10 is the same as the one-dimensional square-well Schrödinger equation. We can therefore adapt the results in eqn 8.4 without further calculation:

$$X_{n_1}(x) = \left( \frac{2}{L_1} \right)^{1/2} \sin \frac{n_1 \pi x}{L_1} \quad Y_{n_2}(y) = \left( \frac{2}{L_2} \right)^{1/2} \sin \frac{n_2 \pi y}{L_2}$$

Then, because  $\psi = XY$  and  $E = E_X + E_Y$ , we obtain

$$\psi_{n_1, n_2}(x, y) = \frac{2}{(L_1 L_2)^{1/2}} \sin \frac{n_1 \pi x}{L_1} \sin \frac{n_2 \pi y}{L_2} \quad (8.11a)$$

Wavefunctions and energies of a particle in a two-dimensional box

$$E_{n_1, n_2} = \left( \frac{n_1^2}{L_1^2} + \frac{n_2^2}{L_2^2} \right) \frac{h^2}{8m} \quad 0 \leq x \leq L_1, 0 \leq y \leq L_2$$

with the quantum numbers taking the values  $n_1 = 1, 2, \dots$  and  $n_2 = 1, 2, \dots$  independently. Some of these functions are plotted in Fig. 8.6. They are the two-dimensional versions of the wavefunctions shown in Fig. 8.3. Note that two quantum numbers are needed in this two-dimensional problem.

**Fig. 8.6** The wavefunctions for a particle confined to a rectangular surface depicted as contours of equal amplitude. (a)  $n_1 = 1$ ,  $n_2 = 1$ , the state of lowest energy, (b)  $n_1 = 1$ ,  $n_2 = 2$ , (c)  $n_1 = 2$ ,  $n_2 = 1$ , and (d)  $n_1 = 2$ ,  $n_2 = 2$ .

 **interActivity** Use mathematical software to generate three-dimensional plots of the functions in this illustration. Deduce a rule for the number of nodal lines in a wavefunction as a function of the values of  $n_x$  and  $n_y$ .

We treat a particle in a three-dimensional box in the same way. The wavefunctions have another factor (for the  $z$ -dependence), and the energy has an additional term in  $n_3^2/L_3^2$ . Solution of the Schrödinger equation by the separation of variables technique then gives

$$\psi_{n_1, n_2, n_3}(x, y, z) = \left( \frac{8}{L_1 L_2 L_3} \right)^{1/2} \sin \frac{n_1 \pi x}{L_1} \sin \frac{n_2 \pi y}{L_2} \sin \frac{n_3 \pi z}{L_3}$$

$$E_{n_1, n_2, n_3} = \left( \frac{n_1^2}{L_1^2} + \frac{n_2^2}{L_2^2} + \frac{n_3^2}{L_3^2} \right) \frac{h^2}{8m} \quad 0 \leq x \leq L_1, 0 \leq y \leq L_2, 0 \leq z \leq L_3 \quad (8.11b)$$

Wavefunctions and energies of a particle in a three-dimensional box

with the quantum numbers taking the values  $n_1 = 1, 2, \dots$ ,  $n_2 = 1, 2, \dots$ , and  $n_3 = 1, 2, \dots$ , independently.

### (b) Degeneracy

An interesting feature of the solutions for a particle in a two-dimensional box is obtained when the plane surface is square, with  $L_1 = L_2 = L$ . Then eqn 8.11a becomes

$$\psi_{n_1, n_2}(x, y) = \frac{2}{L} \sin \frac{n_1 \pi x}{L} \sin \frac{n_2 \pi y}{L} \quad E_{n_1, n_2} = (n_1^2 + n_2^2) \frac{h^2}{8mL^2} \quad (8.12)$$

Consider the cases  $n_1 = 1, n_2 = 2$  and  $n_1 = 2, n_2 = 1$ :

$$\psi_{1,2} = \frac{2}{L} \sin \frac{\pi x}{L} \sin \frac{2\pi y}{L} \quad E_{1,2} = \frac{5h^2}{8mL^2}$$

$$\psi_{2,1} = \frac{2}{L} \sin \frac{2\pi x}{L} \sin \frac{\pi y}{L} \quad E_{2,1} = \frac{5h^2}{8mL^2}$$

We see that, although the wavefunctions are different, they are **degenerate**, meaning that they correspond to the same energy. In this case, in which there are two degenerate wavefunctions, we say that the energy level  $5(h^2/8mL^2)$  is ‘doubly degenerate’.

The occurrence of degeneracy is related to the symmetry of the system. Figure 8.7 shows contour diagrams of the two degenerate functions  $\psi_{1,2}$  and  $\psi_{2,1}$ . As the box is square, we can convert one wavefunction into the other simply by rotating the plane by  $90^\circ$ . Interconversion by rotation through  $90^\circ$  is not possible when the plane is not square, and  $\psi_{1,2}$  and  $\psi_{2,1}$  are then not degenerate. Similar arguments account for the degeneracy of states in a cubic box. We shall see many other examples of degeneracy in the pages that follow (for instance, in the hydrogen atom), and all of them can be traced to the symmetry properties of the system (see Section 11.6).

**Fig. 8.7** The wavefunctions for a particle confined to a square surface. Note that one wavefunction can be converted into the other by a rotation of the box by  $90^\circ$ . The two functions correspond to the same energy. Degeneracy and symmetry are closely related.

## IMPACT ON NANOSCIENCE

### 18.1 Quantum dots

Nanoscience is the study of atomic and molecular assemblies with dimensions ranging from 1 nm to about 100 nm and nanotechnology is concerned with the incorporation of such assemblies into devices. The future economic impact of nanotechnology could be very significant. For example, increased demand for very small digital electronic devices has driven the design of ever smaller and more powerful microprocessors. However, there is an upper limit on the density of electronic circuits that can be incorporated into silicon-based chips with current fabrication technologies. As the ability to process data increases with the number of components in a chip, it follows that soon chips and the devices that use them will have to become bigger if processing

power is to increase indefinitely. One way to circumvent this problem is to fabricate devices from nanometre-sized components.

We shall encounter several concepts of nanoscience throughout the text. Here we explore the possibility of using quantum mechanical effects that render the properties of an assembly dependent on its size.

Ordinary bulk metals conduct electricity because, in the presence of an electric field, electrons become mobile when they are easily excited into closely lying empty energy levels. By ignoring all the electrostatic interactions, we can treat the electrons as occupying the energy levels characteristic of independent particles in a three-dimensional box. Because the box has macroscopic dimensions, we know from eqn 8.7 that the separation between neighbouring levels is so small that they form a virtual continuum. Consequently, we are justified in neglecting energy quantization on the properties of the material. However, in a nanocrystal, a small cluster of atoms with dimensions in the nanometre scale, eqn 8.4a predicts that quantization of energy is significant and affects the properties of the sample. This quantum mechanical effect can be observed in ‘boxes’ of any shape. For example, you are invited to show in Problem 8.38 that the energy levels corresponding to spherically symmetrical wavefunctions of an electron in a spherical cavity of radius  $R$  are given by<sup>1</sup>

$$E_n = \frac{n^2 h^2}{8m_e R^2}$$

The quantization of energy in nanocrystals has important technological implications when the material is a semiconductor, in which electrical conductivity increases with increasing temperature or upon excitation by light. That is, transfer of energy to a semiconductor increases the mobility of electrons in the material (see Chapter 19 for a more detailed discussion). Three-dimensional nanocrystals of semiconducting materials containing 10 to  $10^5$  atoms are called **quantum dots**. They can be made in solution or by depositing atoms on a surface, with the size of the nanocrystal being determined by the details of the synthesis.

First, we see that the energy required to induce electronic transitions from lower to higher energy levels, thereby increasing the mobility of electrons and inducing electrical conductivity, depends on the size of the quantum dot. The electrical properties of large, macroscopic samples of semiconductors cannot be tuned in this way. Second, in many quantum dots, such as the nearly spherical nanocrystals of cadmium selenide (CdSe), mobile electrons can be generated by absorption of visible light and, as the radius of the quantum dot decreases, the excitation wavelength decreases. That is, as the size of the quantum dot varies, so does the colour of the material. This phenomenon is indeed observed in suspensions of CdSe quantum dots of different sizes.

Because quantum dots are semiconductors with tunable electrical properties, there are many uses for these materials in the manufacture of transistors. The special optical properties of quantum dots can also be exploited. Just as the generation of an electron–hole pair requires absorption of light of a specific wavelength, so does recombination of the pair result in the emission of light of a specific wavelength. This property forms the basis for the use of quantum dots in the visualization of biological cells at work. For example, a CdSe quantum dot can be modified by covalent attachment of an organic spacer to its surface. When the other end of the spacer reacts specifically with a cellular component, such as a protein, nucleic acid, or membrane, the cell becomes labelled with a light-emitting quantum dot. The spatial distribution of emission intensity and, consequently, of the labelled molecule can then be measured

<sup>1</sup> There are solutions that are not spherically symmetrical and to which this expression does not apply.

with a microscope. Though this technique has been used extensively with organic molecules as labels, quantum dots are more stable and are stronger light emitters.

### 8.3 Tunnelling

**Key points** Tunnelling is the penetration into or through classically forbidden regions. The transmission probability decreases exponentially with the thickness of the barrier and with the square-root of the mass of the particle.

If the potential energy of a particle does not rise to infinity when it is in the walls of the container, and  $E < V$ , the wavefunction does not decay abruptly to zero. If the walls are thin (so that the potential energy falls to zero again after a finite distance), then the wavefunction oscillates inside the box, varies smoothly inside the region representing the wall, and oscillates again on the other side of the wall outside the box (Fig. 8.8). Hence the particle might be found on the outside of a container even though according to classical mechanics it has insufficient energy to escape. Such leakage by penetration through a classically forbidden region is called **tunnelling**.

The Schrödinger equation can be used to calculate the probability of tunnelling of a particle of mass  $m$  incident on a finite barrier from the left. On the left of the barrier (for  $x < 0$ ) the wavefunctions are those of a particle with  $V = 0$ , so from eqn 8.2 we can write

$$\psi = Ae^{ikx} + Be^{-ikx} \quad k\hbar = (2mE_k)^{1/2} \quad (8.13)$$

The Schrödinger equation for the region representing the barrier (for  $0 \leq x \leq L$ ), where the potential energy has the constant value  $V$ , is

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + V\psi = E\psi \quad (8.14)$$

We shall consider particles that have  $E < V$  (so, according to classical physics, the particle has insufficient energy to pass over the barrier), and therefore  $V - E$  is positive. The general solutions of this equation are

$$\psi = Ce^{\kappa x} + De^{-\kappa x} \quad \kappa\hbar = \{2m(V - E)\}^{1/2} \quad (8.15)$$

as we can readily verify by differentiating  $\psi$  twice with respect to  $x$ . The important feature to note is that the two exponentials are now real functions, as distinct from the complex, oscillating functions for the region where  $V = 0$  (oscillating functions would be obtained if  $E > V$ ). To the right of the barrier ( $x > L$ ), where  $V = 0$  again, the wavefunctions are

$$\psi = A'e^{ikx} + B'e^{-ikx} \quad k\hbar = (2mE)^{1/2} \quad (8.16)$$

The complete wavefunction for a particle incident from the left consists of an incident wave, a wave reflected from the barrier, the exponentially changing amplitudes inside the barrier, and an oscillating wave representing the propagation of the particle to the right after tunnelling through the barrier successfully (Fig. 8.9). The acceptable wavefunctions must obey the conditions set out in Section 7.4b. In particular, they must be continuous at the edges of the barrier (at  $x = 0$  and  $x = L$ , remembering that  $e^0 = 1$ ):

$$A + B = C + D \quad Ce^{\kappa L} + De^{-\kappa L} = A'e^{ikL} + B'e^{-ikL} \quad (8.17)$$

Their slopes (their first derivatives) must also be continuous there (Fig. 8.10):

$$ikA - ikB = \kappa C - \kappa D \quad \kappa Ce^{\kappa L} - \kappa De^{-\kappa L} = ikA'e^{ikL} - ikB'e^{-ikL} \quad (8.18)$$

**Fig. 8.8** A particle incident on a barrier from the left has an oscillating wavefunction, but inside the barrier there are no oscillations (for  $E < V$ ). If the barrier is not too thick, the wavefunction is nonzero at its opposite face, and so oscillations begin again there. (Only the real component of the wavefunction is shown.)

**Fig. 8.9** When a particle is incident on a barrier from the left, the wavefunction consists of a wave representing linear momentum to the right, a reflected component representing momentum to the left, a varying but not oscillating component inside the barrier, and a (weak) wave representing motion to the right on the far side of the barrier.

**Fig. 8.10** The wavefunction and its slope must be continuous at the edges of the barrier. The conditions for continuity enable us to connect the wavefunctions in the three zones and hence to obtain relations between the coefficients that appear in the solutions of the Schrödinger equation.

At this stage, we have four equations for the six unknown coefficients. If the particles are shot towards the barrier from the left, there can be no particles travelling to the left on the right of the barrier. Therefore, we can set  $B' = 0$ , which removes one more unknown. We cannot set  $B = 0$  because some particles may be reflected back from the barrier toward negative  $x$ .

The probability that a particle is travelling towards positive  $x$  (to the right) on the left of the barrier is proportional to  $|A|^2$ , and the probability that it is travelling to the right on the right of the barrier is  $|A'|^2$ . The ratio of these two probabilities is called the **transmission probability**,  $T$ . After some algebra (see Problem 8.8) we find

$$T = \left\{ 1 + \frac{(e^{\kappa L} - e^{-\kappa L})^2}{16\varepsilon(1 - \varepsilon)} \right\}^{-1} \quad \text{Transmission probability} \quad (8.19a)$$

where  $\varepsilon = E/V$ . This function is plotted in Fig. 8.11; the transmission coefficient for  $E > V$  is shown there too. For high, wide barriers (in the sense that  $\kappa L \gg 1$ ), eqn 8.19a simplifies to

$$T \approx 16\varepsilon(1 - \varepsilon)e^{-2\kappa L} \quad \text{Transmission probability for } \kappa L \gg 1 \quad (8.19b)$$

The transmission probability decreases exponentially with the thickness of the barrier and with  $m^{1/2}$ . It follows that particles of low mass are more able to tunnel through barriers than heavy ones (Fig. 8.12). Tunnelling is very important for electrons and muons (elementary particles with mass of about  $207m_e$ ), and moderately important for protons (of mass  $1840m_e$ ); for heavier particles it is less important. A number of effects in chemistry (for example, the very rapid equilibration of proton transfer reactions) is a manifestation of the ability of particles to tunnel through barriers. As we shall see in Chapter 22, electron tunnelling is one of the factors that determine the rates of electron transfer reactions at electrodes and in biological systems.

A problem related to tunnelling is that of a particle in a square-well potential of finite depth (Fig. 8.13). In this kind of potential, the wavefunction penetrates into the walls, where it decays exponentially towards zero, and oscillates within the well. The wavefunctions are found by ensuring, as in the discussion of tunnelling, that they and their slopes are continuous at the edges of the potential. Some of the lowest energy solutions are shown in Fig. 8.14. A further difference from the solutions for an infinitely deep well is that there is only a finite number of bound states. Regardless of the depth

**Fig. 8.11** The transmission probability for passage through a barrier. The horizontal axis is the energy of the incident particle expressed as a multiple of the barrier height. The curves are labelled with the value of  $L(2mV)^{1/2}/\hbar$ . The graph on the left is for  $E < V$  and that on the right for  $E > V$ . Note that  $T > 0$  for  $E < V$ , whereas classically  $T$  would be zero. However,  $T < 1$  for  $E > V$ , whereas classically  $T$  would be 1.

**interActivity** Plot  $T$  against  $\varepsilon$  for a hydrogen molecule, a proton, and an electron.

**Fig. 8.12** The wavefunction of a heavy particle decays more rapidly inside a barrier than that of a light particle. Consequently, a light particle has a greater probability of tunnelling through the barrier.

**Fig. 8.13** A potential well with a finite depth.

**Fig. 8.14** The lowest two bound-state wavefunctions for a particle in the well shown in Fig. 8.13.

and length of the well, however, there is always at least one bound state. Detailed consideration of the Schrödinger equation for the problem shows that in general the number of levels is equal to  $N$ , with

$$N - 1 < \frac{(8mVL)^{1/2}}{h} < N \quad (8.20)$$

where  $V$  is the depth of the well and  $L$  is its length. We see that, the deeper and wider the well, the greater the number of bound states. As the depth becomes infinite, so the number of bound states also becomes infinite, as we have already seen.

## IMPACT ON NANOSCIENCE

### 18.2 Scanning probe microscopy

In *Impact 18.1* we outlined some advantages of working in the nanometre regime. Here we describe *scanning probe microscopy* (SPM), a collection of techniques that can be used to visualize and manipulate objects as small as atoms on surfaces.

One version of SPM is scanning tunnelling microscopy (STM), in which a platinum–rhodium or tungsten needle is scanned across the surface of a conducting solid. When the tip of the needle is brought very close to the surface, electrons tunnel across the intervening space (Fig. 8.15). In the constant-current mode of operation, the stylus moves up and down corresponding to the form of the surface, and the topography of the surface, including any adsorbates, can therefore be mapped on an atomic scale. The vertical motion of the stylus is achieved by fixing it to a piezoelectric cylinder, which contracts or expands according to the potential difference it experiences. In the constant- $z$  mode, the vertical position of the stylus is held constant and the current is monitored. Because the tunnelling probability is very sensitive to the size of the gap, the microscope can detect tiny, atom-scale variations in the height of the surface.

Figure 8.16 shows an example of the kind of image obtained with a surface, in this case of gallium arsenide, that has been modified by addition of atoms, in this case caesium atoms. Each ‘bump’ on the surface corresponds to an atom. In a further variation of the STM technique, the tip may be used to nudge single atoms around on the surface, making possible the fabrication of complex and yet very tiny nanometre-sized structures.

**Fig. 8.15** A scanning tunnelling microscope makes use of the current of electrons that tunnel between the surface and the tip. That current is very sensitive to the distance of the tip above the surface.

**Fig. 8.16** An STM image of caesium atoms on a gallium arsenide surface.

**Example 8.2** Exploring the origin of the current in scanning tunnelling microscopy

To get an idea of the distance dependence of the tunnelling current in STM, suppose that the wavefunction of the electron in the gap between sample and needle is given by  $\psi = Be^{-\kappa x}$ , where  $\kappa = \{2m_e(V - E)/\hbar^2\}^{1/2}$ ; take  $V - E = 2.0$  eV. By what factor would the current drop if the needle is moved from  $L_1 = 0.50$  nm to  $L_2 = 0.60$  nm from the surface?

**Method** We regard the tunnelling current to be proportional to the transmission probability  $T$ , so the ratio of the currents is equal to the ratio of the transmission probabilities. To choose between eqn 8.19a or 8.19b for the calculation of  $T$ , first calculate  $\kappa L$  for the shortest distance  $L_1$ : if  $\kappa L_1 > 1$ , then use eqn 8.19b.

**Answer** When  $L = L_1 = 0.50$  nm and  $V - E = 2.0$  eV  $= 3.20 \times 10^{-19}$  J the value of  $\kappa L$  is

$$\begin{aligned}\kappa L_1 &= \left\{ \frac{2m_e(V - E)}{\hbar^2} \right\}^{1/2} L_1 \\ &= \left\{ \frac{2 \times (9.109 \times 10^{-31} \text{ kg}) \times (3.20 \times 10^{-19} \text{ J})}{(1.054 \times 10^{-34} \text{ J s})^2} \right\}^{1/2} \times (5.0 \times 10^{-10} \text{ m}) \\ &= (7.25 \times 10^9 \text{ m}^{-1}) \times (5.0 \times 10^{-10} \text{ m}) = 3.6\end{aligned}$$

Because  $\kappa L_1 > 1$ , we use eqn 8.19b to calculate the transmission probabilities at the two distances. It follows that

$$\begin{aligned}\frac{\text{current at } L_2}{\text{current at } L_1} &= \frac{T(L_2)}{T(L_1)} = \frac{16\epsilon(1 - \epsilon)e^{-2\kappa L_2}}{16\epsilon(1 - \epsilon)e^{-2\kappa L_1}} = e^{-2\kappa(L_2 - L_1)} \\ &= e^{-2 \times (7.25 \times 10^9 \text{ m}^{-1}) \times (1.0 \times 10^{-10} \text{ m})} = 0.23\end{aligned}$$

We conclude that, at a distance of 0.60 nm between the surface and the needle, the current is 23 per cent of the value measured when the distance is 0.50 nm.

**Self-test 8.5** The ability of a proton to tunnel through a barrier contributes to the rapidity of proton transfer reactions in solution and therefore to the properties of acids and bases. Estimate the relative probabilities that a proton and a deuteron ( $m_d = 3.342 \times 10^{-27}$  kg) can tunnel through the same barrier of height 1.0 eV ( $1.6 \times 10^{-19}$  J) and length 100 pm when their energy is 0.9 eV. Comment on your answer.  
[ $T_H/T_D = 3.1 \times 10^2$ ; proton transfer reactions are expected to be much faster than deuteron transfer reactions.]

## Vibrational motion

A particle undergoes **harmonic motion** if it experiences a ‘Hooke’s law’ restoring force, in which the force is proportional to the displacement from the equilibrium position:

$$F = -k_f x \quad \text{Hooke's law} \quad (8.21)$$

Here,  $k_f$  is the **force constant**: the stiffer the ‘spring’, the greater the value of  $k_f$ . Because force is related to potential energy by  $F = -dV/dx$ , the force in eqn 8.21 corresponds to a potential energy

$$V = \frac{1}{2} k_f x^2 \quad \text{Parabolic potential energy} \quad (8.22)$$

This expression, which is the equation of a parabola (Fig. 8.17), is the origin of the term ‘parabolic potential energy’ for the potential energy characteristic of a harmonic oscillator. The Schrödinger equation for the particle is therefore

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + \frac{1}{2}k_f x^2 \psi = E\psi \quad (8.23)$$

## 8.4 The energy levels

**Key point** The energies of a quantum mechanical harmonic oscillator are quantized with energies that form an equally spaced ladder.

Equation 8.23 is a standard equation in the theory of differential equations and its solutions are well known to mathematicians. Quantization of energy levels arises from the boundary conditions: the oscillator will not be found with infinitely large displacements from equilibrium, so the only allowed solutions are those for which  $\psi = 0$  at  $x = \pm\infty$ . The permitted energy levels are

$$E_v = \left(v + \frac{1}{2}\right)\hbar\omega \quad \omega = \left(\frac{k_f}{m}\right)^{1/2} \quad v = 0, 1, 2, \dots \quad \text{Energy levels of a harmonic oscillator} \quad (8.24)$$

Note that  $\omega$  (omega) increases with increasing force constant and decreasing mass. It follows from eqn 8.24 that the separation between adjacent levels is

$$E_{v+1} - E_v = \hbar\omega \quad (8.25)$$

which is the same for all  $v$ . Therefore, the energy levels form a uniform ladder of spacing  $\hbar\omega$  (Fig. 8.18). The energy separation  $\hbar\omega$  is negligibly small for macroscopic objects (with large mass), but is of great importance for objects with mass similar to that of atoms.

Because the smallest permitted value of  $v$  is 0, it follows from eqn 8.24 that a harmonic oscillator has a zero-point energy

$$E_0 = \frac{1}{2}\hbar\omega \quad \text{Zero-point energy of a harmonic oscillator} \quad (8.26)$$

The mathematical reason for the zero-point energy is that  $v$  cannot take negative values, for if it did the wavefunction would be ill-behaved. The physical reason is the same as for the particle in a square well: the particle is confined, its position is not completely uncertain, and therefore its momentum, and hence its kinetic energy, cannot be exactly zero. We can picture this zero-point state as one in which the particle fluctuates incessantly around its equilibrium position; classical mechanics would allow the particle to be perfectly still.

### • A brief illustration

Atoms vibrate relative to one another in molecules with the bond acting like a spring. Consider an X–H bond, where a heavy X atom forms a stationary anchor for the very light H atom. That is, only the H atom moves, vibrating as a simple harmonic oscillator. Equation 8.24 describes the allowed vibrational energy levels of the bond. The force constant of a typical X–H chemical bond is around  $500 \text{ N m}^{-1}$ . For example,  $k_f = 516.3 \text{ N m}^{-1}$  for the  $^1\text{H}^{35}\text{Cl}$  bond. Because the mass of a proton is about  $1.7 \times 10^{-27} \text{ kg}$ , using  $k_f = 500 \text{ N m}^{-1}$  in eqn 8.24 gives  $\omega \approx 5.4 \times 10^{14} \text{ s}^{-1}$  ( $5.4 \times 10^2 \text{ THz}$ ). It follows from eqn 8.25 that the separation of adjacent levels is  $\hbar\omega \approx 5.7 \times 10^{-20} \text{ J}$  (57 zJ, about 0.36 eV). This energy separation corresponds to  $34 \text{ kJ mol}^{-1}$ , which is chemically significant. From eqn 8.26, the zero-point energy of this molecular oscillator is about 28 zJ, which corresponds to 0.18 eV, or  $17 \text{ kJ mol}^{-1}$ . •

**Fig. 8.17** The parabolic potential energy  $V = \frac{1}{2}k_f x^2$  of a harmonic oscillator, where  $x$  is the displacement from equilibrium. The narrowness of the curve depends on the force constant  $k$ : the larger the value of  $k$ , the narrower the well.

**Fig. 8.18** The energy levels of a harmonic oscillator are evenly spaced with separation  $\hbar\omega$ , with  $\omega = (k_f/m)^{1/2}$ . Even in its lowest state, an oscillator has an energy greater than zero.

## 8.5 The wavefunctions

**Key points** (a) The wavefunctions of a harmonic oscillator have the form  $\psi(x) = N \times (\text{Hermite polynomial in } x) \times (\text{bell-shaped Gaussian function})$ . (b) The virial theorem states that, if the potential energy of a particle has the form  $V = ax^b$ , then its mean potential and kinetic energies are related by  $2\langle E_k \rangle = b\langle V \rangle$ . A quantum mechanical oscillator may be found at extensions that are forbidden by classical physics.

**Fig. 8.19** The graph of the Gaussian function,  $f(x) = e^{-x^2}$ .

**Table 8.1** The Hermite polynomials  $H_v(y)$

| $v$ | $H_v(y)$                        |
|-----|---------------------------------|
| 0   | 1                               |
| 1   | $2y$                            |
| 2   | $4y^2 - 2$                      |
| 3   | $8y^3 - 12y$                    |
| 4   | $16y^4 - 48y^2 + 12$            |
| 5   | $32y^5 - 160y^3 + 120y$         |
| 6   | $64y^6 - 480y^4 + 720y^2 - 120$ |

The Hermite polynomials are solutions of the differential equation

$$H_v'' - 2yH_v' + 2vH_v = 0$$

where primes denote differentiation. They satisfy the recursion relation

$$H_{v+1} - 2yH_v + 2vH_{v-1} = 0$$

An important integral is

$$\int_{-\infty}^{\infty} H_{v'} H_v e^{-y^2} dy = \begin{cases} 0 & \text{if } v' \neq v \\ \pi^{1/2} 2^v v! & \text{if } v' = v \end{cases}$$

It is helpful at the outset to identify the similarities between the harmonic oscillator and the particle in a box, for then we shall be able to anticipate the form of the oscillator wavefunctions without detailed calculation. Like the particle in a box, a particle undergoing harmonic motion is trapped in a symmetrical well in which the potential energy rises to large values (and ultimately to infinity) for sufficiently large displacements (compare Figs. 8.1 and 8.17). However, there are two important differences. First, because the potential energy climbs towards infinity only as  $x^2$  and not abruptly, the wavefunction approaches zero more slowly at large displacements than for the particle in a box. Second, as the kinetic energy of the oscillator depends on the displacement in a more complex way (on account of the variation of the potential energy), the curvature of the wavefunction also varies in a more complex way.

### (a) The form of the wavefunctions

The detailed solution of eqn 8.23 shows that the wavefunction for a harmonic oscillator has the form

$$\psi(x) = N \times (\text{polynomial in } x) \times (\text{bell-shaped Gaussian function})$$

where  $N$  is a normalization constant. A Gaussian function is a function of the form  $e^{-x^2}$  (Fig. 8.19). The precise form of the wavefunctions is

$$\psi_v(x) = N_v H_v(y) e^{-y^2/2} \quad y = \frac{x}{\alpha} \quad \alpha = \left( \frac{\hbar^2}{mk_f} \right)^{1/4} \quad \text{Wavefunctions of a harmonic oscillator} \quad (8.27)$$

The factor  $H_v(y)$  is a **Hermite polynomial** (Table 8.1). Hermite polynomials are members of a class of functions called orthogonal polynomials. These polynomials have a wide range of important properties, which allow a number of quantum mechanical calculations to be done with relative ease.

Because  $H_0(y) = 1$ , the wavefunction for the ground state (the lowest energy state, with  $v = 0$ ) of the harmonic oscillator is

$$\psi_0(x) = N_0 e^{-y^2/2} = N_0 e^{-x^2/2\alpha^2} \quad (8.28)$$

It follows that the probability density is the bell-shaped Gaussian function

$$\psi_0^2(x) = N_0^2 e^{-x^2/\alpha^2} \quad (8.29)$$

The wavefunction and the probability distribution are shown in Fig. 8.20. Both curves have their largest values at zero displacement (at  $x = 0$ ), so they capture the classical picture of the zero-point energy as arising from the ceaseless fluctuation of the particle about its equilibrium position.

**Fig. 8.20** The normalized wavefunction and probability distribution (shown also by shading) for the lowest energy state of a harmonic oscillator.

**Fig. 8.21** The normalized wavefunction and probability distribution (shown also by shading) for the first excited state of a harmonic oscillator.

### • A brief illustration

The wavefunction for the first excited state of the oscillator, the state with  $v = 1$ , is obtained by noting that  $H_1(y) = 2y$  (note that some of the Hermite polynomials are very simple functions!):

$$\psi_1(x) = N_1 \times 2ye^{-y^2/2} \quad (8.30)$$

This function has a node at zero displacement ( $x = 0$ ), and the probability density has maxima at  $x = \pm\alpha$ , corresponding to  $y = \pm 1$  (Fig. 8.21). •

Once again, we should interpret the mathematical expressions we have derived. In the case of the harmonic oscillator wavefunctions in eqn 8.27, we should note the following.

1. The Gaussian function goes quickly to zero as the displacement increases (in either direction), so all the wavefunctions approach zero at large displacements.
2. The exponent  $y^2$  is proportional to  $x^2 \times (mk_f)^{1/2}$ , so the wavefunctions decay more rapidly for large masses and large force constants (stiff springs).
3. As  $v$  increases, the Hermite polynomials become larger at large displacements (as  $x^v$ ), so the wavefunctions grow large before the Gaussian function damps them down to zero: as a result, the wavefunctions spread over a wider range as  $v$  increases.

The shapes of several of the wavefunctions are shown in Fig. 8.22. At high quantum numbers, harmonic oscillator wavefunctions have their largest amplitudes near the turning points of the classical motion (the locations at which  $V = E$ , so the kinetic energy is zero). We see classical properties emerging in the correspondence limit of high quantum numbers, for a classical particle is most likely to be found at the turning points (where it is briefly stationary) and is least likely to be found at zero displacement (where it travels most rapidly).

**Fig. 8.22** The normalized wavefunctions for the first five states of a harmonic oscillator. Even values of  $v$  are purple; odd values are blue. Note that the number of nodes is equal to  $v$  and that alternate wavefunctions are symmetrical or antisymmetrical about  $y = 0$  (zero displacement).

**Example 8.3** Normalizing a harmonic oscillator wavefunction

Find the normalization constant for the harmonic oscillator wavefunctions.

**Method** Normalization is always carried out by evaluating the integral of  $|\psi|^2$  over all space and then finding the normalization factor from eqn 7.19. The normalized wavefunction is then equal to  $N\psi$ . In this one-dimensional problem, the volume element is  $dx$  and the integration is from  $-\infty$  to  $+\infty$ . The wavefunctions are expressed in terms of the dimensionless variable  $y = x/\alpha$ , so begin by expressing the integral in terms of  $y$  by using  $dx = \alpha dy$ . The integrals required are given in Table 8.1.

**Answer** The unnormalized wavefunction is

$$\psi_v(x) = H_v(y)e^{-y^2/2}$$

It follows from the integrals given in Table 8.1 that

$$\int_{-\infty}^{\infty} \psi_v^* \psi_v dx = \alpha \int_{-\infty}^{\infty} \psi_v^* \psi_v dy = \alpha \int_{-\infty}^{\infty} H_v^2(y) e^{-y^2} dy = \alpha \pi^{1/2} 2^v v!$$

where  $v! = v(v-1)(v-2) \dots 1$ . Therefore,

$$N_v = \left( \frac{1}{\alpha \pi^{1/2} 2^v v!} \right)^{1/2}$$

Note that for a harmonic oscillator  $N_v$  is different for each value of  $v$ .

**Self-test 8.6** Confirm, by explicit evaluation of the integral, that  $\psi_0$  and  $\psi_1$  are orthogonal.

[Evaluate the integral  $\int_{-\infty}^{\infty} \psi_0^* \psi_1 dx$  by using the information in Table 8.1]

**Fig. 8.23** The probability distributions for the first five states of a harmonic oscillator and the state with  $v = 20$ . Note how the regions of highest probability move towards the turning points of the classical motion as  $v$  increases.

**InterActivity** To gain some insight into the origins of the nodes in the harmonic oscillator wavefunctions, plot the Hermite polynomials  $H_v(y)$  for  $v = 0$  through 5.

**(b) The properties of oscillators**

With the wavefunctions that are available, we can start calculating the properties of a harmonic oscillator. For instance, we can calculate the expectation values of an observable  $\Omega$  by evaluating integrals of the type

$$\langle \Omega \rangle = \int_{-\infty}^{\infty} \psi_v^* \Omega \psi_v dx \quad (8.31)$$

(Here and henceforth, the wavefunctions are all taken as being normalized to 1.) When the explicit wavefunctions are substituted, the integrals look fearsome, but the Hermite polynomials have many simplifying features. For instance, we show in the following example that the mean displacement,  $\langle x \rangle$ , and the mean square displacement,  $\langle x^2 \rangle$ , of the oscillator when it is in the state with quantum number  $v$  are

$$\langle x \rangle = 0 \quad \langle x^2 \rangle = \left( v + \frac{1}{2} \right) \frac{\hbar}{(mk_f)^{1/2}} \quad (8.32)$$

The result for  $\langle x \rangle$  shows that the oscillator is equally likely to be found on either side of  $x = 0$  (like a classical oscillator). The result for  $\langle x^2 \rangle$  shows that the mean square displacement increases with  $v$ . This increase is apparent from the probability densities in Fig. 8.23, and corresponds to the classical amplitude of swing increasing as the oscillator becomes more highly excited.

**Example 8.4** Calculating properties of a harmonic oscillator

We can imagine the bending motion of a CO<sub>2</sub> molecule as a harmonic oscillation relative to the linear conformation of the molecule. We may be interested in the extent to which the molecule bends. Calculate the mean displacement of the oscillator when it is in a quantum state  $v$ .

**Method** Normalized wavefunctions must be used to calculate the expectation value. The operator for position along  $x$  is multiplication by the value of  $x$  (Section 7.5c). The resulting integral can be evaluated either by inspection (the integrand is the product of an odd and an even function), or by explicit evaluation using the formulas in Table 8.1. To give practice in this type of calculation, we illustrate the latter procedure. We shall need the relation  $x = \alpha y$ , which implies that  $dx = \alpha dy$ .

**Answer** The integral we require is

$$\begin{aligned}\langle x \rangle &= \int_{-\infty}^{\infty} \psi_v^* x \psi_v dx = N_v^2 \int_{-\infty}^{\infty} (H_v e^{-y^2/2}) x (H_v e^{-y^2/2}) dx \\ &= \alpha^2 N_v^2 \int_{-\infty}^{\infty} (H_v e^{-y^2/2}) y (H_v e^{-y^2/2}) dy \\ &= \alpha^2 N_v^2 \int_{-\infty}^{\infty} H_v y H_v e^{-y^2} dy\end{aligned}$$

Now use the recursion relation (see Table 8.1) to form

$$yH_v = vH_{v-1} + \frac{1}{2}H_{v+1}$$

which turns the integral into

$$\int_{-\infty}^{\infty} H_v y H_v e^{-y^2} dy = v \int_{-\infty}^{\infty} H_{v-1} H_v e^{-y^2} dy + \frac{1}{2} \int_{-\infty}^{\infty} H_{v+1} H_v e^{-y^2} dy$$

Both integrals are zero (see Table 8.1), so  $\langle x \rangle = 0$ . As remarked in the text, the mean displacement is zero because the displacement occurs equally on either side of the equilibrium position. The following *Self-test* extends this calculation by examining the mean square displacement, which we can expect to be non-zero and to increase with increasing  $v$ .

**Self-test 8.7** Calculate the mean square displacement  $\langle x^2 \rangle$  of the particle from its equilibrium position. (Use the recursion relation twice.) [eqn 8.32]

The mean potential energy of an oscillator, the expectation value of  $V = \frac{1}{2}kx^2$ , can now be calculated very easily:

$$\langle V \rangle = \langle \frac{1}{2}k_f x^2 \rangle = \frac{1}{2}(v + \frac{1}{2})\hbar \left( \frac{k_f}{m} \right)^{1/2} = \frac{1}{2}(v + \frac{1}{2})\hbar\omega \quad (8.33)$$

Because the total energy in the state with quantum number  $v$  is  $(v + \frac{1}{2})\hbar\omega$ , it follows that

$$\langle V \rangle = \frac{1}{2}E_v \quad (8.34a)$$

The total energy is the sum of the potential and kinetic energies, so it follows at once that the mean kinetic energy of the oscillator is

$$\langle E_k \rangle = \frac{1}{2}E_v \quad (8.34b)$$

**A brief comment**

An even function is one for which  $f(-x) = f(x)$ ; an odd function is one for which  $f(-x) = -f(x)$ . The product of an odd and even function is itself odd, and the integral of an odd function over a symmetrical range about  $x = 0$  is zero.

The result that the mean potential and kinetic energies of a harmonic oscillator are equal (and therefore that both are equal to half the total energy) is a special case of the **virial theorem**:

If the potential energy of a particle has the form  $V = ax^b$ , then its mean potential and kinetic energies are related by

Virial theorem

 (8.35)

$$2\langle E_k \rangle = b\langle V \rangle$$

For a harmonic oscillator  $b = 2$ , so  $\langle E_k \rangle = \langle V \rangle$ , as we have found. The virial theorem is a short cut to the establishment of a number of useful results, and we shall use it again.

An oscillator may be found at extensions with  $V > E$  that are forbidden by classical physics, because they correspond to negative kinetic energy. For example, it follows from the shape of the wavefunction (see Problem 8.15) that in its lowest energy state there is about an 8 per cent chance of finding an oscillator stretched beyond its classical limit and an 8 per cent chance of finding it with a classically forbidden compression. These tunnelling probabilities are independent of the force constant and mass of the oscillator. The probability of being found in classically forbidden regions decreases quickly with increasing  $v$ , and vanishes entirely as  $v$  approaches infinity, as we would expect from the correspondence principle. Macroscopic oscillators (such as pendulums) are in states with very high quantum numbers, so the probability that they will be found in a classically forbidden region is wholly negligible. Molecules, however, are normally in their vibrational ground states, and for them the probability is very significant.

## Rotational motion

The treatment of rotational motion can be broken down into two parts. The first deals with motion in two dimensions and the second with rotation in three dimensions.

### 8.6 Rotation in two dimensions: a particle on a ring

**Key points** (a) The wavefunction of a particle on a ring must satisfy a cyclic boundary condition, and match at points separated by a complete revolution. (b) The energy and angular momentum of a particle on a ring are quantized.

**Fig. 8.24** The angular momentum of a particle of mass  $m$  on a circular path of radius  $r$  in the  $xy$ -plane is represented by a vector  $J$  with the single nonzero component,  $J_z$ , of magnitude  $pr$  perpendicular to the plane.

We consider a particle of mass  $m$  constrained to move in a circular path of radius  $r$  in the  $xy$ -plane with constant potential energy, which may be taken to be zero (Fig. 8.24). The total energy is equal to the kinetic energy, because  $V = 0$  everywhere. We can therefore write  $E = p^2/2m$ . According to classical mechanics, the **angular momentum**,  $J_z$ , around the  $z$ -axis (which lies perpendicular to the  $xy$ -plane) is  $J_z = \pm pr$ , so the energy can be expressed as  $J_z^2/2mr^2$ . Because  $mr^2$  is the **moment of inertia**,  $I$ , of the mass on its path, it follows that

$$E = \frac{J_z^2}{2I} \quad (8.36)$$

We shall now see that not all the values of the angular momentum are permitted in quantum mechanics, and therefore that both angular momentum and rotational energy are quantized.

#### (a) The qualitative origin of quantized rotation

Because  $J_z = \pm pr$ , and since the de Broglie relation gives  $p = h/\lambda$ , the angular momentum about the  $z$ -axis is

$$J_z = \pm \frac{hr}{\lambda}$$

Opposite signs correspond to opposite directions of travel. This equation shows that, the shorter the wavelength of the particle on a circular path of given radius, the greater the angular momentum of the particle. It follows that, if we can see why the wavelength is restricted to discrete values, then we shall understand why the angular momentum is quantized.

Suppose for the moment that  $\lambda$  can take an arbitrary value. In that case, the wavefunction depends on the azimuthal angle  $\phi$  as shown in Fig. 8.25a. When  $\phi$  increases beyond  $2\pi$ , the wavefunction continues to change, but for an arbitrary wavelength it gives rise to a different value at each point, which is unacceptable (Section 7.4b). An acceptable solution is obtained only if the wavefunction reproduces itself on successive circuits, as in Fig. 8.25b. Because only some wavefunctions have this property, it follows that only some angular momenta are acceptable, and therefore that only certain rotational energies exist. Hence, the energy of the particle is quantized. Specifically, the only allowed wavelengths are

$$\lambda = \frac{2\pi r}{m_l}$$

with  $m_l$  the conventional notation for this quantum number, taking integral values including 0. The value  $m_l = 0$  corresponds to  $\lambda = \infty$ ; a 'wave' of infinite wavelength has a constant height at all values of  $\phi$ . The angular momentum is therefore limited to the values

$$J_z = \pm \frac{hr}{\lambda} = \frac{m_l hr}{2\pi r} = \frac{m_l h}{2\pi}$$

where we have allowed  $m_l$  to have positive or negative values. That is,

$$J_z = m_l \hbar \quad m_l = 0, \pm 1, \pm 2, \dots$$

Angular momentum  
of a particle on a ring (8.37)

Positive values of  $m_l$  correspond to rotation in a clockwise sense around the  $z$ -axis (as viewed in the direction of  $z$ , Fig. 8.26) and negative values of  $m_l$  correspond to counterclockwise rotation around  $z$ . It then follows from eqn 8.36 that the energy is limited to the values

$$E = \frac{J_z^2}{2I} = \frac{m_l^2 \hbar^2}{2I} \quad \text{Energy levels of a particle on a ring} \quad (8.38a)$$

We shall see shortly that the corresponding normalized wavefunctions are

$$\psi_{m_l}(\phi) = \frac{e^{im_l \phi}}{(2\pi)^{1/2}} \quad \text{Wavefunctions of a particle on a ring} \quad (8.38b)$$

The wavefunction with  $m_l = 0$  is  $\psi_0(\phi) = 1/(2\pi)^{1/2}$ , and has the same value at all points on the circle.

We have arrived at a number of conclusions about rotational motion by combining some classical notions with the de Broglie relation. Such a procedure can be very useful for establishing the general form (and, as in this case, the exact energies) for a quantum mechanical system. However, to be sure that the correct solutions have been obtained, and to obtain practice for more complex problems where this less formal approach is inadequate, we need to solve the Schrödinger equation explicitly. The formal solution is described in the *Justification* that follows.

**Fig. 8.25** Two solutions of the Schrödinger equation for a particle on a ring. The circumference has been opened out into a straight line; the points at  $\phi = 0$  and  $2\pi$  are identical. The solution in (a) is unacceptable because it is not single-valued. Moreover, on successive circuits it interferes destructively with itself, and does not survive. The solution in (b) is acceptable: it is single-valued, and on successive circuits it reproduces itself.

**Fig. 8.26** The angular momentum of a particle confined to a plane can be represented by a vector of length  $|m_l|$  units along the  $z$ -axis and with an orientation that indicates the direction of motion of the particle. The direction is given by the right-hand screw rule.

**Fig. 8.27** The cylindrical coordinates  $z$ ,  $r$ , and  $\phi$  for discussing systems with axial (cylindrical) symmetry. For a particle confined to the  $xy$ -plane, only  $r$  and  $\phi$  can change.

**Justification 8.3** *The energies and wavefunctions of a particle on a ring*

The hamiltonian for a particle of mass  $m$  in a plane (with  $V=0$ ) is the same as that given in eqn 8.9:

$$\hat{H} = -\frac{\hbar^2}{2m} \left( \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right)$$

and the Schrödinger equation is  $\hat{H}\psi = E\psi$ , with the wavefunction a function of the angle  $\phi$ . It is always a good idea to use coordinates that reflect the full symmetry of the system, so we introduce the coordinates  $r$  and  $\phi$  (Fig. 8.27), where  $x = r \cos \phi$  and  $y = r \sin \phi$ . By standard manipulations we can write

$$\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} = \frac{\partial^2}{\partial r^2} + \frac{1}{r} \frac{\partial}{\partial r} + \frac{1}{r^2} \frac{\partial^2}{\partial \phi^2} \quad (8.39)$$

However, because the radius of the path is fixed, the derivatives with respect to  $r$  can be discarded. The hamiltonian then becomes

$$\hat{H} = -\frac{\hbar^2}{2mr^2} \frac{d^2}{d\phi^2}$$

The moment of inertia  $I = mr^2$  has appeared automatically, so  $\hat{H}$  may be written

$$\hat{H} = -\frac{\hbar^2}{2I} \frac{d^2}{d\phi^2} \quad (8.40)$$

and the Schrödinger equation is

$$\frac{d^2\psi}{d\phi^2} = -\frac{2IE}{\hbar^2} \psi \quad (8.41)$$

The normalized general solutions of the equation are

$$\psi_{m_l}(\phi) = \frac{e^{im_l\phi}}{(2\pi)^{1/2}} \quad m_l = \pm \frac{(2IE)^{1/2}}{\hbar} \quad (8.42)$$

The quantity  $m_l$  is just a dimensionless number at this stage.

We now select the acceptable solutions from among these general solutions by imposing the condition that the wavefunction should be single-valued. That is, the wavefunction  $\psi$  must satisfy a **cyclic boundary condition**, and match at points separated by a complete revolution:  $\psi(\phi + 2\pi) = \psi(\phi)$ . On substituting the general wavefunction into this condition, we find

$$\psi_{m_l}(\phi + 2\pi) = \frac{e^{im_l(\phi+2\pi)}}{(2\pi)^{1/2}} = \frac{e^{im_l\phi} e^{2\pi im_l}}{(2\pi)^{1/2}} = \psi_{m_l}(\phi) e^{2\pi im_l}$$

As  $e^{i\pi} = -1$ , this relation is equivalent to

$$\psi_{m_l}(\phi + 2\pi) = (-1)^{2m_l} \psi_{m_l}(\phi) \quad (8.43)$$

Because we require  $(-1)^{2m_l} = 1$ ,  $2m_l$  must be a positive or a negative even integer (including 0), and therefore  $m_l$  must be an integer:  $m_l = 0, \pm 1, \pm 2, \dots$ . The corresponding energies are therefore those given by eqn 8.38a with  $m_l = 0, \pm 1, \pm 2, \dots$

### (b) Quantization of rotation

We can summarize the conclusions so far as follows. The energy is quantized and restricted to the values given in eqn 8.38a ( $E = m_l^2 \hbar^2 / 2I$ ). The occurrence of  $m_l$  as its square means that the energy of rotation is independent of the sense of rotation (the sign of  $m_l$ ), as we expect physically. In other words, states with a given value of  $|m_l|$  are

doubly degenerate, except for  $m_l = 0$ , which is non-degenerate. Although the result has been derived for the rotation of a single mass point, it also applies to any body of moment of inertia  $I$  constrained to rotate about one axis.

We have also seen that the angular momentum is quantized and confined to the values given in eqn 8.37 ( $J_z = m_l \hbar$ ). The increasing angular momentum is associated with the increasing number of nodes in the real and imaginary parts of the wavefunction: the wavelength decreases stepwise as  $|m_l|$  increases, so the momentum with which the particle travels round the ring increases (Fig. 8.28). As shown in the following *Justification*, we can come to the same conclusion more formally by using the argument about the relation between eigenvalues and the values of observables established in Section 7.5.

**Justification 8.4** *The quantization of angular momentum*

In the discussion of translational motion in one dimension, we saw that the opposite signs in the wavefunctions  $e^{ikx}$  and  $e^{-ikx}$  correspond to opposite directions of travel, and that the linear momentum is given by the eigenvalue of the linear momentum operator. The same conclusions can be drawn here, but now we need the eigenvalues of the angular momentum operator. In classical mechanics the orbital angular momentum  $L_z$  about the  $z$ -axis is defined as

$$L_z = xp_y - yp_x \quad \text{Definition of angular momentum} \quad [8.44]$$

where  $p_x$  is the component of linear motion parallel to the  $x$ -axis and  $p_y$  is the component parallel to the  $y$ -axis.

The operators for the two linear momentum components are given in eqn 7.29, so the operator for angular momentum about the  $z$ -axis, which we denote  $\hat{L}_z$ , is

$$\hat{L}_z = \frac{\hbar}{i} \left( x \frac{\partial}{\partial y} - y \frac{\partial}{\partial x} \right) \quad \text{Angular momentum operator} \quad (8.45)$$

When expressed in terms of the coordinates  $r$  and  $\phi$ , by standard manipulations this equation becomes

$$\hat{L}_z = \frac{\hbar}{i} \frac{\partial}{\partial \phi} \quad \text{Angular momentum operator (polar form)} \quad (8.46)$$

With the angular momentum operator available, we can test the wavefunction in eqn 8.42. Disregarding the normalization constant, we find

$$\hat{L}_z \psi_{m_l} = \frac{\hbar}{i} \frac{d\psi_{m_l}}{d\phi} = im_l \frac{\hbar}{i} e^{im_l \phi} = m_l \hbar \psi_{m_l} \quad (8.47)$$

That is,  $\psi_{m_l}$  is an eigenfunction of  $\hat{L}_z$ , and corresponds to an angular momentum  $m_l \hbar$ . When  $m_l$  is positive, the angular momentum is positive (clockwise when seen from below); when  $m_l$  is negative, the angular momentum is negative (counterclockwise when seen from below). These features are the origin of the vector representation of angular momentum, in which the magnitude is represented by the length of a vector and the direction of motion by its orientation (Fig. 8.29).

To locate the particle given its wavefunction in eqn 8.42, we form the probability density:

$$\psi_{m_l}^* \psi_{m_l} = \left( \frac{e^{im_l \phi}}{(2\pi)^{1/2}} \right)^* \left( \frac{e^{im_l \phi}}{(2\pi)^{1/2}} \right) = \left( \frac{e^{-im_l \phi}}{(2\pi)^{1/2}} \right) \left( \frac{e^{im_l \phi}}{(2\pi)^{1/2}} \right) = \frac{1}{2\pi}$$

**A brief comment**

The complex function  $e^{im_l \phi}$  does not have nodes; however, it may be written as  $\cos m_l \phi + i \sin m_l \phi$ , and the real ( $\cos m_l \phi$ ) and imaginary ( $\sin m_l \phi$ ) components do have nodes.

**Fig. 8.28** The real parts of the wavefunctions of a particle on a ring. As shorter wavelengths are achieved, the magnitude of the angular momentum around the  $z$ -axis grows in steps of  $\hbar$ .

**A brief comment**

The angular momentum in three dimensions is defined as

$$\begin{aligned} \mathbf{L} = \mathbf{r} \times \mathbf{p} &= \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ x & y & z \\ p_x & p_y & p_z \end{vmatrix} \\ &= (yp_z - zp_y)\mathbf{i} - (xp_z - zp_x)\mathbf{j} \\ &\quad + (xp_y - yp_x)\mathbf{k} \end{aligned}$$

where  $\mathbf{i}$ ,  $\mathbf{j}$ , and  $\mathbf{k}$  are unit vectors pointing along the positive directions on the  $x$ -,  $y$ -, and  $z$ -axes. It follows that the  $z$ -component of the angular momentum has a magnitude given by eqn 8.44. For more information on vectors, see *Mathematical background 5* following Chapter 9.

**Fig. 8.29** The basic ideas of the vector representation of angular momentum: the magnitude of the angular momentum is represented by the length of the vector, and the orientation of the motion in space by the orientation of the vector (using the right-hand screw rule).

**Fig. 8.30** The probability density for a particle in a definite state of angular momentum is uniform, so there is an equal probability of finding the particle anywhere on the ring.

**Fig. 8.31** The wavefunction of a particle on the surface of a sphere must satisfy two cyclic boundary conditions; this requirement leads to two quantum numbers for its state of angular momentum.

Because this probability density is independent of  $\phi$ , the probability of locating the particle somewhere on the ring is also independent of  $\phi$  (Fig. 8.30). Hence the location of the particle is completely indefinite, and knowing the angular momentum precisely eliminates the possibility of specifying the location of the particle. Angular momentum and angle are a pair of complementary observables (in the sense defined in Section 7.6), and the inability to specify them simultaneously with arbitrary precision is another example of the uncertainty principle.

## 8.7 Rotation in three dimensions: the particle on a sphere

**Key points** (a) The wavefunction of a particle on a spherical surface must satisfy simultaneously two cyclic boundary conditions. (b) The energy and angular momentum of a particle on a sphere are quantized. (c) Space quantization is the restriction of the component of angular momentum around an axis to discrete values. (d) The vector model of angular momentum uses diagrams to represent the state of angular momentum of a rotating particle.

We now consider a particle of mass  $m$  that is free to move anywhere on the surface of a sphere of radius  $r$ . We shall need the results of this calculation when we come to describe rotating molecules and the states of electrons in atoms. The requirement that the wavefunction should match as a path is traced over the poles as well as around the equator of the sphere surrounding the central point introduces a second cyclic boundary condition and therefore a second quantum number (Fig. 8.31).

### (a) The Schrödinger equation

The hamiltonian for motion in three dimensions (Table 7.1) is

$$\hat{H} = -\frac{\hbar^2}{2m} \nabla^2 + V \quad \nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \quad (8.48)$$

The symbol  $\nabla^2$  is a convenient abbreviation for the sum of the three second derivatives; it is called the **laplacian**, and read either ‘del squared’ or ‘nabla squared’. For the particle confined to a spherical surface,  $V = 0$  wherever it is free to travel, and the radius  $r$  is a constant. The wavefunction is therefore a function of the **colatitude**,  $\theta$ , and the **azimuth**,  $\phi$  (Fig. 8.32), and so we write it as  $\psi(\theta, \phi)$ . The Schrödinger equation is

$$-\frac{\hbar^2}{2m} \nabla^2 \psi = E \psi \quad (8.49)$$

As shown in the following *Justification*, this partial differential equation can be simplified by the separation of variables procedure (*Mathematical background 4*) by expressing the wavefunction (for constant  $r$ ) as the product

$$\psi(\theta, \phi) = \Theta(\theta) \Phi(\phi) \quad \text{Separation of variables} \quad (8.50)$$

where  $\Theta$  is a function only of  $\theta$  and  $\Phi$  is a function only of  $\phi$ .

**Justification 8.5** The separation of variables technique applied to the particle on a sphere

The laplacian in spherical polar coordinates is

$$\nabla^2 = \frac{\partial^2}{\partial r^2} + \frac{2}{r} \frac{\partial}{\partial r} + \frac{1}{r^2} \Lambda^2 \quad \text{laplacian} \quad (8.51a)$$

where the **legendrian**,  $\Lambda^2$ , is

$$\Lambda^2 = \frac{1}{\sin^2 \theta} \frac{\partial^2}{\partial \phi^2} + \frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \sin \theta \frac{\partial}{\partial \theta} \quad \text{legendrian} \quad (8.51b)$$

Because  $r$  is constant, we can discard the part of the laplacian that involves differentiation with respect to  $r$ , and so write the Schrödinger equation as

$$\frac{1}{r^2} \Lambda^2 \psi = -\frac{2mE}{\hbar^2} \psi$$

or, because  $I = mr^2$ , as

$$\Lambda^2 \psi = -\varepsilon \psi \quad \varepsilon = \frac{2IE}{\hbar^2}$$

To verify that this expression is separable, we substitute  $\psi = \Theta\Phi$ :

$$\frac{1}{\sin^2 \theta} \frac{\partial^2 (\Theta\Phi)}{\partial \phi^2} + \frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \sin \theta \frac{\partial (\Theta\Phi)}{\partial \theta} = -\varepsilon \Theta\Phi$$

We now use the fact that  $\Theta$  and  $\Phi$  are each functions of one variable, so the partial derivatives become complete derivatives:

$$\frac{\Theta}{\sin^2 \theta} \frac{d^2 \Phi}{d\phi^2} + \frac{\Phi}{\sin \theta} \frac{d}{d\theta} \sin \theta \frac{d\Theta}{d\theta} = -\varepsilon \Theta\Phi$$

Division through by  $\Theta\Phi$ , multiplication by  $\sin^2 \theta$ , and minor rearrangement gives

$$\frac{1}{\Phi} \frac{d^2 \Phi}{d\phi^2} + \frac{\sin \theta}{\Theta} \frac{d}{d\theta} \sin \theta \frac{d\Theta}{d\theta} + \varepsilon \sin^2 \theta = 0$$

The first term on the left depends only on  $\phi$  and the remaining two terms depend only on  $\theta$ . We met a similar situation when discussing a particle on a rectangular surface (Justification 8.2), and by the same argument, the complete equation can be separated. Thus, if we set the first term equal to the numerical constant  $-m_l^2$  (using a notation chosen with an eye to the future), the separated equations are

$$\frac{1}{\Phi} \frac{d^2 \Phi}{d\phi^2} = -m_l^2 \quad \frac{\sin \theta}{\Theta} \frac{d}{d\theta} \sin \theta \frac{d\Theta}{d\theta} + \varepsilon \sin^2 \theta = m_l^2$$

The first of these two equations is the same as that in Justification 8.3, so it has the same solutions (eqn 8.42). The second is much more complicated to solve, but the solutions are tabulated as the associated Legendre functions. For reasons related to the behaviour of these functions, the cyclic boundary conditions on  $\Theta$  arising from the need for the wavefunctions to match at  $\theta=0$  and  $2\pi$  (the North Pole) result in the introduction of a second quantum number,  $l$ , which identifies the acceptable solutions. The presence of the quantum number  $m_l$  in the second equation implies, as we see below, that the range of acceptable values of  $m_l$  is restricted by the value of  $l$ .

As indicated in Justification 8.5, solution of the Schrödinger equation shows that the acceptable wavefunctions are specified by two quantum numbers  $l$  and  $m_l$  which are restricted to the values

$$l = 0, 1, 2, \dots \quad m_l = l, l-1, \dots, -l \quad (8.52)$$

Note that the **orbital angular momentum quantum number**  $l$  is non-negative and that, for a given value of  $l$ , there are  $2l+1$  permitted values of the **magnetic quantum number**,  $m_l$ . The normalized wavefunctions are usually denoted  $Y_{l,m_l}(\theta, \phi)$  and are called the **spherical harmonics** (Table 8.2).

**Fig. 8.32** Spherical polar coordinates. For a particle confined to the surface of a sphere, only the colatitude,  $\theta$ , and the azimuth,  $\phi$ , can change.

**Table 8.2** The spherical harmonics

| $l$ | $m_l$   | $Y_{l,m_l}(\theta, \phi)$                                                                 |
|-----|---------|-------------------------------------------------------------------------------------------|
| 0   | 0       | $\left(\frac{1}{4\pi}\right)^{1/2}$                                                       |
| 1   | 0       | $\left(\frac{3}{4\pi}\right)^{1/2} \cos \theta$                                           |
|     | $\pm 1$ | $\mp \left(\frac{3}{8\pi}\right)^{1/2} \sin \theta e^{\pm i\phi}$                         |
| 2   | 0       | $\left(\frac{5}{16\pi}\right)^{1/2} (3 \cos^2 \theta - 1)$                                |
|     | $\pm 1$ | $\mp \left(\frac{15}{8\pi}\right)^{1/2} \cos \theta \sin \theta e^{\pm i\phi}$            |
|     | $\pm 2$ | $\left(\frac{15}{32\pi}\right)^{1/2} \sin^2 \theta e^{\pm 2i\phi}$                        |
| 3   | 0       | $\left(\frac{7}{16\pi}\right)^{1/2} (5 \cos^3 \theta - 3 \cos \theta)$                    |
|     | $\pm 1$ | $\mp \left(\frac{21}{64\pi}\right)^{1/2} (5 \cos^2 \theta - 1) \sin \theta e^{\pm i\phi}$ |
|     | $\pm 2$ | $\left(\frac{105}{32\pi}\right)^{1/2} \sin^2 \theta \cos \theta e^{\pm 2i\phi}$           |
|     | $\pm 3$ | $\mp \left(\frac{35}{64\pi}\right)^{1/2} \sin^3 \theta e^{\pm 3i\phi}$                    |

The spherical harmonics are orthogonal and normalized in the following sense:

$$\int_0^\pi \int_0^{2\pi} Y_{l,m_l}(\theta, \phi)^* Y_{l',m_l'}(\theta, \phi) \sin \theta d\theta d\phi = \delta_{ll'} \delta_{m_l m_l'}$$

An important 'triple integral' is

$$\int_0^\pi \int_0^{2\pi} Y_{l,m_l}(\theta, \phi)^* Y_{l',m_l'}(\theta, \phi) Y_{l'',m_l''}(\theta, \phi) \sin \theta d\theta d\phi = 0 \quad \text{unless} \quad m_l'' = m_l' + m_l$$

and we can form a triangle with sides of lengths  $l'', l'$ , and  $l$  (such as 1, 2, and 3 or 1, 1, and 1, but not 1, 2, and 4).

**A brief comment**

The real and imaginary components of the  $\Phi$  component of the wavefunctions,  $e^{im_l\phi} = \cos m_l\phi + i \sin m_l\phi$ , each have  $|m_l|$  angular nodes, but these nodes are not seen when we plot the probability density, because  $|e^{im_l\phi}|^2 = 1$ .

**Fig. 8.33** A representation of the wavefunctions of a particle on the surface of a sphere that emphasizes the location of angular nodes: dark and light shading correspond to different signs of the wavefunction. Note that the number of nodes increases as the value of  $l$  increases. All these wavefunctions correspond to  $m_l = 0$ ; a path round the vertical  $z$ -axis of the sphere does not cut through any nodes.

Figure 8.33 is a representation of the spherical harmonics for  $l = 0$  to 4 and  $m_l = 0$ , which emphasizes how the number of angular nodes (the angles at which the wavefunction passes through zero) increases as the value of  $l$  increases. There are no angular nodes around the  $z$ -axis for functions with  $m_l = 0$ , which corresponds to there being no component of orbital angular momentum about that axis. Figure 8.34 shows the distribution of the particle of a given angular momentum in more detail. In this representation, the value of  $|Y_{l,m_l}|^2$  at each value of  $\theta$  and  $\phi$  is proportional to the distance of the surface from the origin. Note how, for a given value of  $l$ , the most probable location of the particle migrates towards the  $xy$ -plane as the value of  $|m_l|$  increases.

It also follows from the solution of the Schrödinger equation that the energy  $E$  of the particle is restricted to the values

$$E = l(l+1) \frac{\hbar^2}{2I} \quad l = 0, 1, 2, \dots$$

Energy levels of a particle on a sphere

 (8.53)

We see that the energy is quantized, and that it is independent of  $m_l$ . Because there are  $2l+1$  different wavefunctions (one for each value of  $m_l$ ) that correspond to the same energy, it follows that a level with quantum number  $l$  is  $(2l+1)$ -fold degenerate.

**(b) Angular momentum**

The energy of a rotating particle is related classically to its angular momentum  $J$  by  $E = J^2/2I$ . Therefore, by comparing this equation with eqn 8.53, we can deduce that, because the energy is quantized, then so too is the magnitude of the angular momentum, and confined to the values

$$\{l(l+1)\}^{1/2}\hbar \quad l = 0, 1, 2, \dots$$

Magnitude of angular momentum

 (8.54a)

We have already seen (in the context of rotation in a plane) that the angular momentum about the  $z$ -axis is quantized, and that it has the values

$$m_l\hbar \quad m_l = l, l-1, \dots, -l$$

$z$ -Component of angular momentum

 (8.54b)

The fact that the number of nodes in  $\psi_{l,m_l}(\theta, \phi)$  increases with  $l$  reflects the fact that higher angular momentum implies higher kinetic energy, and therefore a more sharply curved wavefunction. We can also see that the states corresponding to high angular momentum around the  $z$ -axis are those in which the most nodal lines cut the equator: a high kinetic energy now arises from motion parallel to the equator because the curvature is greatest in that direction.

**• A brief illustration**

Under certain circumstances, the particle on a sphere is a reasonable model for the description of the rotation of diatomic molecules. Consider, for example, the rotation of a  $^1\text{H}^{127}\text{I}$  molecule: because of the large difference in atomic masses, it is appropriate to picture the  $^1\text{H}$  atom as orbiting a stationary  $^{127}\text{I}$  atom at a distance  $r = 160$  pm, the equilibrium bond distance. The moment of inertia of  $^1\text{H}^{127}\text{I}$  is then  $I = m_{\text{H}}r^2 = 4.288 \times 10^{-47}$  kg m<sup>2</sup>. It follows that

$$\frac{\hbar^2}{2I} = \frac{(1.054\,57 \times 10^{-34} \text{ J s})^2}{2 \times (4.288 \times 10^{-47} \text{ kg m}^2)} = 1.297 \times 10^{-22} \text{ J}$$

or 0.1297 zJ. This energy corresponds to 78.09 J mol<sup>-1</sup>. From eqn 8.53, the first few rotational energy levels are therefore 0 ( $l=0$ ), 0.2594 zJ ( $l=1$ ), 0.7782 zJ ( $l=2$ ), and 1.556 zJ ( $l=3$ ). The degeneracies of these levels are 1, 3, 5, and 7, respectively (from  $2l+1$ ) and

**Fig. 8.34** A more complete representation of the wavefunctions for  $l = 0, 1, 2$ , and  $3$ . The distance of a point on the surface from the origin is proportional to the square modulus of the amplitude of the wavefunction at that point.

 **InterActivity** Plot the first ten energy levels of a particle on spheres of different radius  $r$ . Which of the following statements are true: (a) for a given value of  $r$ , the energy separation between adjacent levels decreases with increasing  $l$ , (b) increasing  $r$  leads to a decrease in the value of the energy for each level, (c) the energy difference between adjacent levels increases as  $r$  increases?

the magnitudes of the angular momentum of the molecule are  $0, 2^{1/2}\hbar, 6^{1/2}\hbar$ , and  $(12)^{1/2}\hbar$  (from eqn 8.54a). It follows from our calculations that the  $l = 0$  and  $l = 1$  levels are separated by  $\Delta E = 0.2594$  zJ. A transition between these two rotational levels of the molecule can be brought about by the emission or absorption of a photon with a frequency given by the Bohr frequency condition (eqn 7.14):

$$\nu = \frac{\Delta E}{h} = \frac{2.594 \times 10^{-22} \text{ J}}{6.626 \times 10^{-34} \text{ J s}} = 3.915 \times 10^{11} \text{ Hz} = 391.5 \text{ GHz}$$

Radiation with this frequency belongs to the microwave region of the electromagnetic spectrum, so microwave spectroscopy is a convenient method for the study of molecular rotations. Because the transition energies depend on the moment of inertia, microwave spectroscopy is a very accurate technique for the determination of bond lengths. We discuss rotational spectra further in Chapter 12. •

**Self-test 8.8** Repeat the calculation for a  $^2\text{H}^{127}\text{I}$  molecule (same bond length as  $^1\text{H}^{127}\text{I}$ ).

[Energies are smaller by a factor of two; same angular momenta and numbers of components]

**Fig. 8.35** The permitted orientations of angular momentum when  $l=2$ . We shall see soon that this representation is too specific because the azimuthal orientation of the vector (its angle around  $z$ ) is indeterminate.

**Fig. 8.36** (a) The experimental arrangement for the Stern-Gerlach experiment: the magnet provides an inhomogeneous field. (b) The classically expected result. (c) The observed outcome using silver atoms.

### (c) Space quantization

The result that  $m_l$  is confined to the values  $l, l-1, \dots, -l$  for a given value of  $l$  means that the component of angular momentum about the  $z$ -axis may take only  $2l+1$  values. If the angular momentum is represented by a vector of length proportional to its magnitude (that is, of length  $\{l(l+1)\}^{1/2}$  units), then to represent correctly the value of the component of angular momentum, the vector must be oriented so that its projection on the  $z$ -axis is of length  $m_l$  units. In classical terms, this restriction means that the plane of rotation of the particle can take only a discrete range of orientations (Fig. 8.35). The remarkable implication is that the orientation of a rotating body is quantized.

The quantum mechanical result that a rotating body may not take up an arbitrary orientation with respect to some specified axis (for example, an axis defined by the direction of an externally applied electric or magnetic field) is called **space quantization**. It had already been observed in an experiment performed by Otto Stern and Walther Gerlach in 1921, who had shot a beam of silver atoms through an inhomogeneous magnetic field (Fig. 8.36). The idea behind the experiment was that a rotating, charged body behaves like a magnet and interacts with the applied magnetic field. According to classical mechanics, because the orientation of the angular momentum can take any value, the associated magnet can take any orientation. Because the direction in which the magnet is driven by the applied inhomogeneous magnetic field depends on the former's orientation, it follows that a broad band of atoms is expected to emerge from the region where the magnetic field acts. In their first experiment, Stern and Gerlach appeared to confirm the classical prediction. However, the experiment is difficult because collisions between the atoms in the beam blurs the bands. When the experiment was repeated with a beam of very low intensity (so that collisions were less frequent) they observed discrete bands, as quantum mechanics was in due course able to explain.

### (d) The vector model

Throughout the preceding discussion, we have referred to the  $z$ -component of angular momentum (the component about an arbitrary axis, which is conventionally denoted  $z$ ), and have made no reference to the  $x$ - and  $y$ -components (the components about the two axes perpendicular to  $z$ ). The reason for this omission is found by examining the operators for the three components, each one being given by a term like that in eqn 8.45:

$$\hat{l}_x = \frac{\hbar}{i} \left( y \frac{\partial}{\partial z} - z \frac{\partial}{\partial y} \right) \quad \hat{l}_y = \frac{\hbar}{i} \left( z \frac{\partial}{\partial x} - x \frac{\partial}{\partial z} \right) \quad \hat{l}_z = \frac{\hbar}{i} \left( x \frac{\partial}{\partial y} - y \frac{\partial}{\partial x} \right) \quad (8.55)$$

Angular momentum operators

As you are invited to show in Problem 8.27, these three operators do not commute with one another:

$$[\hat{l}_x, \hat{l}_y] = i\hbar \hat{l}_z \quad [\hat{l}_y, \hat{l}_z] = i\hbar \hat{l}_x \quad [\hat{l}_z, \hat{l}_x] = i\hbar \hat{l}_y \quad (8.56a)$$

Angular momentum commutation relations

Therefore, we cannot specify more than one component (unless  $l=0$ ). In other words,  $\hat{l}_x$ ,  $\hat{l}_y$ , and  $\hat{l}_z$  are complementary observables. On the other hand, the operator for the square of the magnitude of the angular momentum is

$$\hat{l}^2 = \hat{l}_x^2 + \hat{l}_y^2 + \hat{l}_z^2 = \hbar^2 \Lambda^2 \quad (8.56b)$$

where  $\Lambda^2$  is the legendrian in eqn 8.51b. This operator does commute with all three components:

$$[\hat{l}^2, \hat{l}_q] = 0 \quad q = x, y, \text{ and } z \quad (8.56c)$$

(See Problem 8.29.) Therefore, although we may specify the magnitude of the angular momentum and any of its components if  $l_z$  is known, then it is impossible to ascribe values to the other two components. It follows that the illustration in Fig. 8.35, which is summarized in Fig. 8.37a, gives a false impression of the state of the system, because it suggests definite values for the  $x$ - and  $y$ -components. A better picture must reflect the impossibility of specifying  $l_x$  and  $l_y$  if  $l_z$  is known.

The **vector model** of angular momentum uses pictures like that in Fig. 8.37b. The cones are drawn with side  $\{l(l+1)\}^{1/2}$  units, and represent the magnitude of the angular momentum. Each cone has a definite projection (of  $m_l$  units) on the  $z$ -axis, representing the system's precise value of  $l_z$ . The  $l_x$  and  $l_y$  projections, however, are indefinite. The vector representing the state of angular momentum can be thought of as lying with its tip on any point on the mouth of the cone. At this stage it should not be thought of as sweeping round the cone; that aspect of the model will be added later when we allow the picture to convey more information.

## 8.8 Spin

**Key points** Spin is an intrinsic angular momentum of a fundamental particle. A fermion is a particle with a half-integral spin quantum number; a boson is a particle with an integral spin quantum number. For an electron, the spin quantum number is  $s = \frac{1}{2}$ . The spin magnetic quantum number is  $m_s = s, s-1, \dots, -s$ ; for an electron,  $m_s = \pm \frac{1}{2}$ .

Stern and Gerlach observed two bands of Ag atoms in their experiment. This observation seems to conflict with one of the conclusions from quantum mechanics, because an angular momentum  $l$  gives rise to  $2l+1$  orientations, which is equal to 2 only if  $l = \frac{1}{2}$ , contrary to the conclusion that  $l$  must be an integer. The conflict was resolved by the suggestion that the angular momentum they were observing was not due to orbital angular momentum (the motion of an electron around the atomic nucleus) but arose instead from the motion of the electron about its own axis. This intrinsic angular momentum of the electron is called its **spin**. The explanation of the existence of spin emerged when Dirac combined quantum mechanics with special relativity and established the theory of relativistic quantum mechanics.

The spin of an electron about its own axis does not have to satisfy the same boundary conditions as those for a particle circulating around a central point, so the quantum number for spin angular momentum is subject to different restrictions. To distinguish this spin angular momentum from orbital angular momentum we use the **spin quantum number**  $s$  (in place of  $l$ ; like  $l$ ,  $s$  is a non-negative number) and  $m_s$ , the **spin magnetic quantum number**, for the projection on the  $z$ -axis. The magnitude of the spin angular momentum is  $\{s(s+1)\}^{1/2}\hbar$  and the component  $m_s\hbar$  is restricted to the  $2s+1$  values with

$$m_s = s, s-1, \dots, -s \quad (8.57)$$

The detailed analysis of the spin of a particle is sophisticated and shows that the property should not be taken to be an actual spinning motion. It is better to regard 'spin' as an intrinsic property like mass and charge. However, the picture of an actual spinning motion can be very useful when used with care. For an electron it turns out that only one value of  $s$  is allowed, namely,  $s = \frac{1}{2}$ , corresponding to an angular momentum of magnitude  $(\frac{3}{4})^{1/2}\hbar = 0.866\hbar$ . This spin angular momentum is an intrinsic

**Fig. 8.37** (a) A summary of Fig. 8.35. However, because the azimuthal angle of the vector around the  $z$ -axis is indeterminate, a better representation is as in (b), where each vector lies at an unspecified azimuthal angle on its cone.

**Fig. 8.38** An electron spin ( $s = \frac{1}{2}$ ) can take only two orientations with respect to a specified axis. An  $\alpha$  electron (top) is an electron with  $m_s = +\frac{1}{2}$ ; a  $\beta$  electron (bottom) is an electron with  $m_s = -\frac{1}{2}$ . The vector representing the spin angular momentum lies at an angle of  $55^\circ$  to the  $z$ -axis (more precisely, the half-angle of the cones is  $\arccos(\frac{1}{3}^{1/2})$ ).

property of the electron, like its rest mass and its charge, and every electron has exactly the same value: the magnitude of the spin angular momentum of an electron cannot be changed. The spin may lie in  $2s + 1 = 2$  different orientations (Fig. 8.38). One orientation corresponds to  $m_s = +\frac{1}{2}$  (this state is often denoted  $\alpha$  or  $\uparrow$ ); the other orientation corresponds to  $m_s = -\frac{1}{2}$  (this state is denoted  $\beta$  or  $\downarrow$ ).

The outcome of the Stern–Gerlach experiment can now be explained if we suppose that each Ag atom possesses an angular momentum due to the spin of a single electron, because the two bands of atoms then correspond to the two spin orientations. Why the atoms behave like this is explained in Chapter 9 (but it is already probably familiar from introductory chemistry that the ground-state configuration of a silver atom is  $[\text{Kr}]4d^{10}5s^1$ , a single unpaired electron outside a closed shell).

Like the electron, other elementary particles have characteristic spin. For example, protons and neutrons are spin- $\frac{1}{2}$  particles (that is,  $s = \frac{1}{2}$ ) and invariably spin with angular momentum  $(\frac{3}{4})^{1/2}\hbar = 0.866\hbar$ . Because the masses of a proton and a neutron are so much greater than the mass of an electron, yet they all have the same spin angular momentum, the classical picture would be of these two particles spinning much more slowly than an electron. Some elementary particles have  $s = 1$ , and so have an intrinsic angular momentum of magnitude  $2^{1/2}\hbar$ . Some mesons are spin-1 particles (as are some atomic nuclei), but for our purposes the most important spin-1 particle is the photon. From the discussion in this chapter, we see that the photon has zero rest mass, zero charge, an energy  $h\nu$ , a linear momentum  $h/\lambda$  or  $h\nu/c$ , an intrinsic angular momentum of  $2^{1/2}\hbar$ , and travels at the speed  $c$ . We shall see the importance of photon spin in the next chapter.

Particles with half-integral spin are called **fermions** and those with integral spin (including 0) are called **bosons**. Thus, electrons and protons are fermions and photons are bosons. It is a very deep feature of nature that all the elementary particles that constitute matter are fermions, whereas the elementary particles that are responsible for the forces that bind fermions together are all bosons. Photons, for example, transmit the electromagnetic force that binds together electrically charged particles. Matter, therefore, is an assembly of fermions held together by forces conveyed by bosons.

The properties of angular momentum that we have developed are set out in Table 8.3. As mentioned there, when we use the quantum numbers  $l$  and  $m_l$  we shall mean orbital angular momentum (circulation in space). When we use  $s$  and  $m_s$  we shall mean spin angular momentum (intrinsic angular momentum). When we use  $j$  and  $m_j$  we shall mean either (or, in some contexts to be described in Chapter 9, a combination of orbital and spin momenta).

**Table 8.3** Properties of the angular momentum of an electron

| Quantum number           | Symbol† | Values                     | Specifies                          |
|--------------------------|---------|----------------------------|------------------------------------|
| Orbital angular momentum | $l$     | $0, 1, 2, \dots$ ‡         | Magnitude, $\{l(l+1)\}^{1/2}\hbar$ |
| Magnetic                 | $m_l$   | $l, l-1, \dots, -l$        | Component on $z$ -axis, $m_l\hbar$ |
| Spin                     | $s$     | $\frac{1}{2}$              | Magnitude, $\{s(s+1)\}^{1/2}\hbar$ |
| Spin magnetic            | $m_s$   | $\pm\frac{1}{2}$           | Component on $z$ -axis, $m_s\hbar$ |
| Total*                   | $j$     | $l+s, l+s-1, \dots,  l-s $ | Magnitude, $\{j(j+1)\}^{1/2}\hbar$ |
| Total magnetic           | $m_j$   | $j, j-1, \dots, -j$        | Component on $z$ -axis, $m_j\hbar$ |

\* To combine two angular momenta, use the Clebsch–Gordan series (see Section 9.10a):

$$j = j_1 + j_2, j_1 + j_2 - 1, \dots, |j_1 - j_2|$$

† For many-electron systems, the quantum numbers are designated by upper-case letters ( $L, M_L, S, M_S$ , etc.).

‡ Note that the quantum numbers for magnitude ( $l, s, j$ , etc.) are never negative.

## Checklist of key equations

| Property                                                           | Equation                                                                                   | Comment                                                                          |

| Wavefunctions of a particle in a one-dimensional box of length $L$ | $\psi_n(x) = (2/L)^{1/2} \sin(n\pi x/L)$                                                   | $n = 1, 2, \dots$                                                                |
| Energies of a particle in a one-dimensional box of length $L$      | $E_n = n^2 \hbar^2 / 8mL^2$                                                                | $n = 1, 2, \dots$                                                                |
| Wavefunctions of a particle in a two-dimensional box               | $\psi_{n_1, n_2}(x, y) = \{2/(L_1 L_2)\}^{1/2} \sin(n_1 \pi x/L_1) \sin(n_2 \pi y/L_2)$    | $n_1 = 1, 2, \dots, n_2 = 1, 2, \dots$<br>$0 \leq x \leq L_1, 0 \leq y \leq L_2$ |
| Energies of a particle in a two-dimensional box                    | $E_{n_1, n_2} = (n_1^2/L_1^2 + n_2^2/L_2^2)(\hbar^2/8m)$                                   | $n_1 = 1, 2, \dots, n_2 = 1, 2, \dots$<br>$0 \leq x \leq L_1, 0 \leq y \leq L_2$ |
| Wavefunctions of a harmonic oscillator                             | $\psi_v(x) = N_v H_v(y) e^{-y^2/2}, \quad y = x/\alpha, \quad \alpha = (\hbar^2/mk)^{1/4}$ | The Hermite polynomials $H_v(y)$ are listed in Table 8.1                         |
| Energies of a harmonic oscillator                                  | $E_v = (v + 1/2)\hbar\omega, \quad \omega = (k_f/m)^{1/2}$                                 | $v = 0, 1, 2, \dots$                                                             |
| Wavefunctions of a particle on a ring                              | $\psi_{m_l}(\phi) = (1/2\pi)^{1/2} e^{im_l \phi}$                                          | $m_l = 0, \pm 1, \pm 2, \dots$                                                   |
| Energies of a particle on a ring                                   | $E = m_l^2 \hbar^2 / 2I$                                                                   | $I = mr^2$ and $m_l = 0, \pm 1, \pm 2, \dots$                                    |
| Angular momentum of a particle on a ring                           | $J_z = m_l \hbar$                                                                          | $m_l = 0, \pm 1, \pm 2, \dots$                                                   |
| Wavefunctions of a particle on a sphere                            | Spherical harmonics: $Y_{l, m_l}(\theta, \phi)$                                            | See Table 8.2                                                                    |
| Energies of a particle on a sphere                                 | $E = l(l+1)\hbar^2/2I$                                                                     | $l = 0, 1, 2, \dots$                                                             |
| Magnitude of the angular momentum of a particle on a sphere        | $\{l(l+1)\}^{1/2} \hbar$                                                                   | $l = 0, 1, 2, \dots$                                                             |
| $z$ -component of the angular momentum of a particle on a sphere   | $m_l \hbar$                                                                                | $m_l = l, l-1, \dots, -l$                                                        |

## Discussion questions

- 8.1** Discuss the physical origin of quantization energy for a particle confined to moving inside a one-dimensional box or on a ring.
- 8.2** In what ways does the quantum mechanical description of a harmonic oscillator merge with its classical description at high quantum numbers?
- 8.3** Define, justify, and provide examples of zero-point energy.
- 8.4** Discuss the physical origins of quantum mechanical tunnelling. Why is tunnelling more likely to contribute to the mechanisms of electron transfer

and proton transfer processes than to mechanisms of group transfer reactions, such as  $AB + C \rightarrow A + BC$  (where A, B, and C are large molecular groups)?

- 8.5** Distinguish between a fermion and a boson. Provide examples of each type of particle. What are the consequences of the difference between the types of particles?
- 8.6** Describe the features that stem from nanometre-scale dimensions that are not found in macroscopic objects.

## Exercises

**8.1(a)** Calculate the energy separations in joules, kilojoules per mole, electronvolts, and reciprocal centimetres between the levels (a)  $n = 2$  and  $n = 1$ , (b)  $n = 6$  and  $n = 5$  of an electron in a box of length 1.0 nm.

**8.1(b)** Calculate the energy separations in joules, kilojoules per mole, electronvolts, and reciprocal centimetres between the levels (a)  $n = 3$  and  $n = 1$ , (b)  $n = 7$  and  $n = 6$  of an electron in a box of length 1.50 nm.

**8.2(a)** Calculate the probability that a particle will be found between  $0.49L$  and  $0.51L$  in a box of length  $L$  when it has (a)  $n = 1$ , (b)  $n = 2$ . Take the wavefunction to be a constant in this range.

**8.2(b)** Calculate the probability that a particle will be found between  $0.65L$  and  $0.67L$  in a box of length  $L$  when it has (a)  $n = 1$ , (b)  $n = 2$ . Take the wavefunction to be a constant in this range.

**8.3(a)** Calculate the expectation values of  $p$  and  $p^2$  for a particle in the state  $n = 1$  in a square-well potential.

**8.3(b)** Calculate the expectation values of  $p$  and  $p^2$  for a particle in the state  $n = 2$  in a square-well potential.

**8.4(a)** Calculate the expectation values of  $x$  and  $x^2$  for a particle in the state  $n = 1$  in a square-well potential.

**8.4(b)** Calculate the expectation values of  $x$  and  $x^2$  for a particle in the state  $n = 2$  in a square-well potential.

**8.5(a)** An electron is confined to a square well of length  $L$ . What would be the length of the box such that the zero-point energy of the electron is equal to its rest mass energy,  $m_e c^2$ ? Express your answer in terms of the parameter  $\lambda_C = h/m_e c$ , the 'Compton wavelength' of the electron.

**8.5(b)** Repeat Exercise 8.5a for a general particle of mass  $m$  in a cubic box.

**8.6(a)** What are the most likely locations of a particle in a box of length  $L$  in the state  $n = 3$ ?

**8.6(b)** What are the most likely locations of a particle in a box of length  $L$  in the state  $n = 5$ ?

**8.7(a)** Calculate the percentage change in a given energy level of a particle in a one-dimensional box when the length of the box is increased by 10 per cent.

**8.7(b)** Calculate the percentage change in a given energy level of a particle in a cubic box when the length of the edge of the cube is decreased by 10 per cent in each direction.

**8.8(a)** What is the value of  $n$  of a particle in a one-dimensional box such that the separation between neighbouring levels is equal to the energy of thermal motion ( $\frac{1}{2}kT$ ).

**8.8(b)** A nitrogen molecule is confined in a cubic box of volume  $1.00 \text{ m}^3$ . Assuming that the molecule has an energy equal to  $\frac{3}{2}kT$  at  $T = 300 \text{ K}$ , what is the value of  $n = (n_x^2 + n_y^2 + n_z^2)^{1/2}$  for this molecule? What is the energy separation between the levels  $n$  and  $n + 1$ ? What is its de Broglie wavelength?

**8.9(a)** Calculate the zero-point energy of a harmonic oscillator consisting of a particle of mass  $2.33 \times 10^{-26} \text{ kg}$  and force constant  $155 \text{ N m}^{-1}$ .

**8.9(b)** Calculate the zero-point energy of a harmonic oscillator consisting of a particle of mass  $5.16 \times 10^{-26} \text{ kg}$  and force constant  $285 \text{ N m}^{-1}$ .

**8.10(a)** For a certain harmonic oscillator of effective mass  $1.33 \times 10^{-25} \text{ kg}$ , the difference in adjacent energy levels is  $4.82 \text{ zJ}$ . Calculate the force constant of the oscillator.

**8.10(b)** For a certain harmonic oscillator of effective mass  $2.88 \times 10^{-25} \text{ kg}$ , the difference in adjacent energy levels is  $3.17 \text{ zJ}$ . Calculate the force constant of the oscillator.

**8.11(a)** Calculate the wavelength of a photon needed to excite a transition between neighbouring energy levels of a harmonic oscillator of effective mass equal to that of a proton ( $1.0078m_u$ ) and force constant  $855 \text{ N m}^{-1}$ .

**8.11(b)** Calculate the wavelength of a photon needed to excite a transition between neighbouring energy levels of a harmonic oscillator of effective mass equal to that of an oxygen atom ( $15.9949m_u$ ) and force constant  $544 \text{ N m}^{-1}$ .

**8.12(a)** The vibrational frequency of  $\text{H}_2$  is  $131.9 \text{ THz}$ . What is the vibrational frequency of  $\text{D}_2$  ( $\text{D} = {}^2\text{H}$ )?

**8.12(b)** The vibrational frequency of  $\text{H}_2$  is  $131.9 \text{ THz}$ . What is the vibrational frequency of  $\text{T}_2$  ( $\text{T} = {}^3\text{H}$ )?

**8.13(a)** Calculate the minimum excitation energies of (a) a pendulum of length  $1.0 \text{ m}$  on the surface of the Earth, (b) the balance-wheel of a clockwork watch ( $\nu = 5 \text{ Hz}$ ).

**8.13(b)** Calculate the minimum excitation energies of (a) the  $33 \text{ kHz}$  quartz crystal of a watch, (b) the bond between two O atoms in  $\text{O}_2$ , for which  $k_f = 1177 \text{ N m}^{-1}$ .

**8.14(a)** Confirm that the wavefunction for the ground state of a one-dimensional linear harmonic oscillator given in Table 8.1 is a solution of the Schrödinger equation for the oscillator and that its energy is  $\frac{1}{2}\hbar\omega$ .

**8.14(b)** Confirm that the wavefunction for the first excited state of a one-dimensional linear harmonic oscillator given in Table 8.1 is a solution of the Schrödinger equation for the oscillator and that its energy is  $\frac{3}{2}\hbar\omega$ .

**8.15(a)** Locate the nodes of the harmonic oscillator wavefunction with  $\nu = 4$ .

**8.15(b)** Locate the nodes of the harmonic oscillator wavefunction with  $\nu = 5$ .

**8.16(a)** What are the most probable displacements of a harmonic oscillator with  $\nu = 1$ ?

**8.16(b)** What are the most probable displacements of a harmonic oscillator with  $\nu = 3$ ?

**8.17(a)** Assuming that the vibrations of a  ${}^{35}\text{Cl}_2$  molecule are equivalent to those of a harmonic oscillator with a force constant  $k = 329 \text{ N m}^{-1}$ , what is the zero-point energy of vibration of this molecule? The effective mass of a homonuclear diatomic molecule is half its total mass, and  $m({}^{35}\text{Cl}) = 34.9688m_u$ .

**8.17(b)** Assuming that the vibrations of a  ${}^{14}\text{N}_2$  molecule are equivalent to those of a harmonic oscillator with a force constant  $k = 2293.8 \text{ N m}^{-1}$ , what is the zero-point energy of vibration of this molecule? The effective mass of a homonuclear diatomic molecule is half its total mass, and  $m({}^{14}\text{N}) = 14.0031m_u$ .

**8.18(a)** The wavefunction,  $\psi(\phi)$ , for the motion of a particle in a ring is of the form  $\psi = Ne^{im\phi}$ . Determine the normalization constant,  $N$ .

**8.18(b)** Confirm that wavefunctions for a particle in a ring with different values of the quantum number  $m_l$  are mutually orthogonal.

**8.19(a)** Calculate the minimum excitation energy of a proton constrained to rotate in a circle of radius  $100 \text{ pm}$  around a fixed point.

**8.19(b)** Calculate the value of  $|m_l|$  for the system described in the preceding exercise corresponding to a rotational energy equal to the classical average energy at  $25^\circ\text{C}$  (which is equal to  $\frac{1}{2}kT$ ).

**8.20(a)** Estimate the rotational quantum number of a bicycle wheel of diameter  $60 \text{ cm}$  and mass  $1.0 \text{ kg}$  when the bicycle is travelling at  $20 \text{ km h}^{-1}$ .

**8.20(b)** The mass of a vinyl gramophone record is  $130 \text{ g}$  and its diameter is  $30 \text{ cm}$ . Given that the moment of inertia of a solid uniform disc of mass  $m$  and radius  $r$  is  $I = \frac{1}{2}mr^2$ , estimate the rotational quantum number when the disc is rotating at  $33 \text{ r.p.m.}$

**8.21(a)** The moment of inertia of a  $\text{CH}_4$  molecule is  $5.27 \times 10^{-47} \text{ kg m}^2$ . What is the minimum energy needed to start it rotating?

**8.21(b)** The moment of inertia of an  $\text{SF}_6$  molecule is  $3.07 \times 10^{-45} \text{ kg m}^2$ . What is the minimum energy needed to start it rotating?

**8.22(a)** Use the data in Exercise 8.21a to calculate the energy needed to excite a  $\text{CH}_4$  molecule from a state with  $l = 1$  to a state with  $l = 2$ .

**8.22(b)** Use the data in Exercise 8.21b to calculate the energy needed to excite an  $\text{SF}_6$  molecule from a state with  $l = 2$  to a state with  $l = 3$ .

**8.23(a)** What is the magnitude of the angular momentum of a  $\text{CH}_4$  molecule when it is rotating with its minimum energy?

**8.23(b)** What is the magnitude of the angular momentum of an  $\text{SF}_6$  molecule when it is rotating with its minimum energy?

**8.24(a)** Draw scale vector diagrams to represent the states (a)  $s = \frac{1}{2}$ ,  $m_s = +\frac{1}{2}$ , (b)  $l = 1$ ,  $m_l = +1$ , (c)  $l = 2$ ,  $m_l = 0$ .

**8.24(b)** Draw the vector diagram for all the permitted states of a particle with  $l = 6$ .

## Problems\*

### Numerical problems

**8.1** Calculate the separation between the two lowest levels for an  $\text{O}_2$  molecule in a one-dimensional container of length 5.0 cm. At what value of  $n$  does the energy of the molecule reach  $\frac{1}{2}kT$  at 300 K, and what is the separation of this level from the one immediately below?

**8.2** The mass to use in the expression for the vibrational frequency of a diatomic molecule is the effective mass  $\mu = m_A m_B / (m_A + m_B)$ , where  $m_A$  and  $m_B$  are the masses of the individual atoms. The following data on the infrared absorption wavenumbers (wavenumbers in  $\text{cm}^{-1}$ ) of molecules are taken from *Spectra of diatomic molecules*, G. Herzberg, van Nostrand (1950):

|                          |                          |             |             |             |
|--------------------------|--------------------------|-------------|-------------|-------------|
| $\text{H}^{35}\text{Cl}$ | $\text{H}^{81}\text{Br}$ | $\text{HI}$ | $\text{CO}$ | $\text{NO}$ |
| 2990                     | 2650                     | 2310        | 2170        | 1904        |

Calculate the force constants of the bonds and arrange them in order of increasing stiffness.

**8.3** The rotation of an  $^1\text{H}^{127}\text{I}$  molecule can be pictured as the orbital motion of an H atom at a distance 160 pm from a stationary I atom. (This picture is quite good; to be precise, both atoms rotate around their common centre of mass, which is very close to the I nucleus.) Suppose that the molecule rotates only in a plane. Calculate the energy needed to excite the molecule into rotation. What, apart from 0, is the minimum angular momentum of the molecule?

**8.4** Calculate the energies of the first four rotational levels of  $^1\text{H}^{127}\text{I}$  free to rotate in three dimensions, using for its moment of inertia  $I = \mu R^2$ , with  $\mu = m_{\text{H}} m_{\text{I}} / (m_{\text{H}} + m_{\text{I}})$  and  $R = 160$  pm.

**8.5** Use mathematical software to construct a wavepacket for a particle rotating on a circle of the form

$$\Psi(\phi, t) = \sum_{m_l=0}^{m_{l,\max}} c_{m_l} e^{i(m_l \phi - E_{m_l} t / \hbar)} \quad E_{m_l} = m_l^2 \hbar^2 / 2I$$

with coefficients  $c$  of your choice (for example, all equal). Explore how the wavepacket migrates on the ring but spreads with time.

**8.6** Use mathematical software to construct a harmonic oscillator wavepacket of the form

$$\Psi(x, t) = \sum_{v=0}^N c_v \psi_v(x) e^{iE_v t / \hbar}$$

where the wavefunctions and energies are those of a harmonic oscillator and with coefficients  $c$  of your choice (for example, all equal). Explore how the wavepacket oscillates to and fro.

### Theoretical problems

**8.7** Suppose that 1.0 mol perfect gas molecules all occupy the lowest energy level of a cubic box. How much work must be done to change the volume of the box by  $\Delta V$ ? Would the work be different if the molecules all occupied a state  $n \neq 1$ ? What is the relevance of this discussion to the expression for the expansion work discussed in Chapter 2? Can you identify a distinction between adiabatic and isothermal expansion?

**8.8** Derive eqn 8.19a, the expression for the transmission probability, and show that when  $\kappa L \gg 1$  it reduces to eqn 8.19b.

**8.9†** Consider the one-dimensional space in which a particle can experience one of three potentials depending upon its position. They are:  $V = 0$  for  $-\infty < x \leq 0$ ,  $V = V_2$  for  $0 \leq x \leq L$ , and  $V = V_3$  for  $L \leq x < \infty$ . The particle wavefunction is to have both a component  $e^{ik_1 x}$  that is incident upon the barrier  $V_2$  and a reflected component  $e^{-ik_1 x}$  in region 1 ( $-\infty < x \leq 0$ ). In region 3 the wavefunction has only a forward component,  $e^{ik_3 x}$ , which represents a particle that has traversed the barrier. The energy of the particle,  $E$ , is somewhere in the range of the  $V_2 > E > V_3$ . The transmission probability,  $T$ , is the ratio of the square modulus of the region 3 amplitude to the square modulus of the incident amplitude. (a) Base your calculation on the continuity of the amplitudes and the slope of the wavefunction at the locations of the zone boundaries and derive a general equation for  $T$ . (b) Show that the general equation for  $T$  reduces to eqn 8.19b in the high, wide barrier limit when  $V_1 = V_3 = 0$ . (c) Draw a graph of the probability of proton tunnelling when  $V_3 = 0$ ,  $L = 50$  pm, and  $E = 10$  kJ mol $^{-1}$  in the barrier range  $E < V_2 < 2E$ .

**8.10** The wavefunction inside a long barrier of height  $V$  is  $\psi = Ne^{-\kappa x}$ . Calculate (a) the probability that the particle is inside the barrier and (b) the average penetration depth of the particle into the barrier.

**8.11** Confirm that a function of the form  $e^{-gx^2}$  is a solution of the Schrödinger equation for the ground state of a harmonic oscillator and find an expression for  $g$  in terms of the mass and force constant of the oscillator.

**8.12** Calculate the mean kinetic energy of a harmonic oscillator by using the relations in Table 8.1.

**8.13** Calculate the values of  $\langle x^3 \rangle$  and  $\langle x^4 \rangle$  for a harmonic oscillator by using the relations in Table 8.1.

**8.14** Determine the values of  $\Delta x = (\langle x^2 \rangle - \langle x \rangle^2)^{1/2}$  and  $\Delta p = (\langle p^2 \rangle - \langle p \rangle^2)^{1/2}$  for (a) a particle in a box of length  $L$  and (b) a harmonic oscillator. Discuss these quantities with reference to the uncertainty principle.

**8.15** According to classical mechanics, the turning point,  $x_{\text{tp}}$ , of an oscillator occurs when its kinetic energy is zero, which is when its potential energy  $\frac{1}{2}kx^2$  is equal to its total energy  $E$ . This equality occurs when

$$x_{\text{tp}}^2 = \frac{2E}{k} \quad \text{or} \quad x_{\text{tp}} = \pm \left( \frac{2E}{k} \right)^{1/2}$$

with  $E$  given by eqn 8.24. The probability of finding the oscillator stretched beyond a displacement  $x_{\text{tp}}$  is the sum of the probabilities  $\psi^2 dx$  of finding it in any of the intervals  $dx$  lying between  $x_{\text{tp}}$  and infinity:

$$P = \int_{x_{\text{tp}}}^{\infty} \psi_v^2 dx$$

The variable of integration is best expressed in terms of  $y = x/\alpha$  with  $\alpha = (\hbar^2/mk)^{1/4}$ . (a) Show that the turning points lie at  $y_{\text{tp}} = \pm(2v+1)^{1/2}$ . (b) Go on to show that for the state of lowest energy ( $v=0$ ),  $y_{\text{tp}} = 1$  and the probability is  $P = \frac{1}{2}(1 - \text{erf}1)$ , where the *error function*,  $\text{erf} z$ , is defined as

$$\text{erf} z = 1 - \frac{2}{\pi^{1/2}} \int_z^{\infty} e^{-y^2} dy$$

The values of this function are tabulated and available in mathematical software packages.

**8.16** Extend the calculation in Problem 8.15 by using mathematical software to calculate the probability that a harmonic oscillator will be found outside

\* Problems denoted with the symbol † were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

the classically allowed displacements for general  $v$  and plot the probability as a function of  $v$ .

**8.17** The intensities of spectroscopic transitions between the vibrational states of a molecule are proportional to the square of the integral  $\int \psi_{v'} x \psi_v dx$  over all space. Use the relations between Hermite polynomials given in Table 8.1 to show that the only permitted transitions are those for which  $v' = v \pm 1$  and evaluate the integral in these cases.

**8.18** The potential energy of the rotation of one  $\text{CH}_3$  group relative to its neighbour in ethane can be expressed as  $V(\phi) = V_0 \cos 3\phi$ . Show that for small displacements the motion of the group is harmonic and calculate the energy of excitation from  $v = 0$  to  $v = 1$ . What do you expect to happen to the energy levels and wavefunctions as the excitation increases?

**8.19** Show that, whatever superposition of harmonic oscillator states is used to construct a wavepacket, it is localized at the same place at the times  $0, T, 2T, \dots$ , where  $T$  is the classical period of the oscillator.

**8.20** Use the virial theorem to obtain an expression for the relation between the mean kinetic and potential energies of an electron in a hydrogen atom.

**8.21** Evaluate the  $z$ -component of the angular momentum and the kinetic energy of a particle on a ring that is described by the (unnormalized) wavefunctions (a)  $e^{i\phi}$ , (b)  $e^{-2i\phi}$ , (c)  $\cos \phi$ , and (d)  $(\cos \chi)e^{i\phi} + (\sin \chi)e^{-i\phi}$ .

**8.22** Is the Schrödinger equation for a particle on an elliptical ring of semimajor axes  $a$  and  $b$  separable? *Hint.* Although  $r$  varies with angle  $\phi$ , the two are related by  $r^2 = a^2 \sin^2 \phi + b^2 \cos^2 \phi$ .

**8.23** Confirm that the spherical harmonics (a)  $Y_{0,0}$ , (b)  $Y_{2,-1}$ , and (c)  $Y_{3,+3}$  satisfy the Schrödinger equation for a particle free to rotate in three dimensions, and find its energy and angular momentum in each case.

**8.24** Confirm that  $Y_{3,+3}$  is normalized to 1. (The integration required is over the surface of a sphere.)

**8.25** Derive an expression in terms of  $l$  and  $m_l$  for the half-angle of the apex of the cone used to represent an angular momentum according to the vector model. Evaluate the expression for an  $\alpha$  spin. Show that the minimum possible angle approaches 0 as  $l \rightarrow \infty$ .

**8.26** Show that the function  $f = \cos ax \cos by \cos cz$  is an eigenfunction of  $\nabla^2$ , and determine its eigenvalue.

**8.27** Derive (in Cartesian coordinates) the quantum mechanical operators for the three components of angular momentum starting from the classical definition of angular momentum,  $\mathbf{l} = \mathbf{r} \times \mathbf{p}$ . Show that any two of the components do not mutually commute, and find their commutator.

**8.28** Starting from the operator  $\hat{L}_z = x p_y - y p_x$ , prove that in spherical polar coordinates  $\hat{L}_z = -i\hbar \partial / \partial \phi$ .

**8.29** Show that the commutator  $[\hat{L}_x^2, \hat{L}_z] = 0$ , and then, without further calculation, justify the remark that  $[\hat{L}_x^2, \hat{L}_q] = 0$  for all  $q = x, y$ , and  $z$ .

**8.30†** A particle is confined to move in a one-dimensional box of length  $L$ . (a) If the particle is classical, show that the average value of  $x$  is  $\frac{1}{2}L$  and that the root-mean square value is  $L/3^{1/2}$ . (b) Show that for large values of  $n$ , a quantum particle approaches the classical values. This result is an example of the correspondence principle, which states that, for very large values of the quantum numbers, the predictions of quantum mechanics approach those of classical mechanics.

### Applications: to biology and nanotechnology

**8.31** When  $\beta$ -carotene (1) is oxidized *in vivo*, it breaks in half and forms two molecules of retinal (vitamin A), which is a precursor to the pigment in the retina responsible for vision (see *Impact I13.1*). The conjugated system of retinal consists of 11 C atoms and one O atom. In the ground state of retinal,

1  $\beta$ -Carotene

each level up to  $n = 6$  is occupied by two electrons. Assuming an average internuclear distance of 140 pm, calculate (a) the separation in energy between the ground state and the first excited state in which one electron occupies the state with  $n = 7$ , and (b) the frequency of the radiation required to produce a transition between these two states. (c) Using your results, choose among the words in parentheses to generate a rule for the prediction of frequency shifts in the absorption spectra of linear polyenes:

The absorption spectrum of a linear polyene shifts to (higher/lower) frequency as the number of conjugated atoms (increases/decreases).

**8.32** Many biological electron transfer reactions, such as those associated with biological energy conversion, may be visualized as arising from electron tunnelling between protein-bound co-factors, such as cytochromes, quinones, flavins, and chlorophylls. This tunnelling occurs over distances that are often greater than 1.0 nm, with sections of protein separating electron donor from acceptor. For a specific combination of donor and acceptor, the rate of electron tunnelling is proportional to the transmission probability, with  $\kappa \approx 7 \text{ nm}^{-1}$  (eqn 8.19). By what factor does the rate of electron tunnelling between two co-factors increase as the distance between them changes from 2.0 nm to 1.0 nm?

**8.33** Carbon monoxide binds strongly to the  $\text{Fe}^{2+}$  ion of the haem group of the protein myoglobin. Estimate the vibrational frequency of CO bound to myoglobin by using the data in Problem 8.2 and by making the following assumptions: the atom that binds to the haem group is immobilized, the protein is infinitely more massive than either the C or O atom, the C atom binds to the  $\text{Fe}^{2+}$  ion, and binding of CO to the protein does not alter the force constant of the  $\text{C}\equiv\text{O}$  bond.

**8.34** Of the four assumptions made in Problem 8.33, the last two are questionable. Suppose that the first two assumptions are still reasonable and that you have at your disposal a supply of myoglobin, a suitable buffer in which to suspend the protein,  $^{12}\text{C}^{16}\text{O}$ ,  $^{13}\text{C}^{16}\text{O}$ ,  $^{12}\text{C}^{18}\text{O}$ ,  $^{13}\text{C}^{18}\text{O}$ , and an infrared spectrometer. Assuming that isotopic substitution does not affect the force constant of the  $\text{C}\equiv\text{O}$  bond, describe a set of experiments that: (a) proves which atom, C or O, binds to the haem group of myoglobin, and (b) allows for the determination of the force constant of the  $\text{C}\equiv\text{O}$  bond for myoglobin-bound carbon monoxide.

**8.35** The particle on a ring is a useful model for the motion of electrons around the porphine ring (2), the conjugated macrocycle that forms the structural basis of the haem group and the chlorophylls. We may treat the group as a circular ring of radius 440 pm, with 22 electrons in the conjugated system moving along the perimeter of the ring. In the ground state of the molecule each state is occupied by two electrons. (a) Calculate the energy and angular momentum of an electron in the highest occupied level. (b) Calculate the frequency of radiation that can induce a transition between the highest occupied and lowest unoccupied levels.

2 Porphine (free base form)

**8.36** When in Chapter 18 we come to study macromolecules, such as synthetic polymers, proteins, and nucleic acids, we shall see that one conformation is that of a random coil. For a one-dimensional random coil of  $N$  units, the restoring force at small displacements and at a temperature  $T$  is

$$F = -\frac{kT}{2l} \ln \left( \frac{N+n}{N-n} \right)$$

where  $l$  is the length of each monomer unit and  $nl$  is the distance between the ends of the chain. Show that for small extensions ( $n \ll N$ ) the restoring force is proportional to  $n$  and therefore the coil undergoes harmonic oscillation with force constant  $kT/Nl^2$ . Suppose that the mass to use for the vibrating chain is its total mass  $Nm$ , where  $m$  is the mass of one monomer unit, and deduce the root mean square separation of the ends of the chain due to quantum fluctuations in its vibrational ground state.

**8.37** Here we explore further the idea introduced in *Impact 18.1* that quantum mechanical effects need to be invoked in the description of the electronic properties of metallic nanocrystals, here modelled as three-dimensional boxes. (a) Set up the Schrödinger equation for a particle of mass  $m$  in a three-dimensional rectangular box with sides  $L_1$ ,  $L_2$ , and  $L_3$ . Show that the Schrödinger equation is separable. (b) Show that the wavefunction and the energy are defined by three quantum numbers. (c) Specialize the result from part (b) to an electron moving in a cubic box of side  $L = 5$  nm and draw an energy diagram resembling Fig. 8.2 and showing the first 15 energy levels. Note that each energy level may consist of degenerate energy states. (d) Compare the energy level diagram from part (c) with the energy level diagram for an electron in a one-dimensional box of length  $L = 5$  nm. Are the energy levels more or less sparsely distributed in the cubic box than in the one-dimensional box?

**8.38** We remarked in *Impact 18.1* that the particle in a sphere is a reasonable starting point for the discussion of the electronic properties of spherical metal nanoparticles. Here, we justify the expression for the energy levels with  $l = 0$ . (a) The Hamiltonian for a particle free to move inside a sphere of radius  $R$  is

$$\hat{H} = -\frac{\hbar^2}{2m} \nabla^2$$

Show that the Schrödinger equation is separable into radial and angular components. That is, begin by writing  $\psi(r, \theta, \phi) = u(r)Y(\theta, \phi)$ , where  $u(r)$  depends only on the distance of the particle away from the centre of the sphere, and  $Y(\theta, \phi)$  is a spherical harmonic. Then show that the Schrödinger equation can be separated into two equations, one for  $u$ , the radial equation, and the other for  $Y$ , the angular equation:

$$-\frac{\hbar^2}{2m} \left( \frac{d^2 u(r)}{dr^2} + \frac{2}{r} \frac{du(r)}{dr} \right) + \frac{l(l+1)\hbar^2}{2mr^2} u(r) = Eu(r)$$

$$\Lambda^2 Y = -l(l+1)Y$$

(b) Consider the case  $l = 0$ . Show by differentiation that the solution of the radial equation has the form

$$u(r) = (2\pi R)^{-1/2} \frac{\sin(n\pi r/R)}{r}$$

(c) Now go on to show that the allowed energies are given by:

$$E_n = \frac{n^2 \hbar^2}{8mR^2}$$

which is the expression given in *Impact 18.1* after substituting  $m_e$  for  $m$ .

**8.39** The forces measured by atomic force microscopy (AFM) arise primarily from interactions between electrons of the stylus and on the surface. To get an idea of the magnitudes of these forces, calculate the force acting between two electrons separated by 2.0 nm. *Hint.* The Coulombic potential energy of a charge  $Q_1$  at a distance  $r$  from another charge  $Q_2$  is  $V = Q_1 Q_2 / 4\pi\epsilon_0 r$ , where  $\epsilon_0 = 8.854 \times 10^{-12} \text{ C}^2 \text{ J}^{-1} \text{ m}^{-1}$  is the vacuum permittivity. To calculate the force between the electrons, note that  $F = -dV/dr$ .

## MATHEMATICAL BACKGROUND 4

## Differential equations

A **differential equation** is a relation between a function and its derivatives, as in

$$a \frac{d^2 f}{dx^2} + b \frac{df}{dx} + cf = 0 \quad (\text{MB4.1})$$

where  $f$  is a function of the variable  $x$  and the factors  $a, b, c$  may be either constants or functions of  $x$ . If the unknown function depends on only one variable, as in this example, the equation is called an **ordinary differential equation**; if it depends on more than one variable, as in

$$a \frac{\partial^2 f}{\partial x^2} + b \frac{\partial^2 f}{\partial y^2} + cf = 0 \quad (\text{MB4.2})$$

it is called a **partial differential equation**. Here,  $f$  is a function of  $x$  and  $y$ , and the factors  $a, b, c$  may be either constants or functions of both variables. Note the change in symbol from  $d$  to  $\partial$  to signify a *partial derivative* (see *Mathematical background 1*).

## MB4.1 The structure of differential equations

The **order** of the differential equation is the order of the highest derivative that occurs in it: both examples above are second-order equations. Only rarely in science is a differential equation of order higher than 2 encountered.

A **linear differential equation** is one for which, if  $f$  is a solution, then so is  $\text{constant} \times f$ . Both examples above are linear. If the 0 on the right were replaced by a different number or a function other than  $f$ , then they would cease to be linear.

Solving a differential equation means something different from solving an algebraic equation. In the latter case, the solution is a value of the variable  $x$  (as in the solution  $x = 2$  of the quadratic equation  $x^2 - 4 = 0$ ). The solution of a differential equation is the entire function that satisfies the equation, as in

$$\frac{d^2 f}{dx^2} + f = 0 \quad \text{has the solution} \quad f = A \sin x + B \cos x \quad (\text{MB4.3})$$

with  $A$  and  $B$  constants. The process of finding a solution of a differential equation is called **integrating** the equation. The solution in eqn MB4.3 is an example of a **general solution** of a differential equation, that is, it is the most general solution of the equation and is expressed in terms of a number of constants ( $A$  and  $B$  in this case). When the constants are chosen to accord with certain specified **initial conditions** (if one variable is the time) or certain **boundary conditions** (to fulfil certain spatial restrictions on the solutions), we obtain the **particular solution** of the equation. The particular solution of a first-order differential

equation requires one such condition; a second-order differential equation requires two.

• **A brief illustration**

If we are informed that  $f(0) = 0$ , then, because from eqn MB4.3 it follows that  $f(0) = B$ , we can conclude that  $B = 0$ . That still leaves  $A$  undetermined. If we are also told that  $df/dx = 2$  at  $x = 0$  (that is,  $f'(0) = 2$ , where the prime denotes a first derivative), then, because the general solution (but with  $B = 0$ ) implies that  $f'(x) = A \cos x$ , we know that  $f'(0) = A$ , and therefore  $A = 2$ . The particular solution is therefore  $f(x) = 2 \sin x$ . Figure MB4.1 shows a series of particular solutions corresponding to different boundary conditions. •

## MB4.2 The solution of ordinary differential equations

The first-order linear differential equation

$$\frac{df}{dx} + af = 0 \quad (\text{MB4.4a})$$

with  $a$  a function of  $x$  or a constant can be solved by direct integration. To proceed, we use the fact that the quantities  $df$  and  $dx$  (called *differentials*) can be treated algebraically like any quantity and rearrange the equation into

$$\frac{df}{f} = -a dx \quad (\text{MB4.4b})$$

and integrate both sides. For the left-hand side, we use the familiar result  $\int dy/y = \ln y + \text{constant}$ . After pooling all the constants into a single constant  $A$ , we obtain:

$$\ln f = - \int a dx + A \quad (\text{MB4.4c})$$

**Fig. MB4.1** The solution of the differential equation in eqn MB4.3 with three different boundary conditions (as indicated by the resulting values of the constants  $A$  and  $B$ ).

### • A brief illustration

Suppose that in eqn MB4.4a the factor  $a = 2x$ ; then the general solution, eqn MB4.4c, is

$$\ln f = -2 \int x dx + A = -x^2 + A$$

(We have absorbed the constant of integration into the constant A.) Therefore

$$f = e^A e^{-x^2}$$

If we are told that  $f(0) = 1$ , then we can infer that  $A = 0$  and therefore that  $f = e^{-x^2}$ . •

The solution even of first-order differential equations quickly becomes more complicated. A nonlinear first-order equation of the form

$$\frac{df}{dx} + af = b \quad (\text{MB4.5a})$$

with  $a$  and  $b$  functions of  $x$  (or constants) has a solution of the form

$$f e^{\int a dx} = \int e^{\int a dx} b dx + A \quad (\text{MB4.5b})$$

as may be verified by differentiation. Mathematical software packages can often perform the required integrations.

Second-order differential equations are in general much more difficult to solve than first-order equations. One powerful approach commonly used to lay siege to second-order differential equations is to express the solution as a power series:

$$f(x) = \sum_{n=0}^{\infty} c_n x^n \quad (\text{MB4.6})$$

and then to use the differential equation to find a relation between the coefficients. This approach results, for instance, in the Hermite polynomials that form part of the solution of the Schrödinger equation for the harmonic oscillator (Section 8.5). Many of the second-order differential equations that occur in this text are tabulated in compilations of solutions or can be solved with mathematical software, and the specialized techniques that are needed to establish the form of the solutions may be found in mathematical texts.

### MB4.3 The solution of partial differential equations

The only partial differential equations that we need to solve are those that can be separated into two or more ordinary differential equations by the technique known as **separation of variables**. To discover if the differential equation in eqn MB4.2 can be solved by this method we suppose that the full solution can be factored into functions that depend only on  $x$  or only on  $y$ , and write  $f(x, y) = X(x)Y(y)$ . At this stage there is no guarantee that the solution can be written in this way. Substituting this trial solution into the equation and recognizing that

$$\frac{\partial^2 XY}{\partial x^2} = Y \frac{d^2 X}{dx^2} \quad \frac{\partial^2 XY}{\partial y^2} = X \frac{d^2 Y}{dy^2}$$

we obtain

$$aY \frac{d^2 X}{dx^2} + bX \frac{d^2 Y}{dy^2} + cXY = 0$$

We are using  $d$  instead of  $\partial$  at this stage to denote differentials because each of the functions  $X$  and  $Y$  depends on one variable,  $x$  and  $y$ , respectively. Division through by  $XY$  turns this equation into

$$\frac{a}{X} \frac{d^2 X}{dx^2} + \frac{b}{Y} \frac{d^2 Y}{dy^2} + c = 0$$

Now suppose that  $a$  is a function only of  $x$ ,  $b$  a function of  $y$ , and  $c$  a constant. (There are various other possibilities that permit the argument to continue.) Then the first term depends only on  $x$  and the second only on  $y$ . If  $x$  is varied, only the first term can change. But, as the other two terms do not change and the sum of the three terms is a constant (0), even that first term must be a constant. The same is true of the second term. Therefore because each term is equal to a constant, we can write

$$\frac{a}{X} \frac{d^2 X}{dx^2} = c_1 \quad \frac{b}{Y} \frac{d^2 Y}{dy^2} = c_2 \quad \text{with} \quad c_1 + c_2 = -c$$

We now have two ordinary differential equations to solve by the techniques described in Section MB4.2. An example of this procedure is given in Section 8.2, for a particle in a two-dimensional region.

Problems

We now use the principles of quantum mechanics introduced in the preceding two chapters to describe the internal structures of atoms. We see what experimental information is available from a study of the spectrum of atomic hydrogen. Then we set up the Schrödinger equation for an electron in an atom and separate it into angular and radial parts. The wavefunctions obtained are the ‘atomic orbitals’ of hydrogenic atoms. Next, we use these hydrogenic atomic orbitals to describe the structures of many-electron atoms. In conjunction with the Pauli exclusion principle, we account for the periodicity of atomic properties and the structure of the periodic table. The spectra of many-electron atoms are more complicated than those of hydrogen, but the same principles apply. We see in the closing sections of the chapter how such spectra are described by using term symbols, and the origin of the finer details of the appearance of spectra.

In this chapter we see how to use quantum mechanics to describe the **electronic structure** of an atom, the arrangement of electrons around a nucleus. The concepts we meet are of central importance for understanding the structures and reactions of atoms and molecules, and hence have extensive chemical applications. We need to distinguish between two types of atoms. A **hydrogenic atom** is a one-electron atom or ion of general atomic number  $Z$ ; examples of hydrogenic atoms are  $\text{H}$ ,  $\text{He}^+$ ,  $\text{Li}^{2+}$ ,  $\text{O}^{7+}$ , and even  $\text{U}^{91+}$ . A **many-electron atom** (or *polyelectronic atom*) is an atom or ion with more than one electron; examples include all neutral atoms other than  $\text{H}$ . So even  $\text{He}$ , with only two electrons, is a many-electron atom. Hydrogenic atoms are important because their Schrödinger equations can be solved exactly. They also provide a set of concepts that are used to describe the structures of many-electron atoms and, as we shall see in the next chapter, the structures of molecules too.

## The structure and spectra of hydrogenic atoms

When an electric discharge is passed through gaseous hydrogen, the  $\text{H}_2$  molecules are dissociated and the energetically excited  $\text{H}$  atoms that are produced emit light of discrete frequencies, producing a spectrum of a series of ‘lines’ (Fig. 9.1). The Swedish spectroscopist Johannes Rydberg noted (in 1890) that all the lines are described by the expression

$$\tilde{\nu} = R_{\text{H}} \left( \frac{1}{n_1^2} - \frac{1}{n_2^2} \right) \quad R_{\text{H}} = 109\,677 \text{ cm}^{-1} \quad \text{Spectral lines of a hydrogen atom} \quad (9.1)$$

with  $n_1 = 1$  (the *Lyman series*), 2 (the *Balmer series*), and 3 (the *Paschen series*), and that in each case  $n_2 = n_1 + 1, n_1 + 2, \dots$ . The constant  $R_{\text{H}}$  is now called the **Rydberg constant** for the hydrogen atom.

**Fig. 9.1** The spectrum of atomic hydrogen. Both the observed spectrum and its resolution into overlapping series are shown. Note that the Balmer series lies in the visible region.

**Self-test 9.1** Calculate the shortest wavelength line in the Paschen series.

[821 nm]

The form of eqn 9.1 strongly suggests that the wavenumber of each spectral line can be written as the difference of two terms, each of the form

$$T_n = \frac{R_H}{n^2} \quad (9.2)$$

The **Ritz combination principle** states that *the wavenumber of any spectral line (of any atom, not just hydrogenic atoms) is the difference between two terms*. We say that two terms  $T_1$  and  $T_2$  ‘combine’ to produce a spectral line of wavenumber

$$\tilde{\nu} = T_1 - T_2 \quad \text{Ritz combination principle} \quad (9.3)$$

Thus, if each spectroscopic term represents an energy  $hcT$ , the difference in energy when the atom undergoes a transition between two terms is  $\Delta E = hcT_1 - hcT_2$  and, according to the Bohr frequency condition ( $\Delta E = h\nu$ , Section 7.1c), the frequency of the radiation emitted is given by  $\nu = cT_1 - cT_2$ . This expression rearranges into the Ritz formula when expressed in terms of wavenumbers (on division by  $c$ ;  $\tilde{\nu} = \nu/c$ ). The Ritz combination principle applies to all types of atoms and molecules, but only for hydrogenic atoms do the terms have the simple form  $(\text{constant})/n^2$ .

Because spectroscopic observations show that electromagnetic radiation is absorbed and emitted by atoms only at certain wavenumbers, it follows that only certain energy states of atoms are permitted. Our tasks in the first part of this chapter are to determine the origin of this energy quantization, to find the permitted energy levels, and to account for the value of  $R_H$ .

## 9.1 The structure of hydrogenic atoms

**Key points** (a) The Schrödinger equation for hydrogenic atoms separates into two equations: the solutions of one give the angular variation of the wavefunction and the solution of the other gives its radial dependence. (b) Close to the nucleus the radial wavefunction is proportional to  $r^l$ ; far from the nucleus all wavefunctions approach zero exponentially.

The Coulomb potential energy of an electron in a hydrogenic atom of atomic number  $Z$  and therefore nuclear charge  $Ze$  is

$$V = -\frac{Ze^2}{4\pi\epsilon_0 r} \quad (9.4)$$

where  $r$  is the distance of the electron from the nucleus and  $\epsilon_0$  is the vacuum permittivity. The hamiltonian for the electron and a nucleus of mass  $m_N$  is therefore

$$\begin{aligned}\hat{H} &= \hat{E}_{k,\text{electron}} + \hat{E}_{k,\text{nucleus}} + \hat{V} \\ &= -\frac{\hbar^2}{2m_e} \nabla_e^2 - \frac{\hbar^2}{2m_N} \nabla_N^2 - \frac{Ze^2}{4\pi\epsilon_0 r}\end{aligned}\quad \text{Hamiltonian for a hydrogenic atom} \quad (9.5)$$

The subscripts on  $\nabla^2$  indicate differentiation with respect to the electron or nuclear coordinates.

### (a) The separation of variables

Physical intuition suggests that the full Schrödinger equation ought to separate into two equations, one for the motion of the atom as a whole through space and the other for the motion of the electron relative to the nucleus. We show in *Further information 9.1* how this separation is achieved, and that the Schrödinger equation for the internal motion of the electron relative to the nucleus is

$$-\frac{\hbar^2}{2\mu} \nabla^2 \psi - \frac{Ze^2}{4\pi\epsilon_0 r} \psi = E\psi \quad \frac{1}{\mu} = \frac{1}{m_e} + \frac{1}{m_N} \quad \text{Schrödinger equation for a hydrogenic atom} \quad (9.6)$$

where differentiation is now with respect to the coordinates of the electron relative to the nucleus. The quantity  $\mu$  is called the **reduced mass**. The reduced mass is very similar to the electron mass because  $m_N$ , the mass of the nucleus, is much larger than the mass of an electron, so  $1/\mu \approx 1/m_e$  and therefore  $\mu \approx m_e$ . In all except the most precise work, the reduced mass can be replaced by  $m_e$ .

Because the potential energy is centrosymmetric (independent of angle), we can suspect that the equation for the wavefunction is separable into radial and angular components. Therefore, we write

$$\psi(r, \theta, \phi) = R(r)Y(\theta, \phi) \quad (9.7)$$

and examine whether the Schrödinger equation can be separated into two equations, one for the **radial wavefunction**  $R(r)$  and the other for the **angular wavefunction**  $Y(\theta, \phi)$ . As shown in *Further information 9.1*, the equation does separate, and the equations we have to solve are

$$\Lambda^2 Y = -l(l+1)Y \quad (9.8a)$$

$$-\frac{\hbar^2}{2\mu} \frac{d^2 u}{dr^2} + V_{\text{eff}} u = Eu \quad (9.8b)$$

where  $u(r) = rR(r)$  and

$$V_{\text{eff}} = -\frac{Ze^2}{4\pi\epsilon_0 r} + \frac{l(l+1)\hbar^2}{2\mu r^2} \quad (9.8c)$$

Equation 9.8a is the same as the Schrödinger equation for a particle free to move round a central point, and we considered it in Section 8.7. The solutions are the spherical harmonics (Table 8.2), and are specified by the quantum numbers  $l$  and  $m_l$ . We consider them in more detail shortly. Equation 9.8b is called the **radial wave equation**. The radial wave equation is the description of the motion of a particle of mass  $\mu$  in a one-dimensional region  $0 < r < \infty$  where the potential energy is  $V_{\text{eff}}(r)$ .

### (b) The radial solutions

We can anticipate some features of the shapes of the radial wavefunctions by analysing the form of  $V_{\text{eff}}$ . The first term in eqn 9.8c is the Coulomb potential energy of the electron in the field of the nucleus. The second term stems from what in classical physics

would be called the centrifugal force that arises from the angular momentum of the electron around the nucleus. When  $l = 0$ , the electron has no angular momentum, and the effective potential energy is purely Coulombic and attractive at all radii (Fig. 9.2). When  $l \neq 0$ , the centrifugal term gives a positive (repulsive) contribution to the effective potential energy. When the electron is close to the nucleus ( $r \approx 0$ ), this repulsive term, which is proportional to  $1/r^2$ , dominates the attractive Coulombic component, which is proportional to  $1/r$ , and the net result is an effective repulsion of the electron from the nucleus. The two effective potential energies, the one for  $l = 0$  and the one for  $l \neq 0$ , are therefore qualitatively very different close to the nucleus. However, they are similar at large distances because the centrifugal contribution tends to zero more rapidly (as  $1/r^2$ ) than the Coulombic contribution (as  $1/r$ ). Therefore, we can expect the solutions with  $l = 0$  and  $l \neq 0$  to be quite different near the nucleus but similar far away from it. We show in the following *Justification* the following two important features of the radial wavefunction:

- Close to the nucleus the radial wavefunction is proportional to  $r^l$ , and the higher the orbital angular momentum, the less likely it is that the electron will be found there (Fig. 9.3).
- Far from the nucleus all radial wavefunctions approach zero exponentially.

**Justification 9.1** *The form of the radial wavefunction*

When  $r$  is very small (close to the nucleus),  $u = rR \approx 0$ , so the right-hand side of eqn 9.8b is zero; we can also ignore all but the largest terms (those depending on  $1/r^2$ ) in eqn 9.8b and write

$$-\frac{d^2u}{dr^2} + \frac{l(l+1)}{r^2}u \approx 0$$

The solution of this equation (for  $r \approx 0$ ) is

$$u \approx Ar^{l+1} + \frac{B}{r^l}$$

Because  $R = u/r$ , and  $R$  must be finite everywhere and in particular at  $r = 0$ , we must set  $B = 0$ , and hence obtain  $R \approx Ar^l$ .

Far from the nucleus, when  $r$  is very large, we can ignore terms in  $1/r$  and  $1/r^2$  and eqn 9.8b becomes

$$-\frac{\hbar^2}{2\mu} \frac{d^2u}{dr^2} \approx Eu$$

where  $\approx$  means ‘asymptotically equal to’ in the sense that the values become equal as  $r$  becomes infinite (like an exponentially decaying function tending to zero). Because

$$\begin{aligned} \frac{d^2u}{dr^2} &= \frac{d^2(rR)}{dr^2} = \frac{d}{dr} \frac{d(rR)}{dr} = \frac{d}{dr} \left( R + r \frac{dR}{dr} \right) \\ &= 2 \frac{dR}{dr} + r \frac{d^2R}{dr^2} \approx r \frac{d^2R}{dr^2} \end{aligned}$$

as  $r$  becomes infinite, this equation has the form

$$-\frac{\hbar^2}{2\mu} \frac{d^2R}{dr^2} \approx ER$$

The acceptable (finite) solution of this equation (for  $r$  large) is

$$R \approx e^{-(2\mu|E|/\hbar^2)^{1/2}r}$$

and the wavefunction decays exponentially towards zero as  $r$  increases.

**Fig. 9.2** The effective potential energy of an electron in the hydrogen atom. When the electron has zero orbital angular momentum, the effective potential energy is the Coulombic potential energy. When the electron has nonzero orbital angular momentum, the centrifugal effect gives rise to a positive contribution that is very large close to the nucleus. We can expect the  $l = 0$  and  $l > 0$  wavefunctions to be very different near the nucleus.

**InterActivity** Plot the effective potential energy against  $r$  for several nonzero values of the orbital angular momentum  $l$ . How does the location of the minimum in the effective potential energy vary with  $l$ ?

**Fig. 9.3** Close to the nucleus, orbitals with  $l = 1$  are proportional to  $r$ , orbitals with  $l = 2$  are proportional to  $r^2$ , and orbitals with  $l = 3$  are proportional to  $r^3$ . Electrons are progressively excluded from the neighbourhood of the nucleus as  $l$  increases. An orbital with  $l = 0$  has a finite, nonzero value at the nucleus.

We shall not go through the technical steps of solving the radial equation for the full range of radii, and see how the form  $r^l$  close to the nucleus blends into the exponentially decaying form at great distances. It is sufficient to know that the two limits can be bridged only for integral values of a quantum number  $n$ , and that the allowed energies corresponding to the allowed solutions are

$$E_n = -\frac{Z^2 \mu e^4}{32\pi^2 \epsilon_0^2 \hbar^2 n^2} \quad \text{Bound state energies} \quad (9.9)$$

with  $n = 1, 2, \dots$ . Likewise, the radial wavefunctions depend on the values of both  $n$  and  $l$  (but not on  $m_l$  because only  $l$  appears in the radial wave equation), and all of them have the form

$$R(r) = \overbrace{r^l}^{\text{Dominant close to the nucleus}} \times \overbrace{(\text{polynomial in } r)}^{\text{Bridges the two ends of the function}} \times \overbrace{(\text{decaying exponential in } r)}^{\text{Dominant far from the nucleus}} \quad (9.10)$$

These functions are most simply written in terms of the dimensionless quantity  $\rho$  (rho), where

$$\rho = \frac{2Zr}{na_0} \quad a_0 = \frac{4\pi\epsilon_0 \hbar^2}{m_e e^2} \quad (9.11)$$

The **Bohr radius**,  $a_0$ , has the value 52.9 pm; it is so called because the same quantity appeared in Bohr's early model of the hydrogen atom as the radius of the electron orbit of lowest energy. Specifically, the radial wavefunctions for an electron with quantum numbers  $n$  and  $l$  are the (real) function

$$R_{n,l}(r) = N_{n,l} \rho^l L_{n+1}^{2l+1}(\rho) e^{-\rho/2} \quad \text{Radial wavefunctions} \quad (9.12)$$

where  $L(\rho)$  is a polynomial called an *associated Laguerre polynomial*: it links the  $r \approx 0$  solutions on its left (corresponding to  $R \propto \rho^l$ ) to the exponentially decaying function on its right. The notation might look fearsome, but the polynomials have quite simple forms, such as 1,  $\rho$ , and  $2 - \rho$  (they can be picked out in Table 9.1). The factor  $N$  ensures that the radial wavefunction is normalized to 1 in the sense that

**Table 9.1** Hydrogenic radial wavefunctions

| Orbital | $n$ | $l$ | $R_{n,l}$                                                                       |
|---------|-----|-----|---------------------------------------------------------------------------------|
| 1s      | 1   | 0   | $2\left(\frac{Z}{a}\right)^{3/2} e^{-\rho/2}$                                   |
| 2s      | 2   | 0   | $\frac{1}{8^{1/2}}\left(\frac{Z}{a}\right)^{3/2} (2-\rho)e^{-\rho/2}$           |
| 2p      | 2   | 1   | $\frac{1}{24^{1/2}}\left(\frac{Z}{a}\right)^{3/2} \rho e^{-\rho/2}$             |
| 3s      | 3   | 0   | $\frac{1}{243^{1/2}}\left(\frac{Z}{a}\right)^{3/2} (6-6\rho+\rho^2)e^{-\rho/2}$ |
| 3p      | 3   | 1   | $\frac{1}{486^{1/2}}\left(\frac{Z}{a}\right)^{3/2} (4-\rho)\rho e^{-\rho/2}$    |
| 3d      | 3   | 2   | $\frac{1}{2430^{1/2}}\left(\frac{Z}{a}\right)^{3/2} \rho^2 e^{-\rho/2}$         |

$\rho = (2Z/na)r$  with  $a = 4\pi\epsilon_0 \hbar^2 / \mu e^2$ . For an infinitely heavy nucleus (or one that may be assumed to be so),  $\mu = m_e$  and  $a = a_0$ , the Bohr radius. The full wavefunction is obtained by multiplying  $R$  by the appropriate  $Y$  given in Table 8.2.

$$\int_0^{\infty} R_{n,l}(r)^2 r^2 dr = 1 \quad (9.13)$$

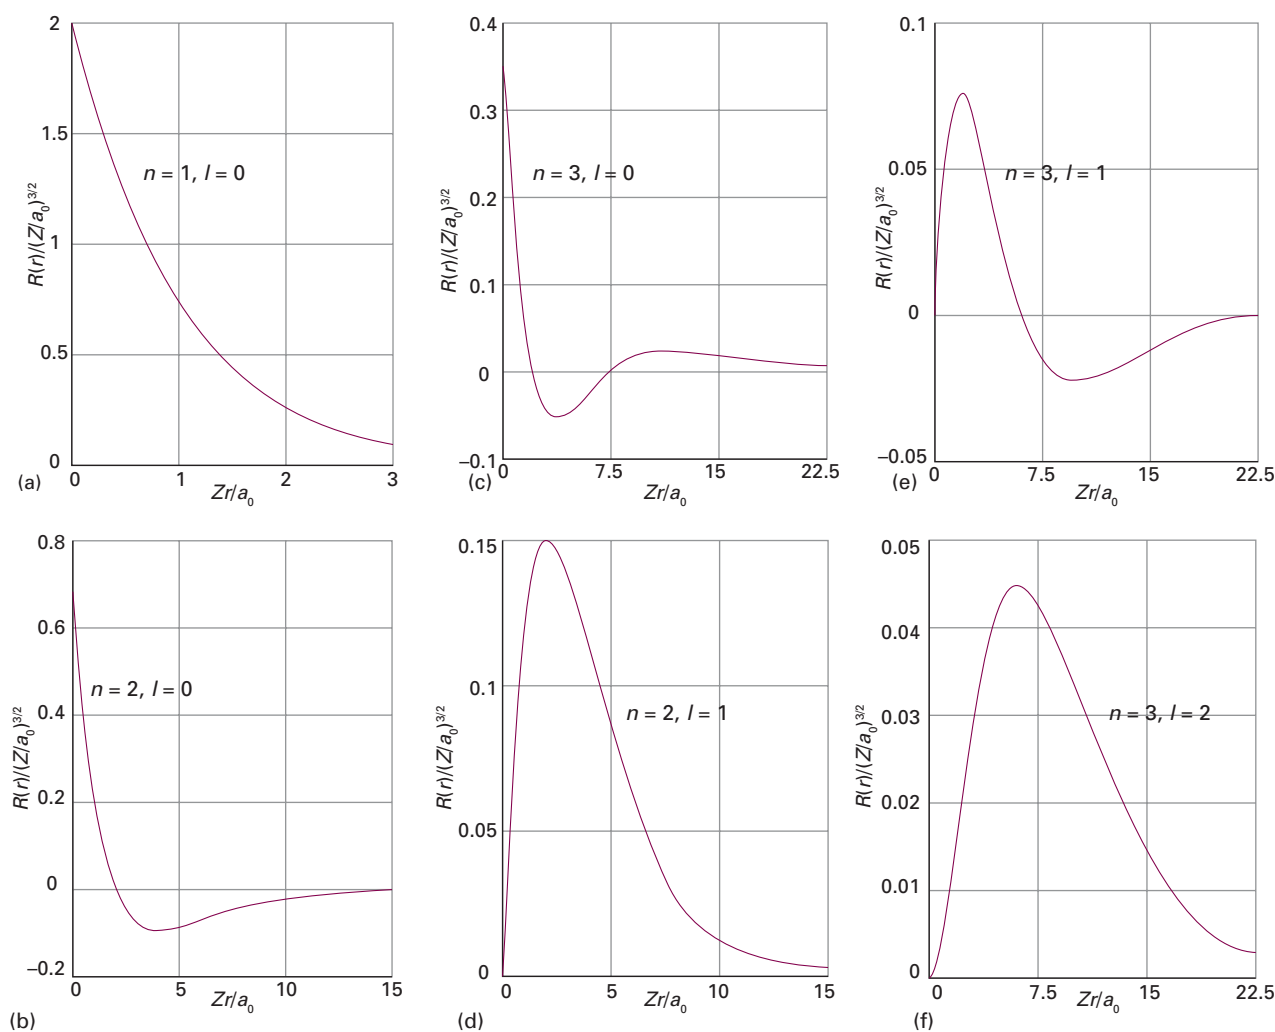

(The  $r^2$  comes from the volume element in spherical coordinates, Section 7.4a.) Specifically, we can interpret the components of eqn 9.12 as follows:

1. The exponential factor ensures that the wavefunction approaches zero far from the nucleus.
2. The factor  $\rho^l$  ensures that (provided  $l > 0$ ) the wavefunction vanishes at the nucleus.
3. The associated Laguerre polynomial is a function that in general oscillates from positive to negative values and accounts for the presence of radial nodes.

Expressions for some radial wavefunctions are given in Table 9.1 and illustrated in Fig. 9.4.

#### A brief comment

The zero at  $r = 0$  is not a radial node because the radial wavefunction does not pass through zero at that point (because  $r$  cannot be negative). Nodes at the nucleus are all angular nodes.

**Fig. 9.4** The radial wavefunctions of the first few states of hydrogenic atoms of atomic number  $Z$ . Note that the orbitals with  $l = 0$  have a nonzero and finite value at the nucleus. The horizontal scales are different in each case: orbitals with high principal quantum numbers are relatively distant from the nucleus.

**InterActivity** Use mathematical software to find the locations of the radial nodes in hydrogenic wavefunctions with  $n$  up to 3.

• **A brief illustration**

To calculate the probability density at the nucleus for an electron with  $n = 1$ ,  $l = 0$ , and  $m_l = 0$ , we evaluate  $\psi$  at  $r = 0$ :

$$\psi_{1,0,0}(0, \theta, \phi) = R_{1,0}(0) Y_{0,0}(\theta, \phi) = 2 \left( \frac{Z}{a_0} \right)^{3/2} \left( \frac{1}{4\pi} \right)^{1/2}$$

The probability density is therefore

$$\psi_{1,0,0}(0, \theta, \phi)^2 = \frac{Z^3}{\pi a_0^3}$$

which evaluates to  $2.15 \times 10^{-6} \text{ pm}^{-3}$  when  $Z = 1$ . •

**Self-test 9.2** Evaluate the probability density at the nucleus of the electron for an electron with  $n = 2$ ,  $l = 0$ ,  $m_l = 0$ .  $[(Z/a_0)^3/8\pi]$

## 9.2 Atomic orbitals and their energies

**Key points** (a) Atomic orbitals are specified by the quantum numbers  $n$ ,  $l$ , and  $m_l$ . (b) The energies of the bound states of hydrogenic atoms are proportional to  $Z^2/n^2$ . (c) The ionization energy of an element is the minimum energy required to remove an electron from the ground state of one of its atoms. (d) Orbitals of a given value of  $n$  form a shell of an atom, and within that shell orbitals of the same value of  $l$  form subshells. (e) s Orbitals are spherically symmetrical and have nonzero probability density at the nucleus. (f) A radial distribution function is the probability density for the distribution of the electron as a function of distance from the nucleus. (g) There are three p orbitals in a given subshell; each one has an angular node. (h) There are five d orbitals in a given subshell; each one has two angular nodes.

An **atomic orbital** is a one-electron wavefunction for an electron in an atom. Each hydrogenic atomic orbital is defined by three quantum numbers, designated  $n$ ,  $l$ , and  $m_l$ . When an electron is described by one of these wavefunctions, we say that it ‘occupies’ that orbital. We could go on to say that the electron is in the state  $|n, l, m_l\rangle$ . For instance, an electron described by the wavefunction  $\psi_{1,0,0}$  and in the state  $|1, 0, 0\rangle$  is said to ‘occupy’ the orbital with  $n = 1$ ,  $l = 0$ , and  $m_l = 0$ .

### (a) The specification of orbitals

The quantum number  $n$  is called the **principal quantum number**; it can take the value  $n = 1, 2, 3, \dots$  and determines the energy of the electron:

- An electron in an orbital with quantum number  $n$  has an energy given by eqn 9.9.

The two other quantum numbers,  $l$  and  $m_l$ , come from the angular solutions, and specify the angular momentum of the electron around the nucleus:

- An electron in an orbital with quantum number  $l$  has an angular momentum of magnitude  $\{l(l+1)\}^{1/2}\hbar$ , with  $l = 0, 1, 2, \dots, n-1$ .
- An electron in an orbital with quantum number  $m_l$  has a  $z$ -component of angular momentum  $m_l\hbar$ , with  $m_l = 0, \pm 1, \pm 2, \dots, \pm l$ .

Note how the value of the principal quantum number,  $n$ , controls the maximum value of  $l$  and  $l$  controls the range of values of  $m_l$ .

To define the state of an electron in a hydrogenic atom fully we need to specify not only the orbital it occupies but also its spin state. We saw in Section 8.8 that an electron

possesses an intrinsic angular momentum that is described by the two quantum numbers  $s$  and  $m_s$  (the analogues of  $l$  and  $m_l$ ). The value of  $s$  is fixed at  $\frac{1}{2}$  for an electron, so we do not need to consider it further at this stage. However,  $m_s$  may be either  $+\frac{1}{2}$  or  $-\frac{1}{2}$ , and to specify the state of an electron in a hydrogenic atom we need to specify which of these values describes it. It follows that, to specify the state of an electron in a hydrogenic atom, we need to give the values of four quantum numbers, namely  $n$ ,  $l$ ,  $m_l$ , and  $m_s$ .

### (b) The energy levels

The energy levels predicted by eqn 9.9 are depicted in Fig. 9.5. The energies, and also the separation of neighbouring levels, are proportional to  $Z^2$ , so the levels are four times as wide apart (and the ground state four times deeper in energy) in  $\text{He}^+$  ( $Z = 2$ ) than in  $\text{H}$  ( $Z = 1$ ). All the energies given by eqn 9.9 are negative. They refer to the **bound states** of the atom, in which the energy of the atom is lower than that of the infinitely separated, stationary electron and nucleus (which corresponds to the zero of energy). There are also solutions of the Schrödinger equation with positive energies. These solutions correspond to **unbound states** of the electron, the states to which an electron is raised when it is ejected from the atom by a high-energy collision or photon. The energies of the unbound electron are not quantized and form the continuum states of the atom.

Equation 9.9 is consistent with the spectroscopic result summarized by eqn 9.1, and we can identify the Rydberg constant for hydrogen ( $Z = 1$ ) as

$$hcR_{\text{H}} = \frac{\mu_{\text{H}}e^4}{32\pi^2\epsilon_0^2\hbar^2} \quad (9.14)$$

where  $\mu_{\text{H}}$  is the reduced mass for hydrogen. The **Rydberg constant** itself,  $R_{\infty}$ , is defined by the same expression except for the replacement of  $\mu_{\text{H}}$  by the mass of an electron,  $m_e$ , corresponding to a nucleus of infinite mass:

$$R_{\text{H}} = \frac{\mu_{\text{H}}}{m_e} R_{\infty} \quad R_{\infty} = \frac{m_e e^4}{8\epsilon_0^2 h^3 c} \quad \text{Rydberg constant} \quad [9.15]$$

Insertion of the values of the fundamental constants into the expression for  $R_{\text{H}}$  gives almost exact agreement with the experimental value. The only discrepancies arise from the neglect of relativistic corrections (in simple terms, the increase of mass with speed), which the non-relativistic Schrödinger equation ignores.

### (c) Ionization energies

The **ionization energy**,  $I$ , of an element is the minimum energy required to remove an electron from the ground state, the state of lowest energy, of one of its atoms in the gas phase. Because the ground state of hydrogen is the state with  $n = 1$ , with energy  $E_1 = -hcR_{\text{H}}$  and the atom is ionized when the electron has been excited to the level corresponding to  $n = \infty$  (see Fig. 9.5), the energy that must be supplied is

$$I = hcR_{\text{H}} \quad (9.16)$$

The value of  $I$  is 2.179 aJ (a, for atto, is the prefix that denotes  $10^{-18}$ ), which corresponds to 13.60 eV.

#### Example 9.1 Measuring an ionization energy spectroscopically

The emission spectrum of atomic hydrogen shows lines at 82 259, 97 492, 102 824, 105 292, 106 632, and 107 440  $\text{cm}^{-1}$ , which correspond to transitions to the same lower state. Determine (a) the ionization energy of the lower state, (b) the value of the Rydberg constant.

**Fig. 9.5** The energy levels of a hydrogen atom. The values are relative to an infinitely separated, stationary electron and a proton.

**A note on good practice** Ionization energies are sometimes referred to as *ionization potentials*. That is incorrect, but not uncommon. If the term is used at all, it should denote the potential difference through which an electron must be moved for its potential energy to change by an amount equal to the ionization energy, and reported in volts.

**Fig. 9.6** The plot of the data in Example 9.1 used to determine the ionization energy of an atom (in this case, of H).

**InterActivity** The initial value of  $n$  was not specified in Example 9.1. Show that the correct value can be determined by making several choices and selecting the one that leads to a straight line. The slope is, in this instance, numerically the same as  $R_H$ , so  $R_H = 109\,679 \text{ cm}^{-1}$ . A similar extrapolation procedure can be used for many-electron atoms (see Section 9.7).

**Method** The spectroscopic determination of ionization energies depends on the determination of the series limit, the wavenumber at which the series terminates and becomes a continuum. If the upper state lies at an energy  $-hcR_H/n^2$ , then, when the atom makes a transition to  $E_{\text{lower}}$ , a photon of wavenumber

$$\tilde{\nu} = -\frac{R_H}{n^2} - \frac{E_{\text{lower}}}{hc}$$

is emitted. However, because  $I = -E_{\text{lower}}$ , it follows that

$$\tilde{\nu} = \frac{I}{hc} - \frac{R_H}{n^2}$$

A plot of the wavenumbers against  $1/n^2$  should give a straight line of slope  $-R_H$  and intercept  $I/hc$ . Use a computer to make a least-squares fit of the data in order to obtain a result that reflects the precision of the data.

**Answer** The wavenumbers are plotted against  $1/n^2$  in Fig. 9.6. The (least-squares) intercept lies at  $109\,679 \text{ cm}^{-1}$ , so the ionization energy is  $2.1788 \text{ aJ}$  ( $1312.1 \text{ kJ mol}^{-1}$ ).

**Self-test 9.3** The emission spectrum of atomic deuterium shows lines at  $15\,238$ ,  $20\,571$ ,  $23\,039$ , and  $24\,380 \text{ cm}^{-1}$ , which correspond to transitions to the same lower state. Determine (a) the ionization energy of the lower state, (b) the ionization energy of the ground state, (c) the mass of the deuteron (by expressing the Rydberg constant in terms of the reduced mass of the electron and the deuteron, and solving for the mass of the deuteron).

[(a)  $328.1 \text{ kJ mol}^{-1}$ , (b)  $1312.4 \text{ kJ mol}^{-1}$ , (c)  $2.8 \times 10^{-27} \text{ kg}$ , a result very sensitive to  $R_D$ ]

**Fig. 9.7** The energy levels of the hydrogen atom showing the subshells and (in square brackets) the numbers of orbitals in each subshell. In hydrogenic atoms, all orbitals of a given shell have the same energy.

#### (d) Shells and subshells

All the orbitals of a given value of  $n$  are said to form a single **shell** of the atom. In a hydrogenic atom, all orbitals of given  $n$ , and therefore belonging to the same shell, have the same energy. It is common to refer to successive shells by letters:

|       |   |   |   |      |
|-------|---|---|---|------|
| $n =$ | 1 | 2 | 3 | 4... |
|       | K | L | M | N... |

Specification of shells

Thus, all the orbitals of the shell with  $n = 2$  form the L shell of the atom, and so on.

The orbitals with the same value of  $n$  but different values of  $l$  are said to form a **subshell** of a given shell. These subshells are generally referred to by letters:

|       |   |   |   |   |   |   |      |
|-------|---|---|---|---|---|---|------|
| $l =$ | 0 | 1 | 2 | 3 | 4 | 5 | 6... |
|       | s | p | d | f | g | h | i... |

Specification of subshells

The letters then run alphabetically (j is not used because in some languages i and j are not distinguished). Figure 9.7 is a version of Fig. 9.5 that shows the subshells explicitly. Because  $l$  can range from 0 to  $n - 1$ , giving  $n$  values in all, it follows that there are  $n$  subshells of a shell with principal quantum number  $n$ . Thus, when  $n = 1$ , there is only one subshell, the one with  $l = 0$ . When  $n = 2$ , there are two subshells, the 2s subshell (with  $l = 0$ ) and the 2p subshell (with  $l = 1$ ).

When  $n = 1$  there is only one subshell, that with  $l = 0$ , and that subshell contains only one orbital, with  $m_l = 0$  (the only value of  $m_l$  permitted). When  $n = 2$ , there are four orbitals, one in the s subshell with  $l = 0$  and  $m_l = 0$ , and three in the  $l = 1$  subshell with  $m_l = +1, 0, -1$ . When  $n = 3$  there are nine orbitals (one with  $l = 0$ , three with  $l = 1$ ,

and five with  $l=2$ ). The organization of orbitals in the shells is summarized in Fig. 9.8. In general, the number of orbitals in a shell of principal quantum number  $n$  is  $n^2$ , so in a hydrogenic atom each energy level is  $n^2$ -fold degenerate.

### (e) s Orbitals

The orbital occupied in the ground state is the one with  $n=1$  (and therefore with  $l=0$  and  $m_l=0$ , the only possible values of these quantum numbers when  $n=1$ ). From Table 9.1 and  $Y_{0,0}=1/2\pi^{1/2}$  we can write (for  $Z=1$ ):

$$\psi = \frac{1}{(\pi a_0^3)^{1/2}} e^{-r/a_0} \quad (9.17)$$

This wavefunction is independent of angle and has the same value at all points of constant radius, that is, the 1s orbital is *spherically symmetrical*. The wavefunction decays exponentially from a maximum value of  $1/(\pi a_0^3)^{1/2}$  at the nucleus (at  $r=0$ ). It follows that the probability density of the electron is greatest at the nucleus itself.

We can understand the general form of the ground-state wavefunction by considering the contributions of the potential and kinetic energies to the total energy of the atom. The closer the electron is to the nucleus on average, the lower its average potential energy. This dependence suggests that the lowest potential energy should be obtained with a sharply peaked wavefunction that has a large amplitude at the nucleus and is zero everywhere else (Fig. 9.9). However, this shape implies a high kinetic energy, because such a wavefunction has a very high average curvature. The electron would have very low kinetic energy if its wavefunction had only a very low average curvature. However, such a wavefunction spreads to great distances from the nucleus and the average potential energy of the electron will be correspondingly high. The actual ground-state wavefunction is a compromise between these two extremes: the wavefunction spreads away from the nucleus (so the expectation value of the potential energy is not as low as in the first example, but nor is it very high) and has a

**Fig. 9.8** The organization of orbitals (white squares) into subshells (characterized by  $l$ ) and shells (characterized by  $n$ ).

**Fig. 9.9** The balance of kinetic and potential energies that accounts for the structure of the ground state of hydrogen (and similar atoms). (a) The sharply curved but localized orbital has high mean kinetic energy, but low mean potential energy; (b) the mean kinetic energy is low, but the potential energy is not very favourable; (c) the compromise of moderate kinetic energy and moderately favourable potential energy.

**Fig. 9.10** Representations of the 1s and 2s hydrogenic atomic orbitals in terms of their electron densities (as represented by the density of shading).

**Fig. 9.11** The boundary surface of an s orbital, within which there is a 90 per cent probability of finding the electron.

reasonably low average curvature (so the expectation of the kinetic energy is not very low, but nor is it as high as in the first example).

By the virial theorem with  $b = -1$  (eqn 8.35),  $\langle E_k \rangle = -\frac{1}{2}\langle V \rangle$  and therefore  $E = \langle E_k \rangle + \langle V \rangle = \frac{1}{2}\langle V \rangle$ , so the total energy of an s electron becomes less negative as  $n$  increases and it is found at greater distances from the nucleus with a less negative potential energy. Thus, as  $n$  approaches infinity,

1. The kinetic energy becomes less positive and has fallen to zero when  $n = \infty$ .
2. The potential energy becomes less negative and has risen to zero when  $n = \infty$ .
3. The total energy becomes less negative and has risen to zero when  $n = \infty$ .

One way of depicting the probability density of the electron is to represent  $|\psi|^2$  by the density of shading (Fig. 9.10). A simpler procedure is to show only the **boundary surface**, the surface that captures a high proportion (typically about 90 per cent) of the electron probability. For the 1s orbital, the boundary surface is a sphere centred on the nucleus (Fig. 9.11).

### Example 9.2 Calculating the mean radius of an orbital

Use hydrogenic orbitals to calculate the mean radius of a 1s orbital.

**Method** The mean radius is the expectation value

$$\langle r \rangle = \int \psi^* r \psi d\tau = \int r |\psi|^2 d\tau$$

We therefore need to evaluate the integral using the wavefunctions given in Table 9.1 and  $d\tau = r^2 dr \sin \theta d\theta d\phi$ . The angular parts of the wavefunction (Table 8.2) are normalized in the sense that

$$\int_0^\pi \int_0^{2\pi} |Y_{l,m_l}|^2 \sin \theta d\theta d\phi = 1$$

The integral over  $r$  required is given in Example 7.4.

**Answer** With the wavefunction written in the form  $\psi = RY$ , the integration is

$$\langle r \rangle = \int_0^\infty \int_0^\pi \int_0^{2\pi} r R_{n,l}^2 |Y_{l,m_l}|^2 r^2 dr \sin \theta d\theta d\phi = \int_0^\infty r^3 R_{n,l}^2 dr$$

For a 1s orbital

$$R_{1,0} = 2 \left( \frac{Z}{a_0} \right)^{3/2} e^{-Zr/a_0}$$

Hence

$$\langle r \rangle = \frac{4Z^3}{a_0^3} \int_0^\infty r^3 e^{-2Zr/a_0} dr = \frac{3a_0}{2Z}$$

**Self-test 9.4** Evaluate the mean radius of a 3s orbital by integration. [ $27a_0/2Z$ ]

All s orbitals are spherically symmetric, but differ in the number of radial nodes. For example, the 1s, 2s, and 3s orbitals have 0, 1, and 2 radial nodes, respectively. In

general, an  $ns$  orbital has  $n - 1$  radial nodes. As  $n$  increases, the radius of the spherical boundary surface that captures a given fraction of the probability also increases.

**Self-test 9.5** (a) Use the fact that a  $2s$  orbital has radial nodes where the polynomial factor (Table 9.1) is equal to zero, and locate the radial node at  $2a_0/Z$  (see Fig. 9.4). (b) Similarly, locate the two nodes of a  $3s$  orbital.

[(a)  $2a_0/Z$ ; (b)  $1.90a_0/Z$  and  $7.10a_0/Z$ ]

### (f) Radial distribution functions

The wavefunction tells us, through the value of  $|\psi|^2$ , the probability of finding an electron in any region. We can imagine a probe with a volume  $d\tau$  and sensitive to electrons, and which we can move around near the nucleus of a hydrogen atom. Because the probability density in the ground state of the atom is  $|\psi|^2 \propto e^{-2Zr/a_0}$ , the reading from the detector decreases exponentially as the probe is moved out along any radius but is constant if the probe is moved on a circle of constant radius (Fig. 9.12).

Now consider the total probability of finding the electron *anywhere* between the two walls of a spherical shell of thickness  $dr$  at a radius  $r$ . The sensitive volume of the probe is now the volume of the shell (Fig. 9.13), which is  $4\pi r^2 dr$  (the product of its surface area,  $4\pi r^2$ , and its thickness,  $dr$ ). The probability that the electron will be found between the inner and outer surfaces of this shell is the probability density at the radius  $r$  multiplied by the volume of the probe, or  $|\psi|^2 \times 4\pi r^2 dr$ . This expression has the form  $P(r)dr$ , where

$$P(r) = 4\pi r^2 \psi^2 \quad (9.18a)$$

The more general expression, which also applies to orbitals that are not spherically symmetrical, is derived in the following *Justification*, and is

$$P(r) = r^2 R(r)^2 \quad (9.18b)$$

Radial distribution function

where  $R(r)$  is the radial wavefunction for the orbital in question.

#### Justification 9.2 The general form of the radial distribution function

The probability of finding an electron in a volume element  $d\tau$  when its wavefunction is  $\psi = RY$  is  $|RY|^2 d\tau$  with  $d\tau = r^2 dr \sin \theta d\theta d\phi$ . The total probability of finding the electron at any angle at a constant radius is the integral of this probability over the surface of a sphere of radius  $r$ , and is written  $P(r)dr$ , so

$$\begin{aligned} P(r)dr &= \int_0^\pi \int_0^{2\pi} R(r)^2 |Y(\theta, \phi)|^2 r^2 dr \sin \theta d\theta d\phi \\ &= r^2 R(r)^2 dr \underbrace{\int_0^\pi \int_0^{2\pi} |Y(\theta, \phi)|^2 \sin \theta d\theta d\phi}_1 = r^2 R(r)^2 dr \end{aligned}$$

The last equality follows from the fact that the spherical harmonics are normalized to 1 (see Example 9.2). It follows that  $P(r) = r^2 R(r)^2$ , as stated in the text.

The **radial distribution function**,  $P(r)$ , is a probability density in the sense that, when it is multiplied by  $dr$ , it gives the probability of finding the electron anywhere between the two walls of a spherical shell of thickness  $dr$  at the radius  $r$ . For a  $1s$  orbital,

**Fig. 9.12** A constant-volume electron-sensitive detector (the small cube) gives its greatest reading at the nucleus, and a smaller reading elsewhere. The same reading is obtained anywhere on a circle of given radius: the  $s$  orbital is spherically symmetrical.

**Fig. 9.13** The radial distribution function  $P$  gives the probability density that the electron will be found anywhere in a shell of radius  $r$ . For a  $1s$  electron in hydrogen,  $P$  is a maximum when  $r$  is equal to the Bohr radius  $a_0$ . The value of  $P$  is equivalent to the reading that a detector shaped like a spherical shell would give as its radius is varied.

$$P(r) = \frac{4Z^3}{a_0^3} r^2 e^{-2Zr/a_0} \quad (9.19)$$

Let's interpret this expression:

1. Because  $r^2 = 0$  at the nucleus,  $P(0) = 0$ . The volume of the shell of inspection is zero when  $r = 0$ .
2. As  $r \rightarrow \infty$ ,  $P(r) \rightarrow 0$  on account of the exponential term. The wavefunction has fallen to zero at great distances from the nucleus.
3. The increase in  $r^2$  and the decrease in the exponential factor means that  $P$  passes through a maximum at an intermediate radius (see Fig. 9.13).

The maximum of  $P(r)$ , which can be found by differentiation, marks the most probable radius at which the electron will be found, and for a 1s orbital in hydrogen occurs at  $r = a_0$ , the Bohr radius. When we carry through the same calculation for the radial distribution function of the 2s orbital in hydrogen, we find that the most probable radius is  $5.2a_0 = 275$  pm. This larger value reflects the expansion of the atom as its energy increases.

### Example 9.3 Calculating the most probable radius

Calculate the most probable radius,  $r^*$ , at which an electron will be found when it occupies a 1s orbital of a hydrogenic atom of atomic number  $Z$ , and tabulate the values for the one-electron species from H to  $\text{Ne}^{9+}$ .

**Method** We find the radius at which the radial distribution function of the hydrogenic 1s orbital has a maximum value by solving  $dP/dr = 0$ . If there are several maxima, then we choose the one corresponding to the greatest amplitude.

**Answer** The radial distribution function is given in eqn 9.19. It follows that

$$\frac{dP}{dr} = \frac{4Z^3}{a_0^3} \left( 2r - \frac{2Zr^2}{a_0} \right) e^{-2Zr/a_0}$$

This function is zero where the term in parentheses is zero, which (other than at  $r = 0$ ) is at

$$r^* = \frac{a_0}{Z}$$

Then, with  $a_0 = 52.9$  pm, the most probable radius is

|                 | H    | He <sup>+</sup> | Li <sup>2+</sup> | Be <sup>3+</sup> | B <sup>4+</sup> | C <sup>5+</sup> | N <sup>6+</sup> | O <sup>7+</sup> | F <sup>8+</sup> | Ne <sup>9+</sup> |
|-----------------|------|-----------------|------------------|------------------|-----------------|-----------------|-----------------|-----------------|-----------------|------------------|
| $r^*/\text{pm}$ | 52.9 | 26.5            | 17.6             | 13.2             | 10.6            | 8.82            | 7.56            | 6.61            | 5.88            | 5.29             |

Notice how the 1s orbital is drawn towards the nucleus as the nuclear charge increases. At uranium the most probable radius is only 0.58 pm, almost 100 times closer than for hydrogen. (On a scale where  $r^* = 10$  cm for H,  $r^* = 1$  mm for U, Fig. 9.14.) We need to be cautious, though, in extending this result to very heavy atoms because relativistic effects are then important and complicate the calculation.

**Self-test 9.6** Find the most probable distance of a 2s electron from the nucleus in a hydrogenic atom.  $[(3 + 5^{1/2})a_0/Z]$

**Fig. 9.14** A representation of the most probable radii of a variety of one-electron atoms and ions.

### (g) p Orbitals

The three 2p orbitals are distinguished by the three different values that  $m_l$  can take when  $l = 1$ . Because the quantum number  $m_l$  tells us the orbital angular momentum

**Fig. 9.15** The boundary surfaces of p orbitals. A nodal plane passes through the nucleus and separates the two lobes of each orbital. The dark and light areas denote regions of opposite sign of the wavefunction.

**interActivity** Use mathematical software to plot the boundary surfaces of the real parts of the spherical harmonics  $Y_{1,m_l}(\theta, \phi)$ . The resulting plots are not strictly the p orbital boundary surfaces, but sufficiently close to be reasonable representations of the shapes of hydrogenic orbitals.

around an axis, these different values of  $m_l$  denote orbitals in which the electron has different orbital angular momenta around an arbitrary z-axis but the same magnitude of that momentum (because  $l$  is the same for all three). The orbital with  $m_l = 0$ , for instance, has zero angular momentum around the z-axis. Its angular variation is proportional to  $\cos \theta$ , so the probability density, which is proportional to  $\cos^2 \theta$ , has its maximum value on either side of the nucleus along the z-axis (at  $\theta = 0$  and  $180^\circ$ ). The wavefunction of a 2p orbital with  $m_l = 0$  is

$$\begin{aligned}\psi_{p_0} &= R_{2,1}(r)Y_{1,0}(\theta, \phi) = \frac{1}{4(2\pi)^{1/2}} \left(\frac{Z}{a_0}\right)^{5/2} r \cos \theta e^{-Zr/2a_0} \\ &= r \cos \theta f(r)\end{aligned}\quad (9.20a)$$

where  $f(r)$  is a function only of  $r$ . Because in spherical polar coordinates  $z = r \cos \theta$ , this wavefunction may also be written

$$\psi_{p_0} = zf(r) \quad (9.20b)$$

All p orbitals with  $m_l = 0$  have wavefunctions of this form, but  $f(r)$  depends on the value of  $n$ . This way of writing the orbital is the origin of the name ‘ $p_z$  orbital’: its boundary surface is shown in Fig. 9.15. The wavefunction is zero everywhere in the  $xy$ -plane, where  $z = 0$ , so the  $xy$ -plane is a **nodal plane** of the orbital: the wavefunction changes sign on going from one side of the plane to the other.

The wavefunctions of 2p orbitals with  $m_l = \pm 1$  have the following form:

$$\begin{aligned}\psi_{p_{\pm 1}} &= R_{2,1}(r)Y_{1,\pm 1}(\theta, \phi) = \mp \frac{1}{8\pi^{1/2}} \left(\frac{Z}{a_0}\right)^{5/2} r \sin \theta e^{\pm i\phi} e^{-Zr/2a_0} \\ &= \mp \frac{1}{2^{1/2}} r \sin \theta e^{\pm i\phi} f(r)\end{aligned}\quad (9.21)$$

We saw in Chapter 8 that a particle that has net motion is described by a complex wavefunction. In the present case, the functions correspond to nonzero angular momentum about the z-axis:  $e^{+i\phi}$  corresponds to clockwise rotation when viewed from below, and  $e^{-i\phi}$  corresponds to counterclockwise rotation (from the same viewpoint). They have zero amplitude where  $\theta = 0$  and  $180^\circ$  (along the z-axis) and maximum amplitude at  $90^\circ$ , which is in the  $xy$ -plane. To draw the functions it is usual to represent them as standing waves. To do so, we take the real linear combinations

$$\begin{aligned}\psi_{p_x} &= -\frac{1}{2^{1/2}}(p_{+1} - p_{-1}) = r \sin \theta \cos \phi f(r) = xf(r) \\ \psi_{p_y} &= \frac{i}{2^{1/2}}(p_{+1} + p_{-1}) = r \sin \theta \sin \phi f(r) = yf(r)\end{aligned}\quad (9.22)$$

(See the following *Justification*.) These linear combinations are indeed standing waves with no net orbital angular momentum around the  $z$ -axis, as they are superpositions of states with equal and opposite values of  $m_l$ . The  $p_x$  orbital has the same shape as a  $p_z$  orbital, but it is directed along the  $x$ -axis (see Fig. 9.15); the  $p_y$  orbital is similarly directed along the  $y$ -axis. The wavefunction of any  $p$  orbital of a given shell can be written as a product of  $x$ ,  $y$ , or  $z$  and the same radial function (which depends on the value of  $n$ ).

**Justification 9.3** *The linear combination of degenerate wavefunctions*

We justify here the step of taking linear combinations of degenerate orbitals when we want to indicate a particular point. The freedom to do so rests on the fact that, whenever two or more wavefunctions correspond to the same energy, any linear combination of them is an equally valid solution of the Schrödinger equation.

Suppose  $\psi_1$  and  $\psi_2$  are both solutions of the Schrödinger equation with energy  $E$ ; then we know that

$$\hat{H}\psi_1 = E\psi_1 \quad \hat{H}\psi_2 = E\psi_2$$

Now consider the linear combination  $\psi = c_1\psi_1 + c_2\psi_2$  where  $c_1$  and  $c_2$  are arbitrary coefficients. Then it follows that

$$\hat{H}\psi = \hat{H}(c_1\psi_1 + c_2\psi_2) = c_1\hat{H}\psi_1 + c_2\hat{H}\psi_2 = c_1E\psi_1 + c_2E\psi_2 = E\psi$$

Hence, the linear combination is also a solution corresponding to the same energy  $E$ .

**(h) d Orbitals**

When  $n = 3$ ,  $l$  can be 0, 1, or 2. As a result, this shell consists of one  $3s$  orbital, three  $3p$  orbitals, and five  $3d$  orbitals. Each value of the quantum number  $m_l = +2, +1, 0, -1, -2$  corresponds to a different value for the component of the angular momentum about the  $z$ -axis. As for the  $p$  orbitals,  $d$  orbitals with opposite values of  $m_l$  (and hence opposite senses of motion around the  $z$ -axis) may be combined in pairs to give real standing waves, and the boundary surfaces of the resulting shapes are shown in Fig. 9.16. The real linear combinations have the following forms:

**Fig. 9.16** The boundary surfaces of  $d$  orbitals. Two nodal planes in each orbital intersect at the nucleus and separate the lobes of each orbital. The dark and light areas denote regions of opposite sign of the wavefunction.

**interActivity** To gain insight into the shapes of the  $f$  orbitals, use mathematical software to plot the boundary surfaces of the spherical harmonics  $Y_{3,m_l}(\theta, \phi)$ .

$$\begin{aligned}
d_{xy} &= xyf(r) & d_{yz} &= yzf(r) & d_{zx} &= zxf(r) \\
d_{x^2-y^2} &= \frac{1}{2}(x^2 - y^2)f(r) & d_{z^2} &= \left(\frac{1}{2}\sqrt{3}\right)(3z^2 - r^2)f(r)
\end{aligned}
\quad (9.23)$$

### 9.3 Spectroscopic transitions and selection rules

**Key point** Allowed spectroscopic transitions of atoms are governed by selection rules that stem from the unit angular momentum of a photon and the conservation of angular momentum.

The energies of the hydrogenic atoms are given by eqn 9.9. When the electron undergoes a **transition**, a change of state, from an orbital with quantum numbers  $n_1, l_1, m_{l1}$  to another (lower energy) orbital with quantum numbers  $n_2, l_2, m_{l2}$ , it undergoes a change of energy  $\Delta E$  and discards the excess energy as a photon of electromagnetic radiation with a frequency  $\nu$  given by the Bohr frequency condition (eqn 7.14).

It is tempting to think that all possible transitions are permissible, and that a spectrum arises from the transition of an electron from any initial orbital to any other orbital. However, this is not so, because a photon has an intrinsic spin angular momentum corresponding to  $s = 1$  (Section 8.8). Because total angular momentum is conserved, the change in angular momentum of the electron must compensate for the angular momentum carried away by the photon. Thus, an electron in a d orbital ( $l = 2$ ) cannot make a transition into an s orbital ( $l = 0$ ) because the photon cannot carry away enough angular momentum. Similarly, an s electron cannot make a transition to another s orbital, because there would then be no change in the angular momentum of the electron to make up for the angular momentum carried away by the photon. It follows that some spectroscopic transitions are **allowed**, meaning that they can occur, whereas others are **forbidden**, meaning that they cannot occur.

A **selection rule** is a statement about which transitions are allowed. They are derived (for atoms) by identifying the transitions that conserve angular momentum when a photon is emitted or absorbed. We show in the following *Justification* that the selection rules for hydrogenic atoms are

$$\Delta l = \pm 1 \quad \Delta m_l = 0, \pm 1$$

Selection rules for  
hydrogenic atoms

(9.24)

The principal quantum number  $n$  can change by any amount consistent with the  $\Delta l$  for the transition, because it does not relate directly to the angular momentum.

#### Justification 9.4 The identification of selection rules

The underlying classical idea behind a spectroscopic transition is that, for an atom or molecule to be able to interact with the electromagnetic field and absorb or create a photon of frequency  $\nu$ , it must possess, at least transiently, a dipole oscillating at that frequency. This transient dipole is expressed quantum mechanically in terms of the **transition dipole moment**,  $\mu_{fi}$ , between the initial and final states, where<sup>1</sup>

$$\mu_{fi} = \int \psi_f^* \hat{\mu} \psi_i d\tau \quad (9.25)$$

and  $\hat{\mu}$  is the electric dipole moment operator. For a one-electron atom  $\hat{\mu}$  is multiplication by  $-er$  with components  $\mu_x = -ex$ ,  $\mu_y = -ey$ , and  $\mu_z = -ez$ . If the transition dipole moment is zero, then the transition is forbidden; the transition is allowed if the transition moment is nonzero.

<sup>1</sup> See our *Quanta, matter, and change* (2009) for a detailed development of the form of eqn 9.25.

To evaluate a transition dipole moment, we consider each component in turn. For example, for the  $z$ -component,

$$\mu_{z,fi} = -e \int \psi_f^* z \psi_i d\tau$$

To evaluate the integral, we note from Table 8.2 that  $z = (4\pi/3)^{1/2} r Y_{1,0}$ , so

$$\int \psi_f^* z \psi_i d\tau = \int_0^\infty \int_0^\pi \int_0^{2\pi} \overbrace{R_{n_f, l_f}^* Y_{l_f, m_{l_f}}^*}^{\psi_f^*} \overbrace{\left(\frac{4\pi}{3}\right)^{1/2} r Y_{1,0}}^z \overbrace{R_{n_i, l_i} Y_{l_i, m_{l_i}} \psi_i}^{\psi_i} \overbrace{r^2 dr \sin \theta d\theta d\phi}^{d\tau}$$

This multiple integral is the product of three factors, an integral over  $r$  and two integrals over the angles, so the factors on the right can be grouped as follows:

$$\int \psi_f^* z \psi_i d\tau = \left(\frac{4\pi}{3}\right)^{1/2} \int_0^\infty R_{n_f, l_f}^* r R_{n_i, l_i} r^2 dr \int_0^\pi \int_0^{2\pi} Y_{l_f, m_{l_f}}^* Y_{1,0} Y_{l_i, m_{l_i}} \sin \theta d\theta d\phi$$

It follows from the properties of the spherical harmonics (Table 8.2) that the integral

$$\int_0^\pi \int_0^{2\pi} Y_{l_f, m_{l_f}}^* Y_{1,0} Y_{l_i, m_{l_i}} \sin \theta d\theta d\phi$$

is zero unless  $l_f = l_i \pm 1$  and  $m_{l_f} = m_{l_i} + m$ . Because  $m = 0$  in the present case, the angular integral, and hence the  $z$ -component of the transition dipole moment, is zero unless  $\Delta l = \pm 1$  and  $\Delta m_l = 0$ , which is a part of the set of selection rules. The same procedure, but considering the  $x$ - and  $y$ -components, results in the complete set of rules.

**Fig. 9.17** A Grotrian diagram that summarizes the appearance and analysis of the spectrum of atomic hydrogen. The transitions are labelled with their wavenumbers (in  $\text{cm}^{-1}$ ).

#### • A brief illustration

To identify the orbitals to which a 4d electron may make radiative transitions, we first identify the value of  $l$  and then apply the selection rule for this quantum number. Because  $l = 2$ , the final orbital must have  $l = 1$  or 3. Thus, an electron may make a transition from a 4d orbital to any  $np$  orbital (subject to  $\Delta m_l = 0, \pm 1$ ) and to any  $nf$  orbital (subject to the same rule). However, it cannot undergo a transition to any other orbital, so a transition to any  $ns$  orbital or to another  $nd$  orbital is forbidden. •

**Self-test 9.7** To what orbitals may a 4s electron make electric-dipole allowed radiative transitions? [to  $np$  orbitals only]

The selection rules and the atomic energy levels jointly account for the structure of a **Grotrian diagram** (Fig. 9.17), which summarizes the energies of the states and the transitions between them. The thicknesses of the transition lines in the diagram denote their relative intensities in the spectrum; we see how to determine transition intensities in Section 13.2.

## The structures of many-electron atoms

The Schrödinger equation for a many-electron atom is highly complicated because all the electrons interact with one another. One very important consequence of these interactions is that orbitals of the same value of  $n$  but different values of  $l$  are no longer degenerate in a many-electron atom. Moreover, even for a helium atom, with its two electrons, no analytical expression for the orbitals and energies can be given, and we are forced to make approximations. We shall adopt a simple approach based on what

we already know about the structure of hydrogenic atoms. Later we shall see the kind of numerical computations that are currently used to obtain accurate wavefunctions and energies.

## 9.4 The orbital approximation

**Key points** In the orbital approximation, each electron is regarded as occupying its own orbital.

(a) A configuration is a statement of the occupied orbitals. (b) The Pauli exclusion principle, a special case of the Pauli principle, limits to two the number of electrons that can occupy a given orbital. (c) In many-electron atoms, s orbitals lie at a lower energy than p orbitals of the same shell due to the combined effects of penetration and shielding. (d) The building-up principle is an algorithm for predicting the ground-state electron configuration of an atom. (e) Ionization energies and electron affinities vary periodically through the periodic table.

The wavefunction of a many-electron atom is a very complicated function of the coordinates of all the electrons, and we should write it  $\Psi(r_1, r_2, \dots)$ , where  $r_i$  is the vector from the nucleus to electron  $i$  (upper-case  $\Psi$  is commonly used to denote a many-electron wavefunction). However, in the **orbital approximation** we suppose that a reasonable first approximation to this exact wavefunction is obtained by thinking of each electron as occupying its 'own' orbital, and write

$$\Psi(r_1, r_2, \dots) = \psi(r_1)\psi(r_2) \dots \quad (9.26)$$

Orbital  
approximation

We can think of the individual orbitals as resembling the hydrogenic orbitals, but corresponding to nuclear charges modified by the presence of all the other electrons in the atom. This description is only approximate, as the following *Justification* reveals, but it is a useful model for discussing the chemical properties of atoms, and is the starting point for more sophisticated descriptions of atomic structure.

### Justification 9.5 The orbital approximation

The orbital approximation would be exact if there were no interactions between electrons. To demonstrate the validity of this remark, we need to consider a system in which the hamiltonian for the energy is the sum of two contributions, one for electron 1 and the other for electron 2:

$$\hat{H} = \hat{H}_1 + \hat{H}_2$$

In an actual atom (such as helium atom), there is an additional term (proportional to  $1/r_{12}$ ) corresponding to the interaction of the two electrons:

$$\hat{H} = \overbrace{-\frac{\hbar^2}{2m_e}\nabla_1^2 - \frac{e^2}{4\pi\epsilon_0 r_1}}^{\hat{H}_1} - \overbrace{\frac{\hbar^2}{2m_e}\nabla_2^2 - \frac{e^2}{4\pi\epsilon_0 r_2}}^{\hat{H}_2} + \frac{e^2}{4\pi r_{12}}$$

but we are ignoring that term. We shall now show that, if  $\psi(r_1)$  is an eigenfunction of  $\hat{H}_1$  with energy  $E_1$ , and  $\psi(r_2)$  is an eigenfunction of  $\hat{H}_2$  with energy  $E_2$ , then the product  $\Psi(r_1, r_2) = \psi(r_1)\psi(r_2)$  is an eigenfunction of the combined hamiltonian  $\hat{H}$ . To do so we write

$$\begin{aligned}\hat{H}\Psi(r_1, r_2) &= (\hat{H}_1 + \hat{H}_2)\psi(r_1)\psi(r_2) = \hat{H}_1\psi(r_1)\psi(r_2) + \psi(r_1)\hat{H}_2\psi(r_2) \\ &= E_1\psi(r_1)\psi(r_2) + \psi(r_1)E_2\psi(r_2) = (E_1 + E_2)\psi(r_1)\psi(r_2) \\ &= E\Psi(r_1, r_2)\end{aligned}$$

where  $E = E_1 + E_2$ . This is the result we need to prove. However, if the electrons interact (as they do in fact), then the proof fails.

**(a) The helium atom**

The orbital approximation allows us to express the electronic structure of an atom by reporting its **configuration**, a statement of its occupied orbitals (usually, but not necessarily, in its ground state). Thus, as the ground state of a hydrogenic atom consists of the single electron in a 1s orbital, we report its configuration as  $1s^1$  (read ‘one-ess-one’).

A He atom has two electrons. We can imagine forming the atom by adding the electrons in succession to the orbitals of the bare nucleus (of charge  $2e$ ). The first electron occupies a 1s hydrogenic orbital, but because  $Z = 2$  that orbital is more compact than in H itself. The second electron joins the first in the 1s orbital, so the electron configuration of the ground state of He is  $1s^2$ .

**(b) The Pauli principle**

Lithium, with  $Z = 3$ , has three electrons. The first two occupy a 1s orbital drawn even more closely than in He around the more highly charged nucleus. The third electron, however, does not join the first two in the 1s orbital because that configuration is forbidden by the **Pauli exclusion principle**:

No more than two electrons may occupy any given orbital, and if two do occupy one orbital, then their spins must be paired.

Pauli exclusion principle

**Fig. 9.18** Electrons with paired spins have zero resultant spin angular momentum. They can be represented by two vectors that lie at an indeterminate position on the cones shown here, but, wherever one lies on its cone, the other points in the opposite direction; their resultant is zero.

Electrons with paired spins, denoted  $\uparrow\downarrow$ , have zero net spin angular momentum because the spin of one electron is cancelled by the spin of the other. Specifically, one electron has  $m_s = +\frac{1}{2}$ , the other has  $m_s = -\frac{1}{2}$ , and they are orientated on their respective cones so that the resultant spin is zero (Fig. 9.18). The exclusion principle is the key to the structure of complex atoms, to chemical periodicity, and to molecular structure. It was proposed by Wolfgang Pauli in 1924 when he was trying to account for the absence of some lines in the spectrum of helium. Later he was able to derive a very general form of the principle from theoretical considerations.

The Pauli exclusion principle in fact applies to any pair of identical fermions (particles with half integral spin). Thus it applies to protons, neutrons, and  $^{13}\text{C}$  nuclei (all of which have spin  $\frac{1}{2}$ ) and to  $^{35}\text{Cl}$  nuclei (which have spin  $\frac{3}{2}$ ). It does not apply to identical bosons (particles with integral spin), which include photons (spin 1),  $^{12}\text{C}$  nuclei (spin 0). Any number of identical bosons may occupy the same state (that is, be described by the same wavefunction).

The Pauli *exclusion* principle is a special case of a general statement called the **Pauli principle**:

When the labels of any two identical fermions are exchanged, the total wavefunction changes sign; when the labels of any two identical bosons are exchanged, the sign of the total wavefunction remains the same.

Pauli principle

By ‘total wavefunction’ is meant the entire wavefunction, including the spin of the particles. To see that the Pauli principle implies the Pauli exclusion principle, we consider the wavefunction for two electrons  $\psi(1,2)$ . The Pauli principle implies that it is a fact of nature (which has its roots in the theory of relativity) that the wavefunction must change sign if we interchange the labels 1 and 2 wherever they occur in the function:

$$\Psi(2,1) = -\Psi(1,2) \quad (9.27)$$

Suppose the two electrons in an atom occupy an orbital  $\psi$ , then in the orbital approximation the overall wavefunction is  $\psi(1)\psi(2)$ . To apply the Pauli principle, we must deal with the total wavefunction, the wavefunction including spin. There are several

possibilities for two spins: both  $\alpha$ , denoted  $\alpha(1)\alpha(2)$ , both  $\beta$ , denoted  $\beta(1)\beta(2)$ , and one  $\alpha$  the other  $\beta$ , denoted either  $\alpha(1)\beta(2)$  or  $\alpha(2)\beta(1)$ . Because we cannot tell which electron is  $\alpha$  and which is  $\beta$ , in the last case it is appropriate to express the spin states as the (normalized) linear combinations

$$\begin{aligned}\sigma_+(1,2) &= (1/2^{1/2})\{\alpha(1)\beta(2) + \beta(1)\alpha(2)\} \\ \sigma_-(1,2) &= (1/2^{1/2})\{\alpha(1)\beta(2) - \beta(1)\alpha(2)\}\end{aligned}\quad (9.28)$$

These combinations allow one spin to be  $\alpha$  and the other  $\beta$  with equal probability. The total wavefunction of the system is therefore the product of the orbital part and one of the four spin states:

$$\begin{aligned}\psi(1)\psi(2)\alpha(1)\alpha(2) & \quad \psi(1)\psi(2)\beta(1)\beta(2) \\ \psi(1)\psi(2)\sigma_+(1,2) & \quad \psi(1)\psi(2)\sigma_-(1,2)\end{aligned}\quad (9.29)$$

The Pauli principle says that, for a wavefunction to be acceptable (for electrons), it must change sign when the electrons are exchanged. In each case, exchanging the labels 1 and 2 converts the factor  $\psi(1)\psi(2)$  into  $\psi(2)\psi(1)$ , which is the same, because the order of multiplying the functions does not change the value of the product. The same is true of  $\alpha(1)\alpha(2)$  and  $\beta(1)\beta(2)$ . Therefore, the first two overall products are not allowed, because they do not change sign. The combination  $\sigma_+(1,2)$  changes to

$$\sigma_+(2,1) = (1/2^{1/2})\{\alpha(2)\beta(1) + \beta(2)\alpha(1)\} = \sigma_+(1,2)$$

because it is simply the original function written in a different order. The third overall product is therefore also disallowed. Finally, consider  $\sigma_-(1,2)$ :

$$\begin{aligned}\sigma_-(2,1) &= (1/2^{1/2})\{\alpha(2)\beta(1) - \beta(2)\alpha(1)\} \\ &= -(1/2^{1/2})\{\alpha(1)\beta(2) - \beta(1)\alpha(2)\} = -\sigma_-(1,2)\end{aligned}$$

This combination does change sign (it is 'antisymmetric'). The product  $\psi(1)\psi(2)\sigma_-(1,2)$  also changes sign under particle exchange, and therefore it is acceptable.

Now we see that only one of the four possible states is allowed by the Pauli principle, and the one that survives has paired  $\alpha$  and  $\beta$  spins. This is the content of the Pauli exclusion principle. The exclusion principle is irrelevant when the orbitals occupied by the electrons are different, and both electrons may then have (but need not have) the same spin state. Nevertheless, even then the overall wavefunction must still be antisymmetric overall, and must still satisfy the Pauli principle itself.

A final point in this connection is that the acceptable product wavefunction  $\psi(1)\psi(2)\sigma_-(1,2)$  can be expressed as a determinant:

$$\begin{aligned}\frac{1}{2^{1/2}} \begin{vmatrix} \psi(1)\alpha(1) & \psi(2)\alpha(2) \\ \psi(1)\beta(1) & \psi(2)\beta(2) \end{vmatrix} &= \frac{1}{2^{1/2}} \{\psi(1)\alpha(1)\psi(2)\beta(2) - \psi(2)\alpha(2)\psi(1)\beta(1)\} \\ &= \psi(1)\psi(2)\sigma_-(1,2)\end{aligned}$$

Any acceptable wavefunction for a closed-shell species can be expressed as a **Slater determinant**, as such determinants are known. In general, for  $N$  electrons in orbitals  $\psi_a, \psi_b, \dots$

$$\Psi(1,2, \dots, N) = \frac{1}{(N!)^{1/2}} \begin{vmatrix} \psi_a(1)\alpha(1) & \psi_a(2)\alpha(2) & \psi_a(3)\alpha(3) & \dots & \psi_a(N)\alpha(N) \\ \psi_a(1)\beta(1) & \psi_a(2)\beta(2) & \psi_a(3)\beta(3) & \dots & \psi_a(N)\beta(N) \\ \psi_b(1)\alpha(1) & \psi_b(2)\alpha(2) & \psi_b(3)\alpha(3) & \dots & \psi_b(N)\alpha(N) \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ \psi_z(1)\beta(1) & \psi_z(2)\beta(2) & \psi_z(3)\beta(3) & \dots & \psi_z(N)\beta(N) \end{vmatrix} \quad [9.30a]$$

#### A brief comment

A stronger justification for taking linear combinations in eqn 9.28 is that they correspond to eigenfunctions of the total spin operators  $S^2$  and  $S_z$ , with  $M_S = 0$  and, respectively,  $S = 1$  and 0.

**Fig. 9.19** An electron at a distance  $r$  from the nucleus experiences a Coulombic repulsion from all the electrons within a sphere of radius  $r$  and which is equivalent to a point negative charge located on the nucleus. The negative charge reduces the effective nuclear charge of the nucleus from  $Ze$  to  $Z_{\text{eff}}e$ .

**Fig. 9.20** An electron in an s orbital (here a 3s orbital) is more likely to be found close to the nucleus than an electron in a p orbital of the same shell (note the closeness of the innermost peak of the 3s orbital to the nucleus at  $r=0$ ). Hence an s electron experiences less shielding and is more tightly bound than a p electron.

**interActivity** Calculate and plot the graphs given above for  $n=4$ .

Writing a many-electron wavefunction in this way ensures that it is antisymmetric under the interchange of any pair of electrons, as is explored in Problem 9.23. Because a Slater determinant takes up a lot of space, it is normally reported by writing only its diagonal elements, as in

$$\Psi(1,2,\dots,N) = \left(\frac{1}{N!}\right)^{1/2} \det|\psi_a^\alpha(1)\psi_a^\beta(2)\psi_b^\alpha(3)\dots\psi_z^\beta(N)| \quad \text{[9.30b]}$$

Notation for a Slater determinant

Now we can return to lithium. In Li ( $Z=3$ ), the third electron cannot enter the 1s orbital because that orbital is already full: we say the K shell is *complete* and that the two electrons form a **closed shell**. Because a similar closed shell is characteristic of the He atom, we denote it [He]. The third electron is excluded from the K shell and must occupy the next available orbital, which is one with  $n=2$  and hence belonging to the L shell. However, we now have to decide whether the next available orbital is the 2s orbital or a 2p orbital, and therefore whether the lowest energy configuration of the atom is [He]2s<sup>1</sup> or [He]2p<sup>1</sup>.

### (c) Penetration and shielding

Unlike in hydrogenic atoms, the 2s and 2p orbitals (and, in general, all subshells of a given shell) are not degenerate in many-electron atoms. An electron in a many-electron atom experiences a Coulombic repulsion from all the other electrons present. If it is at a distance  $r$  from the nucleus, it experiences an average repulsion that can be represented by a point negative charge located at the nucleus and equal in magnitude to the total charge of the electrons within a sphere of radius  $r$  (Fig. 9.19). The effect of this point negative charge, when averaged over all the locations of the electron, is to reduce the full charge of the nucleus from  $Ze$  to  $Z_{\text{eff}}e$ , the **effective nuclear charge**. In everyday parlance,  $Z_{\text{eff}}$  itself is commonly referred to as the ‘effective nuclear charge’. We say that the electron experiences a **shielded** nuclear charge, and the difference between  $Z$  and  $Z_{\text{eff}}$  is called the **shielding constant**,  $\sigma$ :

$$Z_{\text{eff}} = Z - \sigma$$

Effective nuclear charge [9.31]

The electrons do not actually ‘block’ the full Coulombic attraction of the nucleus: the shielding constant is simply a way of expressing the net outcome of the nuclear attraction and the electronic repulsions in terms of a single equivalent charge at the centre of the atom.

The shielding constant is different for s and p electrons because they have different radial distributions (Fig. 9.20). An s electron has a greater **penetration** through inner shells than a p electron, in the sense that it is more likely to be found close to the nucleus than a p electron of the same shell (the wavefunction of a p orbital, remember, is zero at the nucleus). Because only electrons inside the sphere defined by the location of the electron contribute to shielding, an s electron experiences less shielding than a p electron. Consequently, by the combined effects of penetration and shielding, an s electron is more tightly bound than a p electron of the same shell. Similarly, a d electron penetrates less than a p electron of the same shell (recall that the wavefunction of a d orbital varies as  $r^2$  close to the nucleus, whereas a p orbital varies as  $r$ ), and therefore experiences more shielding.

Shielding constants for different types of electrons in atoms have been calculated from their wavefunctions obtained by numerical solution of the Schrödinger equation for the atom (Table 9.2). We see that, in general, valence-shell s electrons do experience higher effective nuclear charges than p electrons, although there are some discrepancies. We return to this point shortly.

The consequence of penetration and shielding is that the energies of subshells of a shell in a many-electron atom (those with the same values of  $n$  but different values of  $l$ ) in general lie in the order  $s < p < d < f$ . The individual orbitals of a given subshell (those with the same value of  $l$  but different values of  $m_l$ ) remain degenerate because they all have the same radial characteristics and so experience the same effective nuclear charge.

We can now complete the Li story. Because the shell with  $n = 2$  consists of two nondegenerate subshells, with the 2s orbital lower in energy than the three 2p orbitals, the third electron occupies the 2s orbital. This occupation results in the ground-state configuration  $1s^2 2s^1$ , with the central nucleus surrounded by a complete helium-like shell of two 1s electrons, and around that a more diffuse 2s electron. The electrons in the outermost shell of an atom in its ground state are called the **valence electrons** because they are largely responsible for the chemical bonds that the atom forms. Thus, the valence electron in Li is a 2s electron and its other two electrons belong to its core.

#### (d) The building-up principle

The extension of this argument is called the **building-up principle**, or the *Aufbau principle*, from the German word for building up, which will be familiar from introductory courses. In brief, we imagine the bare nucleus of atomic number  $Z$ , and then feed into the orbitals  $Z$  electrons in succession. The order of occupation is

1s 2s 2p 3s 3p 4s 3d 4p 5s 4d 5p 6s

and each orbital may accommodate up to two electrons. As an example, consider the carbon atom, for which  $Z = 6$  and there are six electrons to accommodate. Two electrons enter and fill the 1s orbital, two enter and fill the 2s orbital, leaving two electrons to occupy the orbitals of the 2p subshell. Hence the ground-state configuration of C is  $1s^2 2s^2 2p^2$ , or more succinctly  $[\text{He}] 2s^2 2p^2$ , with  $[\text{He}]$  the helium-like  $1s^2$  core. However, we can be more precise: we can expect the last two electrons to occupy different 2p orbitals because they will then be further apart on average and repel each other less than if they were in the same orbital. Thus, one electron can be thought of as occupying the  $2p_x$  orbital and the other the  $2p_y$  orbital (the  $x, y, z$  designation is arbitrary, and it would be equally valid to use the complex forms of these orbitals), and the lowest energy configuration of the atom is  $[\text{He}] 2s^2 2p_x^1 2p_y^1$ . The same rule applies whenever degenerate orbitals of a subshell are available for occupation. Thus, another rule of the building-up principle is:

Electrons occupy different orbitals of a given subshell before doubly occupying any one of them.

For instance, nitrogen ( $Z = 7$ ) has the configuration  $[\text{He}] 2s^2 2p_x^1 2p_y^1 2p_z^1$ , and only when we get to oxygen ( $Z = 8$ ) is a 2p orbital doubly occupied, giving  $[\text{He}] 2s^2 2p_x^2 2p_y^1 2p_z^1$ .

When electrons occupy orbitals singly we invoke **Hund's maximum multiplicity rule**:

An atom in its ground state adopts a configuration with the greatest number of unpaired electrons.

Hund's maximum  
multiplicity rule

The explanation of Hund's rule is subtle, but it reflects the quantum mechanical property of **spin correlation**, that, as we demonstrate in the following *Justification*, electrons with parallel spins behave as if they have a tendency to stay well apart, and hence repel each other less. In essence, the effect of spin correlation is to allow the atom to shrink slightly, so the electron–nucleus interaction is improved when the spins are parallel. We can now conclude that, in the ground state of the carbon atom, the two 2p electrons have the same spin, that all three 2p electrons in the N atoms have the same spin (that is, they are parallel), and that the two 2p electrons in different orbitals in the O atom have the same spin (the two in the  $2p_x$  orbital are necessarily paired).

**Table 9.2\*** Effective nuclear charge,  $Z_{\text{eff}} = Z - \sigma$

| Element | $Z$ | Orbital | $Z_{\text{eff}}$ |
|---------|-----|---------|------------------|
| He      | 2   | 1s      | 1.6875           |
| C       | 6   | 1s      | 5.6727           |
|         |     | 2s      | 3.2166           |
|         |     | 2p      | 3.1358           |

\* More values are given in the *Data section*.

**Justification 9.6** Spin correlation

Suppose electron 1 is described by a wavefunction  $\psi_a(r_1)$  and electron 2 is described by a wavefunction  $\psi_b(r_2)$ ; then, in the orbital approximation, the joint wavefunction of the electrons is the product  $\Psi = \psi_a(r_1)\psi_b(r_2)$ . However, this wavefunction is not acceptable, because it suggests that we know which electron is in which orbital, whereas we cannot keep track of electrons. According to quantum mechanics, the correct description is either of the two following wavefunctions:

$$\Psi_{\pm} = (1/2^{1/2})\{\psi_a(r_1)\psi_b(r_2) \pm \psi_b(r_1)\psi_a(r_2)\}$$

According to the Pauli principle, because  $\Psi_+$  is symmetrical under particle interchange, it must be multiplied by an antisymmetric spin function (the one denoted  $\sigma_-$ ). That combination corresponds to a spin-paired state. Conversely,  $\Psi_-$  is antisymmetric, so it must be multiplied by one of the three symmetric spin states. These three symmetric states correspond to electrons with parallel spins (see Section 9.8 for an explanation).

Now consider the values of the two combinations when one electron approaches another, and  $r_1 = r_2$ . We see that  $\Psi_-$  vanishes, which means that there is zero probability of finding the two electrons at the same point in space when they have parallel spins. The other combination does not vanish when the two electrons are at the same point in space. Because the two electrons have different relative spatial distributions depending on whether their spins are parallel or not, it follows that their Coulombic interaction is different, and hence that the two states have different energies.

Neon, with  $Z = 10$ , has the configuration  $[\text{He}]2s^22p^6$ , which completes the L shell. This closed-shell configuration is denoted  $[\text{Ne}]$ , and acts as a core for subsequent elements. The next electron must enter the 3s orbital and begin a new shell, so an Na atom, with  $Z = 11$ , has the configuration  $[\text{Ne}]3s^1$ . Like lithium with the configuration  $[\text{He}]2s^1$ , sodium has a single s electron outside a complete core. This analysis has brought us to the origin of chemical periodicity. The L shell is completed by eight electrons, so the element with  $Z = 3$  (Li) should have similar properties to the element with  $Z = 11$  (Na). Likewise, Be ( $Z = 4$ ) should be similar to  $Z = 12$  (Mg), and so on, up to the noble gases He ( $Z = 2$ ), Ne ( $Z = 10$ ), and Ar ( $Z = 18$ ).

Ten electrons can be accommodated in the five 3d orbitals, which accounts for the electron configurations of scandium to zinc. Calculations of the type discussed in Section 9.5 show that for these atoms the energies of the 3d orbitals are always lower than the energy of the 4s orbital. However, spectroscopic results show that Sc has the configuration  $[\text{Ar}]3d^14s^2$ , instead of  $[\text{Ar}]3d^3$  or  $[\text{Ar}]3d^24s^1$ . To understand this observation, we have to consider the nature of electron–electron repulsions in 3d and 4s orbitals. The most probable distance of a 3d electron from the nucleus is less than that for a 4s electron, so two 3d electrons repel each other more strongly than two 4s electrons. As a result, Sc has the configuration  $[\text{Ar}]3d^14s^2$  rather than the two alternatives, for then the strong electron–electron repulsions in the 3d orbitals are minimized. The total energy of the atom is least despite the cost of allowing electrons to populate the high energy 4s orbital (Fig. 9.21). The effect just described is generally true for scandium through zinc, so their electron configurations are of the form  $[\text{Ar}]3d^n4s^2$ , where  $n = 1$  for scandium and  $n = 10$  for zinc. Two notable exceptions, which are observed experimentally, are Cr, with electron configuration  $[\text{Ar}]3d^54s^1$ , and Cu, with electron configuration  $[\text{Ar}]3d^{10}4s^1$ .

At gallium, the building-up principle is used in the same way as in preceding periods. Now the 4s and 4p subshells constitute the valence shell, and the period terminates with krypton. Because 18 electrons have intervened since argon, this period is

**Fig. 9.21** Strong electron–electron repulsions in the 3d orbitals are minimized in the ground state of Sc if the atom has the configuration  $[\text{Ar}]3d^14s^2$  (shown on the left) instead of  $[\text{Ar}]3d^24s^1$  (shown on the right). The total energy of the atom is lower when it has the  $[\text{Ar}]3d^14s^2$  configuration despite the cost of populating the high energy 4s orbital.

the first ‘long period’ of the periodic table. The existence of the d-block elements (the ‘transition metals’) reflects the stepwise occupation of the 3d orbitals, and the subtle shades of energy differences and effects of electron–electron repulsion along this series give rise to the rich complexity of inorganic d-metal chemistry. A similar intrusion of the f orbitals in Periods 6 and 7 accounts for the existence of the f block of the periodic table (the lanthanoids and actinoids).

We derive the configurations of cations of elements in the s, p, and d blocks of the periodic table by removing electrons from the ground-state configuration of the neutral atom in a specific order. First, we remove valence p electrons, then valence s electrons, and then as many d electrons as are necessary to achieve the specified charge. For instance, because the configuration of V is  $[\text{Ar}]3d^34s^2$ , the  $\text{V}^{2+}$  cation has the configuration  $[\text{Ar}]3d^3$ . It is reasonable that we remove the more energetic 4s electrons in order to form the cation, but it is not obvious why the  $[\text{Ar}]3d^3$  configuration is preferred in  $\text{V}^{2+}$  over the  $[\text{Ar}]3d^14s^2$  configuration, which is found in the isoelectronic Sc atom. Calculations show that the energy difference between  $[\text{Ar}]3d^3$  and  $[\text{Ar}]3d^14s^2$  depends on  $Z_{\text{eff}}$ . As  $Z_{\text{eff}}$  increases, transfer of a 4s electron to a 3d orbital becomes more favourable because the electron–electron repulsions are compensated by attractive interactions between the nucleus and the electrons in the spatially compact 3d orbital. Indeed, calculations reveal that, for a sufficiently large  $Z_{\text{eff}}$ ,  $[\text{Ar}]3d^3$  is lower in energy than  $[\text{Ar}]3d^14s^2$ . This conclusion explains why  $\text{V}^{2+}$  has a  $[\text{Ar}]3d^3$  configuration and also accounts for the observed  $[\text{Ar}]4s^03d^n$  configurations of the  $\text{M}^{2+}$  cations of Sc through Zn.

The configurations of anions of the p-block elements are derived by continuing the building-up procedure and adding electrons to the neutral atom until the configuration of the next noble gas has been reached. Thus, the configuration of the  $\text{O}^{2-}$  ion is achieved by adding two electrons to  $[\text{He}]2s^22p^4$ , giving  $[\text{He}]2s^22p^6$ , the same as the configuration of neon.

### (e) Ionization energies and electron affinities

The minimum energy necessary to remove an electron from a many-electron atom in the gas phase is the **first ionization energy**,  $I_1$ , of the element. The **second ionization energy**,  $I_2$ , is the minimum energy needed to remove a second electron (from the singly charged cation). The variation of the first ionization energy through the periodic table is shown in Fig. 9.22 and some numerical values are given in Table 9.3. In thermodynamic calculations we often need the **standard enthalpy of ionization**,  $\Delta_{\text{ion}}H^\circ$ . As shown in the following *Justification*, the two are related by

$$\Delta_{\text{ion}}H^\circ(T) = I_1 + \frac{5}{2}RT \quad (9.32)$$

**Table 9.3\*** First and second ionization energies

| Element | $I_1/(\text{kJ mol}^{-1})$ | $I_2/(\text{kJ mol}^{-1})$ |
|---------|----------------------------|----------------------------|
| H       | 1312                       |                            |
| He      | 2372                       | 5251                       |
| Mg      | 738                        | 1451                       |
| Na      | 496                        | 4562                       |

\* More values are given in the *Data section*.

**Fig. 9.22** The first ionization energies of the elements plotted against atomic number.

At 298 K, the difference between the ionization enthalpy and the corresponding ionization energy is  $6.20 \text{ kJ mol}^{-1}$ .

**Justification 9.7** *The ionization enthalpy and the ionization energy*

It follows from Kirchhoff's law (Section 2.9 and eqn 2.36) that the reaction enthalpy for

at a temperature  $T$  is related to the value at  $T = 0$  by

$$\Delta_r H^\circ(T) = \Delta_r H^\circ(0) + \int_0^T \Delta_r C_p^\circ dT$$

The molar constant-pressure heat capacity of each species in the reaction is  $\frac{5}{2}R$ , so  $\Delta_r C_p^\circ = +\frac{5}{2}R$ . The integral in this expression therefore evaluates to  $+\frac{5}{2}RT$ . The reaction enthalpy at  $T = 0$  is the same as the (molar) ionization energy,  $I_1$ . Equation 9.32 then follows. The same expression applies to each successive ionization step, so the overall ionization enthalpy for the formation of  $\text{M}^{2+}$  is

$$\Delta_r H^\circ(T) = I_1 + I_2 + 5RT$$

**Table 9.4\*** Electron affinities,  $E_a/(\text{kJ mol}^{-1})$

|    |     |              |      |
|----|-----|--------------|------|
| Cl | 349 |              |      |
| F  | 322 |              |      |
| H  | 73  |              |      |
| O  | 141 | $\text{O}^-$ | -844 |

\* More values are given in the Data section.

The **electron affinity**,  $E_{\text{ea}}$ , is the energy released when an electron attaches to a gas-phase atom (Table 9.4). In a common, logical (given its name), but not universal convention (which we adopt), the electron affinity is positive if energy is released when the electron attaches to the atom (that is,  $E_{\text{ea}} > 0$  implies that electron attachment is exothermic). It follows from a similar argument to that given in the *Justification* above that the **standard enthalpy of electron gain**,  $\Delta_{\text{eg}} H^\circ$ , at a temperature  $T$  is related to the electron affinity by

$$\Delta_{\text{eg}} H^\circ(T) = -E_{\text{ea}} - \frac{5}{2}RT \quad (9.33)$$

Note the change of sign. In typical thermodynamic cycles the  $\frac{5}{2}RT$  that appears in eqn 9.32 cancels that in eqn 9.33, so ionization energies and electron affinities can be used directly. A final preliminary point is that the electron-gain enthalpy of a species  $X$  is the negative of the ionization enthalpy of its negative ion:

$$\Delta_{\text{eg}} H^\circ(X) = -\Delta_{\text{ion}} H^\circ(X^-) \quad (9.34)$$

As ionization energy is often easier to measure than electron affinity; this relation can be used to determine numerical values of the latter.

As will be familiar from introductory chemistry, ionization energies and electron affinities show periodicities. The former is more regular and we concentrate on it. Lithium has a low first ionization energy because its outermost electron is well shielded from the nucleus by the core ( $Z_{\text{eff}} = 1.3$ , compared with  $Z = 3$ ). The ionization energy of beryllium ( $Z = 4$ ) is greater but that of boron is lower than that of beryllium because in the latter the outermost electron occupies a 2p orbital and is less strongly bound than if it had been a 2s electron. The ionization energy increases from boron to nitrogen on account of the increasing nuclear charge. However, the ionization energy of oxygen is less than would be expected by simple extrapolation. The explanation is that at oxygen a 2p orbital must become doubly occupied, and the electron–electron repulsions are increased above what would be expected by simple extrapolation along the row. In addition, the loss of a 2p electron results in a configuration with a half-filled subshell (like that of N), which is an arrangement of low energy, so the energy of  $\text{O}^+ + \text{e}^-$  is lower than might be expected, and the ionization energy is correspondingly low too. (The kink is less pronounced in the next row, between phosphorus and sulfur,

because their orbitals are more diffuse.) The values for oxygen, fluorine, and neon fall roughly on the same line, the increase of their ionization energies reflecting the increasing attraction of the more highly charged nuclei for the outermost electrons.

The outermost electron in sodium ( $Z = 11$ ) is 3s. It is far from the nucleus, and the latter's charge is shielded by the compact, complete neon-like core, with the result that  $Z_{\text{eff}} \approx 2.5$ . As a result, the ionization energy of sodium is substantially lower than that of neon ( $Z = 10$ ,  $Z_{\text{eff}} \approx 5.8$ ). The periodic cycle starts again along this row, and the variation of the ionization energy can be traced to similar reasons.

Electron affinities are greatest close to fluorine, for the incoming electron enters a vacancy in a compact valence shell and can interact strongly with the nucleus. The attachment of an electron to an anion (as in the formation of  $\text{O}^{2-}$  from  $\text{O}^-$ ) is invariably endothermic, so  $E_{\text{ea}}$  is negative. The incoming electron is repelled by the charge already present. Electron affinities are also small, and may be negative, when an electron enters an orbital that is far from the nucleus (as in the heavier alkali metal atoms) or is forced by the Pauli principle to occupy a new shell (as in the noble gas atoms).

## 9.5 Self-consistent field orbitals

---

**Key point** The Schrödinger equation for many-electron atoms is solved numerically and iteratively until the solutions are self-consistent.

---

The central difficulty of the Schrödinger equation is the presence of the electron–electron interaction terms. The potential energy of the electrons is

$$V = - \sum_i \frac{Ze^2}{4\pi\epsilon_0 r_i} + \frac{1}{2} \sum_{i,j}' \frac{e^2}{4\pi\epsilon_0 r_{ij}} \quad (9.35)$$

The prime on the second sum indicates that  $i \neq j$ , and the factor of one-half prevents double-counting of electron pair repulsions (1 interacting with 2 is the same as 2 interacting with 1). The first term is the total attractive interaction between the electrons and the nucleus. The second term is the total repulsive interaction between the electrons;  $r_{ij}$  is the distance between electrons  $i$  and  $j$ . It is hopeless to expect to find analytical solutions of a Schrödinger equation with such a complicated potential energy term, but computational techniques are available that give very detailed and reliable numerical solutions for the wavefunctions and energies. The techniques were originally introduced by D.R. Hartree (before computers were available) and then modified by V. Fock to take into account the Pauli principle correctly. In broad outline, the **Hartree–Fock self-consistent field** (HF-SCF) procedure is as follows.

Imagine that we have a rough idea of the structure of the atom. In the Ne atom, for instance, the orbital approximation suggests the configuration  $1s^2 2s^2 2p^6$  with the orbitals approximated by hydrogenic atomic orbitals. Now consider one of the 2p electrons. A Schrödinger equation can be written for this electron by ascribing to it a potential energy due to the nuclear attraction and the repulsion from the other electrons. This equation has the form

$$\begin{aligned} \hat{H}(1)\psi_{2p}(1) + V(\text{other electrons})\psi_{2p}(1) \\ - V(\text{exchange correction})\psi_{2p}(1) = E_{2p}\psi_{2p}(1) \end{aligned} \quad (9.36)$$

Although the equation is for the 2p orbital in neon, it depends on the wavefunctions of all the other occupied orbitals in the atom. A similar equation can be written for the 1s and 2s orbitals in the atom. The various terms are as follows:

- The first term on the left is the contribution of the kinetic energy and the attraction of the electron to the nucleus, just as in a hydrogenic atom.

**Fig. 9.23** The radial distribution functions for the orbitals of Na based on SCF calculations. Note the shell-like structure, with the 3s orbital outside the inner K and L shells.

- The second term takes into account the potential energy of the electron of interest due to the electrons in the other occupied orbitals.
- The third term is an *exchange correction* that takes into account the spin correlation effects discussed earlier.

There is no hope of solving eqn 9.36 analytically. However, it can be solved numerically if we guess an approximate form of the wavefunctions of all the orbitals except 2p. The procedure is then repeated for the other orbitals in the atom, the 1s and 2s orbitals. This sequence of calculations gives the form of the 2p, 2s, and 1s orbitals, and in general they will differ from the set used initially to start the calculation. These improved orbitals can be used in another cycle of calculation, and a second improved set of orbitals is obtained. The recycling continues until the orbitals and energies obtained are insignificantly different from those used at the start of the current cycle. The solutions are then self-consistent and accepted as solutions of the problem.

Figure 9.23 shows plots of some of the HF-SCF radial distribution functions for sodium. They show the grouping of electron density into shells, as was anticipated by the early chemists, and the differences of penetration as discussed above. These SCF calculations therefore support the qualitative discussions that are used to explain chemical periodicity. They also considerably extend that discussion by providing detailed wavefunctions and precise energies.

## The spectra of complex atoms

The spectra of atoms rapidly become very complicated as the number of electrons increases, but there are some important and moderately simple features that make atomic spectroscopy useful in the study of the composition of samples as large and as complex as stars. The general idea is straightforward: lines in the spectrum (in either emission or absorption) occur when the atom undergoes a transition with a change of energy  $|\Delta E|$ , and emits or absorbs a photon of frequency  $\nu = |\Delta E|/h$  and  $\tilde{\nu} = |\Delta E|/hc$ . Hence, we can expect the spectrum to give information about the energies of electrons in atoms. However, the actual energy levels are not given solely by the energies of the orbitals, because the electrons interact with one another in various ways, and there are contributions to the energy in addition to those we have already considered.

### 9.6 Linewidths

**Key points** (a) Doppler broadening of a spectral line is caused by the distribution of molecular and atomic speeds in a sample. (b) Lifetime broadening arises from the finite lifetime of an excited state and a consequent blurring of energy levels. Collisions between atoms can affect excited state lifetimes and spectral linewidths. The natural linewidth of a transition is an intrinsic property that depends on the rate of spontaneous emission at the transition frequency.

A number of effects contribute to the widths of spectroscopic lines. Some contributions to linewidths can be modified by changing the conditions, and to achieve high resolutions we need to know how to minimize these contributions. Other contributions cannot be changed, and represent an inherent limitation on resolution.

#### (a) Doppler broadening

One important broadening process in gaseous samples is the **Doppler effect**, in which radiation is shifted in frequency when the source is moving towards or away from the

observer. When a source emitting electromagnetic radiation of frequency  $\nu$  moves with a speed  $s$  relative to an observer, the observer detects radiation of frequency

$$\nu_{\text{receding}} = \nu \left( \frac{1 - s/c}{1 + s/c} \right)^{1/2} \quad \nu_{\text{approaching}} = \nu \left( \frac{1 + s/c}{1 - s/c} \right)^{1/2} \quad \text{Doppler shifts} \quad (9.37a)$$

where  $c$  is the speed of light. For nonrelativistic speeds ( $s \ll c$ ), these expressions simplify to

$$\nu_{\text{receding}} \approx \frac{\nu}{1 + s/c} \quad \nu_{\text{approaching}} \approx \frac{\nu}{1 - s/c} \quad (9.37b)$$

Atoms reach high speeds in all directions in a gas, and a stationary observer detects the corresponding Doppler-shifted range of frequencies. Some atoms approach the observer, some move away; some move quickly, others slowly. The detected spectral ‘line’ is the absorption or emission profile arising from all the resulting Doppler shifts. As shown in the following *Justification*, the profile reflects the distribution of velocities parallel to the line of sight, which is a bell-shaped Gaussian curve. The Doppler line shape is therefore also a Gaussian (Fig. 9.24), and we show in the *Justification* that, when the temperature is  $T$  and the mass of the atom is  $m$ , then the observed width of the line at half-height (in terms of frequency or wavelength) is

$$\delta\nu_{\text{obs}} = \frac{2\nu}{c} \left( \frac{2kT \ln 2}{m} \right)^{1/2} \quad \delta\lambda_{\text{obs}} = \frac{2\lambda}{c} \left( \frac{2kT \ln 2}{m} \right)^{1/2} \quad \text{Doppler broadening} \quad (9.38)$$

For an atom like Si at room temperature ( $T \approx 300$  K),  $\delta\nu/\nu \approx 2.3 \times 10^{-6}$ . Doppler broadening increases with temperature because the molecules acquire a wider range of speeds. Therefore, to obtain spectra of maximum sharpness, it is best to work with cool samples.

#### Justification 9.8 Doppler broadening

We know from the Boltzmann distribution (*Fundamentals F.5a*) that the probability that an atom of mass  $m$  and speed  $s$  in a gas phase sample at a temperature  $T$  has kinetic energy  $E_k = \frac{1}{2}ms^2$  is proportional to  $e^{-ms^2/2kT}$ . The observed frequencies,  $\nu_{\text{obs}}$ , emitted or absorbed by the molecule are related to its speed by eqn 9.37b. When  $s \ll c$ , the Doppler shift in the frequency is

$$\nu_{\text{obs}} - \nu \approx \pm \nu s/c$$

which implies a symmetrical distribution of observed frequencies with respect to atomic speeds. More specifically, the intensity  $I$  of a transition at  $\nu_{\text{obs}}$  is proportional to the probability of finding the atom that emits or absorbs at  $\nu_{\text{obs}}$ , so it follows from the Boltzmann distribution and the expression for the Doppler shift that

$$I(\nu_{\text{obs}}) \propto e^{-mc^2(\nu_{\text{obs}} - \nu)^2/2\nu^2kT}$$

which has the form of a Gaussian function. The width at half-height can be calculated directly from the exponent to give eqn 9.38.

#### (b) Lifetime broadening

It is found that spectroscopic lines from gas-phase samples are not infinitely sharp even when Doppler broadening has been largely eliminated by working at low temperatures. This residual broadening is due to quantum mechanical effects. Specifically, when the Schrödinger equation is solved for a system that is changing with time,

**Fig. 9.24** The Gaussian shape of a Doppler-broadened spectral line reflects the Maxwell distribution of speeds in the sample at the temperature of the experiment. Notice that the line broadens as the temperature is increased.

**interActivity** In a spectrometer that makes use of phase-sensitive detection, the output signal is proportional to the first derivative of the signal intensity,  $dI/d\nu$ . Plot the resulting line shape for various temperatures. How is the separation of the peaks related to the temperature?

#### A brief comment

A Gaussian function of the general form  $y(x) = ae^{-(x-b)^2/2\sigma^2}$ , where  $a$ ,  $b$ , and  $\sigma$  are constants, has a maximum  $y(b) = a$  and a width at half-height  $\delta x = 2\sigma(2 \ln 2)^{1/2}$ .

**A note on good practice** Although eqn 9.39 is reminiscent of the uncertainty principle, its origin and interpretation are quite different and consequently it is best to avoid the term ‘uncertainty broadening’. The uncertainty principle relates conjugate observables, observables represented by operators that do not commute. There is no operator for time in quantum mechanics, so there is no observable conjugate to time. Equation 9.39 is a consequence of the time-dependent Schrödinger equation.

it is found that it is impossible to specify the energy levels exactly. If on average a system survives in a state for a time  $\tau$  (tau), the **lifetime** of the state, then its energy levels are blurred to an extent of order  $\delta E$ , where

$$\delta E \approx \frac{\hbar}{\tau} \quad \text{Lifetime broadening} \quad (9.39)$$

This expression is reminiscent of the Heisenberg uncertainty principle (eqn 7.39), and consequently this **lifetime broadening** is often called ‘uncertainty broadening’. No excited state has an infinite lifetime; therefore, all states are subject to some lifetime broadening and the shorter the lifetimes of the states involved in a transition the broader the corresponding spectral lines.

#### • A brief illustration

When the energy spread is expressed as a wavenumber through  $\delta E = hc\delta\tilde{\nu}$ , and the values of the fundamental constants introduced, this relation becomes

$$\delta\tilde{\nu} \approx \frac{5.3 \text{ cm}^{-1}}{\tau/\text{ps}}$$

A typical electronic excited state natural lifetime is about  $10^{-8}$  s (10 ns), corresponding to a natural width of about  $5 \times 10^{-4} \text{ cm}^{-1}$  (15 MHz). A typical natural lifetime of a molecular rotation is about  $10^3$  s, corresponding to a natural linewidth of only  $5 \times 10^{-15} \text{ cm}^{-1}$  (of the order of  $10^{-4}$  Hz). •

Two processes are responsible for the finite lifetimes of excited states. The dominant one for low frequency transitions is **collisional deactivation**, which arises from collisions between atoms or with the walls of the container. If the **collisional lifetime**, the mean time between collisions, is  $\tau_{\text{col}}$ , the resulting collisional linewidth is  $\delta E_{\text{col}} \approx \hbar/\tau_{\text{col}}$ . Because  $\tau_{\text{col}} = 1/z$ , where  $z$  is the collision frequency, and from the kinetic model of gases (Section 1.2) we know that  $z$  is proportional to the pressure, we see that the collisional linewidth is proportional to the pressure. The collisional linewidth can therefore be minimized by working at low pressures.

The rate of spontaneous emission cannot be changed. Hence it is a natural limit to the lifetime of an excited state, and the resulting lifetime broadening is the **natural linewidth** of the transition. The natural linewidth is an intrinsic property of the transition, and cannot be changed by modifying the conditions. Natural linewidths depend strongly on the transition frequency (as explained in Section 13.4, they increase as  $\nu^3$ ), so low frequency transitions have smaller natural linewidths than high frequency transitions.

## 9.7 Quantum defects and ionization limits

**Key point** The general form of the expression for the energy of a level in a many-electron atom can be preserved by introducing an empirical quantum defect.

One application of atomic spectroscopy is to the determination of ionization energies. However, we cannot use the procedure illustrated in Example 9.1 indiscriminately because the energy levels of a many-electron atom do not in general vary as  $1/n^2$ . If we confine attention to the outermost electrons, then we know that, as a result of penetration and shielding, they experience a nuclear charge of slightly more than  $1e$  because in a neutral atom the other  $Z - 1$  electrons cancel all but about one unit of nuclear charge. Typical values of  $Z_{\text{eff}}$  are a little more than 1, so we expect binding energies to

be given by a term of the form  $-hcR/n^2$ , but lying slightly lower in energy than this formula predicts. We therefore introduce a **quantum defect**,  $\delta$ , and write the energy as  $-hcR/(n - \delta)^2$ . The quantum defect is best regarded as a purely empirical quantity.

There are some excited states that are so diffuse that  $\delta \rightarrow 0$  and the  $1/n^2$  variation is valid: these states are called **Rydberg states**. In such cases we can write

$$\tilde{\nu} = \frac{I}{hc} - \frac{R}{n^2} \quad (9.40)$$

and a plot of wavenumber against  $1/n^2$  can be used to obtain  $I$  by extrapolation; in practice, one would use a linear regression fit using a computer. If the lower state is not the ground state (a possibility if we wish to generalize the concept of ionization energy), the ionization energy of the ground state can be determined by adding the appropriate energy difference to the ionization energy obtained as described here.

## 9.8 Singlet and triplet states

**Key points** Two electrons with paired spins form a singlet state; if their spins are parallel, they form a triplet state.

Suppose we were interested in the energy levels of a He atom, with its two electrons. We know that the ground-state configuration is  $1s^2$ , and can anticipate that an excited configuration will be one in which one of the electrons has been promoted into a  $2s$  orbital, giving the configuration  $1s^1 2s^1$ . The two electrons need not be paired because they occupy different orbitals. According to Hund's maximum multiplicity rule, the state of the atom with the spins parallel lies lower in energy than the state in which they are paired. Both states are permissible, and can contribute to the spectrum of the atom.

Parallel and antiparallel (paired) spins differ in their overall spin angular momentum. In the paired case, the two spin momenta cancel each other, and there is zero net spin (as was depicted in Fig. 9.18). The paired-spin arrangement is called a **singlet**. Its spin state is the one we denoted  $\sigma_-$  in the discussion of the Pauli principle:

$$\sigma_-(1,2) = (1/2^{1/2})\{\alpha(1)\beta(2) - \beta(1)\alpha(2)\} \quad \text{Singlet spin function} \quad (9.41a)$$

The angular momenta of two parallel spins add together to give a nonzero total spin, and the resulting state is called a **triplet**. As illustrated in Fig. 9.25, there are three ways of achieving a nonzero total spin, but only one way to achieve zero spin. The three spin states are the symmetric combinations introduced earlier:

$$\begin{aligned} &\alpha(1)\alpha(2) \\ \sigma_+(1,2) &= (1/2^{1/2})\{\alpha(1)\beta(2) + \beta(1)\alpha(2)\} \\ &\beta(1)\beta(2) \end{aligned} \quad \text{Triplet spin functions} \quad (9.41b)$$

The fact that the parallel arrangement of spins in the  $1s^1 2s^1$  configuration of the He atom lies lower in energy than the antiparallel arrangement can now be expressed by saying that the triplet state of the  $1s^1 2s^1$  configuration of He lies lower in energy than the singlet state. This is a general conclusion that applies to other atoms (and molecules) and, *for states arising from the same configuration, the triplet state generally lies lower than the singlet state*. The origin of the energy difference lies in the effect of spin correlation on the Coulombic interactions between electrons, as we saw in the case of Hund's rule for ground-state configurations. Because the Coulombic interaction between electrons in an atom is strong, the difference in energies between singlet

**Fig. 9.25** When two electrons have parallel spins, they have a nonzero total spin angular momentum. There are three ways of achieving this resultant, which are shown by these vector representations. Note that, although we cannot know the orientation of the spin vectors on the cones, the angle between the vectors is the same in all three cases, for all three arrangements have the same total spin angular momentum (that is, the resultant of the two vectors has the same length in each case, but points in different directions). Compare this diagram with Fig. 9.18, which shows the antiparallel case. Note that, whereas two paired spins are precisely antiparallel, two 'parallel' spins are not strictly parallel.

and triplet states of the same configuration can be large. The two states of  $1s^1 2s^1$  He, for instance, differ by  $6421\text{ cm}^{-1}$  (corresponding to  $0.80\text{ eV}$ ).

The spectrum of atomic helium is more complicated than that of atomic hydrogen, but there are two simplifying features. One is that the only excited configurations it is necessary to consider are of the form  $1s^1 n l^1$ : that is, only one electron is excited. Excitation of two electrons requires an energy greater than the ionization energy of the atom, so the  $\text{He}^+$  ion is formed instead of the doubly excited atom. Second, no radiative transitions take place between singlet and triplet states because the relative orientation of the two electron spins cannot change during a transition. Thus, there is a spectrum arising from transitions between singlet states (including the ground state) and between triplet states, but not between the two. Spectroscopically, helium behaves like two distinct species, and the early spectroscopists actually thought of helium as consisting of ‘parahelium’ and ‘orthohelium’. The Grotrian diagram for helium in Fig. 9.26 shows the two sets of transitions.

### 9.9 Spin–orbit coupling

**Key points** The orbital and spin angular momenta interact magnetically. (a) Spin–orbit coupling results in the levels of a term having different energies. (b) Fine structure in a spectrum is due to transitions to different levels of a term.

#### A brief comment

We have already remarked that the electron’s spin is a purely quantum mechanical phenomenon that has no classical counterpart. However, a classical model can give us partial insight into the origin of an electron’s magnetic moment. Namely, the magnetic field generated by a spinning electron, regarded classically as a moving charge, induces a magnetic moment. This model is merely a visualization aid and cannot be used to explain the magnitude of the magnetic moment of the electron or the origin of spin magnetic moments in electrically neutral particles, such as the neutron.

An electron has a magnetic moment that arises from its spin (Fig. 9.27). Similarly, an electron with orbital angular momentum (that is, an electron in an orbital with  $l > 0$ ) is in effect a circulating current, and possesses a magnetic moment that arises from its orbital momentum. The interaction of the spin magnetic moment with the magnetic field arising from the orbital angular momentum is called **spin–orbit coupling**. The strength of the coupling, and its effect on the energy levels of the atom, depend on the relative orientations of the spin and orbital magnetic moments, and therefore on the relative orientations of the two angular momenta (Fig. 9.28).

**Fig. 9.26** Part of the Grotrian diagram for a helium atom. Note that there are no transitions between the singlet and triplet levels, denoted respectively by the left superscripts 1 and 3.

**Fig. 9.27** Angular momentum gives rise to a magnetic moment ( $\mu$ ). For an electron, the magnetic moment is antiparallel to the orbital angular momentum, but proportional to it. For spin angular momentum, there is a factor of 2, which increases the magnetic moment to twice its expected value (see Section 9.10).

**(a) The total angular momentum**

One way of expressing the dependence of the spin-orbit interaction on the relative orientation of the spin and orbital momenta is to say that it depends on the total angular momentum of the electron, the vector sum of its spin and orbital momenta. Thus, when the spin and orbital angular momenta are nearly parallel, the total angular momentum is high; when the two angular momenta are opposed, the total angular momentum is low.

The total angular momentum of an electron is described by the quantum numbers  $j$  and  $m_j$ , with  $j = l + \frac{1}{2}$  (when the two angular momenta are in the same direction) or  $j = l - \frac{1}{2}$  (when they are opposed, Fig. 9.29). The different values of  $j$  that can arise for a given value of  $l$  label levels of a term. For  $l = 0$ , the only permitted value is  $j = \frac{1}{2}$  (the total angular momentum is the same as the spin angular momentum because there is no other source of angular momentum in the atom). When  $l = 1$ ,  $j$  may be either  $\frac{3}{2}$  (the spin and orbital angular momenta are in the same sense) or  $\frac{1}{2}$  (the spin and angular momenta are in opposite senses).

**Example 9.4** Identifying the levels of a configuration

Identify the levels that may arise from the configurations (a)  $d^1$ , (b)  $s^1$ .

**Method** In each case, identify the value of  $l$  and then the possible values of  $j$ . For these one-electron systems, the total angular momentum is the sum and difference of the orbital and spin momenta.

**Answer** (a) For a  $d$  electron,  $l = 2$  and there are two levels in the configuration, one with  $j = 2 + \frac{1}{2} = \frac{5}{2}$  and the other with  $j = 2 - \frac{1}{2} = \frac{3}{2}$ . (b) For an  $s$  electron  $l = 0$ , so only one level is possible, and  $j = \frac{1}{2}$ .

**Self-test 9.8** Identify the levels of the configurations (a)  $p^1$  and (b)  $f^1$ .

[(a)  $\frac{3}{2}, \frac{1}{2}$ ; (b)  $\frac{7}{2}, \frac{5}{2}$ ]

The dependence of the spin-orbit interaction on the value of  $j$  is expressed in terms of the **spin-orbit coupling constant**,  $\tilde{A}$  (which is typically expressed as a wavenumber). The quantum mechanical calculation outlined in *Further information* 9.2 leads to the result that the energies of the levels with quantum numbers  $s$ ,  $l$ , and  $j$  are given by

$$E_{l,s,j} = \frac{1}{2}hc\tilde{A}\{j(j+1) - l(l+1) - s(s+1)\} \quad (9.42)$$

• **A brief illustration**

The unpaired electron in the ground state of an alkali metal atom has  $l = 0$ , so  $j = \frac{1}{2}$ . Because the orbital angular momentum is zero in this state, the spin-orbit coupling energy is zero (as is confirmed by setting  $j = s$  and  $l = 0$  in eqn 9.42). When the electron is excited to an orbital with  $l = 1$ , it has orbital angular momentum and can give rise to a magnetic field that interacts with its spin. In this configuration the electron can have  $j = \frac{3}{2}$  or  $j = \frac{1}{2}$ , and the energies of these levels are

$$E_{3/2} = \frac{1}{2}hc\tilde{A}\left\{\frac{3}{2} \times \frac{5}{2} - 1 \times 2 - \frac{1}{2} \times \frac{3}{2}\right\} = \frac{1}{2}hc\tilde{A}$$

$$E_{1/2} = \frac{1}{2}hc\tilde{A}\left\{\frac{1}{2} \times \frac{3}{2} - 1 \times 2 - \frac{1}{2} \times \frac{3}{2}\right\} = -hc\tilde{A}$$

The corresponding energies are shown in Fig. 9.30. Note that the baricentre (the 'centre of gravity') of the levels is unchanged, because there are four states of energy  $\frac{1}{2}hc\tilde{A}$  and two of energy  $-hc\tilde{A}$ . •

**Fig. 9.28** Spin-orbit coupling is a magnetic interaction between spin and orbital magnetic moments. When the angular momenta are parallel, as in (a), the magnetic moments are aligned unfavourably; when they are opposed, as in (b), the interaction is favourable. This magnetic coupling is the cause of the splitting of a configuration into levels.

**Fig. 9.29** The coupling of the spin and orbital angular momenta of a  $d$  electron ( $l = 2$ ) gives two possible values of  $j$  depending on the relative orientations of the spin and orbital angular momenta of the electron.

**Fig. 9.30** The levels of a  $^2P$  term arising from spin–orbit coupling. Note that the low- $j$  level lies below the high- $j$  level in energy.

**Fig. 9.31** The energy-level diagram for the formation of the sodium D lines. The splitting of the spectral lines (by  $17\text{ cm}^{-1}$ ) reflects the splitting of the levels of the  $^2P$  term.

The strength of the spin–orbit coupling depends on the nuclear charge. To understand why this is so, imagine riding on the orbiting electron and seeing a charged nucleus apparently orbiting around us (like the Sun rising and setting). As a result, we find ourselves at the centre of a ring of current. The greater the nuclear charge, the greater this current, and therefore the stronger the magnetic field we detect. Because the spin magnetic moment of the electron interacts with this orbital magnetic field, it follows that the greater the nuclear charge, the stronger the spin–orbit interaction. The coupling increases sharply with atomic number (as  $Z^4$ ). Whereas it is only small in H (giving rise to shifts of energy levels of no more than about  $0.4\text{ cm}^{-1}$ ), in heavy atoms like Pb it is very large (giving shifts of the order of thousands of reciprocal centimetres).

### (b) Fine structure

Two spectral lines are observed when the p electron of an electronically excited alkali metal atom undergoes a transition and falls into a lower s orbital. One line is due to a transition starting in a  $j = \frac{3}{2}$  level and the other line is due to a transition starting in the  $j = \frac{1}{2}$  level of the same configuration. The two lines are an example of the **fine structure** of a spectrum, the structure in a spectrum due to spin–orbit coupling. Fine structure can be clearly seen in the emission spectrum from sodium vapour excited by an electric discharge (for example, in one kind of street lighting). The yellow line at 589 nm (close to  $17\,000\text{ cm}^{-1}$ ) is actually a doublet composed of one line at 589.76 nm ( $16\,956.2\text{ cm}^{-1}$ ) and another at 589.16 nm ( $16\,973.4\text{ cm}^{-1}$ ); the components of this doublet are the ‘D lines’ of the spectrum (Fig. 9.31). Therefore, in Na, the spin–orbit coupling affects the energies by about  $17\text{ cm}^{-1}$ .

#### Example 9.5 Analysing a spectrum for the spin–orbit coupling constant

The origin of the D lines in the spectrum of atomic sodium is shown in Fig. 9.31. Calculate the spin–orbit coupling constant for the upper configuration of the Na atom.

**Method** We see from Fig. 9.31 that the splitting of the lines is equal to the energy separation of the  $j = \frac{3}{2}$  and  $\frac{1}{2}$  levels of the excited configuration. This separation can be expressed in terms of  $\tilde{A}$  by using eqn 9.42. Therefore, set the observed splitting equal to the energy separation calculated from eqn 9.42 and solve the equation for  $\tilde{A}$ .

**Answer** The two levels are split by

$$\Delta\tilde{\nu} = \tilde{A} \left\{ \frac{1}{2} \left( \frac{3}{2} + 1 \right) - \frac{1}{2} \left( \frac{1}{2} + 1 \right) \right\} = \frac{3}{2} \tilde{A}$$

The experimental value of  $\Delta\tilde{\nu}$  is  $17.2\text{ cm}^{-1}$ ; therefore

$$\tilde{A} = \frac{2}{3} \times (17.2\text{ cm}^{-1}) = 11.5\text{ cm}^{-1}$$

The same calculation repeated for the other alkali metal atoms gives Li:  $0.23\text{ cm}^{-1}$ , K:  $38.5\text{ cm}^{-1}$ , Rb:  $158\text{ cm}^{-1}$ , Cs:  $370\text{ cm}^{-1}$ . Note the increase of  $\tilde{A}$  with atomic number (but more slowly than  $Z^4$  for these many-electron atoms).

**Self-test 9.9** The configuration  $\dots 4p^6 5d^1$  of rubidium has two levels at  $25\,700.56\text{ cm}^{-1}$  and  $25\,703.52\text{ cm}^{-1}$  above the ground state. What is the spin–orbit coupling constant in this excited state?  $[1.18\text{ cm}^{-1}]$

## 9.10 Term symbols and selection rules

**Key points** A term symbol specifies the angular momentum states of an atom. (a) Angular momenta are combined into a resultant by using the Clebsch–Gordan series. (b) The multiplicity of a term is the value of  $2S + 1$ . (c) The total angular momentum in light atoms is obtained on the basis of Russell–Saunders coupling; in heavy atoms,  $jj$ -coupling is used. (d) Selection rules for light atoms include the fact that changes of total spin do not occur.

We have used expressions such as ‘the  $j = \frac{3}{2}$  level of a configuration’. A **term symbol**, which is a symbol looking like  $^2P_{3/2}$  or  $^3D_2$ , conveys this information much more succinctly. The convention of using lower-case letters to label orbitals and upper-case letters to label overall states applies throughout spectroscopy, not just to atoms.

A term symbol gives three pieces of information:

- The letter (P or D in the examples) indicates the total orbital angular momentum quantum number,  $L$ .
- The left superscript in the term symbol (the 2 in  $^2P_{3/2}$ ) gives the multiplicity of the term.
- The right subscript in the term symbol (the  $\frac{3}{2}$  in  $^2P_{3/2}$ ) is the value of the total angular momentum quantum number,  $J$ .

We shall now say what each of these statements means; the contributions to the energies that we are about to discuss are summarized in Fig. 9.32.

### (a) The total orbital angular momentum

When several electrons are present, it is necessary to judge how their individual orbital angular momenta add together or oppose each other. The **total orbital angular momentum quantum number**,  $L$ , tells us the magnitude of the angular momentum through  $\{L(L + 1)\}^{1/2}\hbar$ . It has  $2L + 1$  orientations distinguished by the quantum number  $M_L$ , which can take the values  $L, L - 1, \dots, -L$ . Similar remarks apply to the **total spin quantum number**,  $S$ , and the quantum number  $M_S$ , and the **total angular momentum quantum number**,  $J$ , and the quantum number  $M_J$ .

The value of  $L$  (a non-negative integer) is obtained by coupling the individual orbital angular momenta by using the **Clebsch–Gordan series**:

$$L = l_1 + l_2, l_1 + l_2 - 1, \dots, |l_1 - l_2| \quad \text{Clebsch–Gordan series} \quad (9.43)$$

The modulus signs are attached to  $l_1 - l_2$  because  $L$  is non-negative. The maximum value,  $L = l_1 + l_2$ , is obtained when the two orbital angular momenta are in the same direction; the lowest value,  $|l_1 - l_2|$ , is obtained when they are in opposite directions. The intermediate values represent possible intermediate relative orientations of the two momenta (Fig. 9.33). For two p electrons (for which  $l_1 = l_2 = 1$ ),  $L = 2, 1, 0$ . The code for converting the value of  $L$  into a letter is the same as for the s, p, d, f, ... designation of orbitals, but uses upper-case Roman letters:

|      |   |   |   |   |   |   |      |
|------|---|---|---|---|---|---|------|
| $L:$ | 0 | 1 | 2 | 3 | 4 | 5 | 6... |
|      | S | P | D | F | G | H | I... |

Thus, a  $p^2$  configuration can give rise to D, P, and S terms. The terms differ in energy on account of the different spatial distribution of the electrons and the consequent differences in repulsion between them.

**Fig. 9.32** A summary of the types of interaction that are responsible for the various kinds of splitting of energy levels in atoms. For light atoms, magnetic interactions are small, but in heavy atoms they may dominate the electrostatic (charge–charge) interactions.

**Fig. 9.33** The total orbital angular momenta of a p electron and a d electron correspond to  $L = 3, 2$ , and  $1$  and reflect the different relative orientations of the two momenta.

A closed shell has zero orbital angular momentum because all the individual orbital angular momenta sum to zero. Therefore, when working out term symbols, we need consider only the electrons of the unfilled shell. In the case of a single electron outside a closed shell, the value of  $L$  is the same as the value of  $l$ ; so the configuration  $[\text{Ne}]3s^1$  has only an S term.

**Example 9.6** Deriving the total orbital angular momentum of a configuration

Find the terms that can arise from the configurations (a)  $d^2$ , (b)  $p^3$ .

**Method** Use the Clebsch–Gordan series and begin by finding the minimum value of  $L$  (so that we know where the series terminates). When there are more than two electrons to couple together, use two series in succession: first couple two electrons, and then couple the third to each combined state, and so on.

**Answer** (a) The minimum value is  $|l_1 - l_2| = |2 - 2| = 0$ . Therefore,

$$L = 2 + 2, 2 + 2 - 1, \dots, 0 = 4, 3, 2, 1, 0$$

corresponding to G, F, D, P, S terms, respectively. (b) Coupling two electrons gives a minimum value of  $|1 - 1| = 0$ . Therefore,

$$L' = 1 + 1, 1 + 1 - 1, \dots, 0 = 2, 1, 0$$

Now couple  $l_3$  with  $L' = 2$ , to give  $L = 3, 2, 1$ ; with  $L' = 1$ , to give  $L = 2, 1, 0$ ; and with  $L' = 0$ , to give  $L = 1$ . The overall result is

$$L = 3, 2, 2, 1, 1, 1, 0$$

giving one F, two D, three P, and one S term.

**A note on good practice**

Throughout our discussion of atomic spectroscopy, distinguish italic  $S$ , the total spin quantum number, from roman  $S$ , the term label.

**Self-test 9.10** Repeat the question for the configurations (a)  $f^1d^1$  and (b)  $d^3$ .

[(a) H, G, F, D, P; (b) I, 2H, 3G, 4F, 5D, 3P, S]

**Fig. 9.34** For two electrons (each of which has  $s = \frac{1}{2}$ ), only two total spin states are permitted ( $S = 0, 1$ ). The state with  $S = 0$  can have only one value of  $M_S$  ( $M_S = 0$ ) and is a singlet; the state with  $S = 1$  can have any of three values of  $M_S$  ( $+1, 0, -1$ ) and is a triplet. The vector representations of the singlet and triplet states are shown in Figs. 9.18 and 9.25, respectively.

**(b) The multiplicity**

When there are several electrons to be taken into account, we must assess their total spin angular momentum quantum number,  $S$  (a non-negative integer or half integer). Once again, we use the Clebsch–Gordan series in the form

$$S = s_1 + s_2, s_1 + s_2 - 1, \dots, |s_1 - s_2| \quad (9.44)$$

to decide on the value of  $S$ , noting that each electron has  $s = \frac{1}{2}$ , which gives  $S = 1, 0$  for two electrons (Fig. 9.34). If there are three electrons, the total spin angular momentum is obtained by coupling the third spin to each of the values of  $S$  for the first two spins, which results in  $S = \frac{3}{2}$  and  $S = \frac{1}{2}$ .

The **multiplicity** of a term is the value of  $2S + 1$ . When  $S = 0$  (as for a closed shell, like  $1s^2$ ) the electrons are all paired and there is no net spin: this arrangement gives a singlet term,  $^1S$ . A single electron has  $S = s = \frac{1}{2}$ , so a configuration such as  $[\text{Ne}]3s^1$  can give rise to a doublet term,  $^2S$ . Likewise, the configuration  $[\text{Ne}]3p^1$  is a doublet,  $^2P$ . When there are two unpaired electrons  $S = 1$ , so  $2S + 1 = 3$ , giving a triplet term, such as  $^3D$ . We discussed the relative energies of singlets and triplets in Section 9.8 and saw that their energies differ on account of the different effects of spin correlation.

**(c) The total angular momentum**

As we have seen, the quantum number  $j$  tells us the relative orientation of the spin and orbital angular momenta of a single electron. The **total angular momentum quantum**

number,  $J$  (a non-negative integer or half integer), does the same for several electrons. If there is a single electron outside a closed shell,  $J = j$ , with  $j$  either  $l + \frac{1}{2}$  or  $|l - \frac{1}{2}|$ . The  $[\text{Ne}]3s^1$  configuration has  $j = \frac{1}{2}$  (because  $l = 0$  and  $s = \frac{1}{2}$ ), so the  $^2S$  term has a single level, which we denote  $^2S_{1/2}$ . The  $[\text{Ne}]3p^1$  configuration has  $l = 1$ ; therefore  $j = \frac{3}{2}$  and  $\frac{1}{2}$ ; the  $^2P$  term therefore has two levels,  $^2P_{3/2}$  and  $^2P_{1/2}$ . These levels lie at different energies on account of the magnetic spin-orbit interaction.

If there are several electrons outside a closed shell we have to consider the coupling of all the spins and all the orbital angular momenta. This complicated problem can be simplified when the spin-orbit coupling is weak (for atoms of low atomic number), for then we can use the **Russell–Saunders coupling** scheme. This scheme is based on the view that, if spin-orbit coupling is weak, then it is effective only when all the orbital momenta are operating cooperatively. We therefore imagine that all the orbital angular momenta of the electrons couple to give a total  $L$ , and that all the spins are similarly coupled to give a total  $S$ . Only at this stage do we imagine the two kinds of momenta coupling through the spin-orbit interaction to give a total  $J$ . The permitted values of  $J$  are given by the Clebsch–Gordan series

$$J = L + S, L + S - 1, \dots, |L - S| \quad (9.45)$$

For example, in the case of the  $^3D$  term of the configuration  $[\text{Ne}]2p^13p^1$ , the permitted values of  $J$  are 3, 2, 1 (because  $^3D$  has  $L = 2$  and  $S = 1$ ), so the term has three levels,  $^3D_3$ ,  $^3D_2$ , and  $^3D_1$ .

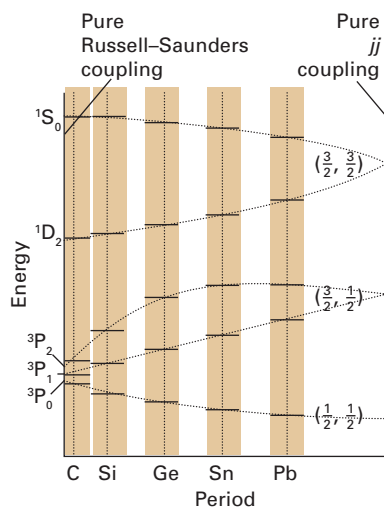

When  $L \geq S$ , the multiplicity is equal to the number of levels. For example, a  $^2P$  term has the two levels  $^2P_{3/2}$  and  $^2P_{1/2}$ , and  $^3D$  has the three levels  $^3D_3$ ,  $^3D_2$ , and  $^3D_1$ . However, this is not the case when  $L < S$ : the term  $^2S$ , for example, has only the one level  $^2S_{1/2}$ .

#### Example 9.7 Deriving term symbols

Write the term symbols arising from the ground-state configurations of (a) Na, (b) F, and (c) the excited configuration  $1s^22s^22p^13p^1$  of C.

**Method** Begin by writing the configurations, but ignore inner closed shells. Then couple the orbital momenta to find  $L$  and the spins to find  $S$ . Next, couple  $L$  and  $S$  to find  $J$ . Finally, express the term as  $^{2S+1}\{L\}_J$ , where  $\{L\}$  is the appropriate letter. For F, for which the valence configuration is  $2p^5$ , treat the single gap in the closed-shell  $2p^6$  configuration as a single particle.

**Answer** (a) For Na, the configuration is  $[\text{Ne}]3s^1$ , and we consider the single  $3s$  electron. Because  $L = l = 0$  and  $S = s = \frac{1}{2}$ , it is possible for  $J = j = s = \frac{1}{2}$  only. Hence the term symbol is  $^2S_{1/2}$ . (b) For F, the configuration is  $[\text{He}]2s^22p^5$ , which we can treat as  $[\text{Ne}]2p^{-1}$  (where the notation  $2p^{-1}$  signifies the absence of a  $2p$  electron). Hence  $L = 1$ , and  $S = s = \frac{1}{2}$ . Two values of  $J = j$  are allowed:  $J = \frac{3}{2}, \frac{1}{2}$ . Hence, the term symbols for the two levels are  $^2P_{3/2}, ^2P_{1/2}$ . (c) We are treating an excited configuration of carbon because, in the ground configuration,  $2p^2$ , the Pauli principle forbids some terms, and deciding which survive ( $^1D, ^3P, ^1S$ , in fact) is quite complicated. That is, there is a distinction between ‘equivalent electrons’, which are electrons that occupy the same orbitals, and ‘inequivalent electrons’, which are electrons that occupy different orbitals. The excited configuration of C under consideration is effectively  $2p^13p^1$ . This is a two-electron problem, and  $l_1 = l_2 = 1, s_1 = s_2 = \frac{1}{2}$ . It follows that  $L = 2, 1, 0$  and  $S = 1, 0$ . The terms are therefore  $^3D$  and  $^1D, ^3P$  and  $^1P$ , and  $^3S$  and  $^1S$ . For  $^3D$ ,  $L = 2$  and  $S = 1$ ; hence  $J = 3, 2, 1$  and the levels are  $^3D_3, ^3D_2$ , and  $^3D_1$ . For  $^1D$ ,  $L = 2$  and  $S = 0$ , so the single level is  $^1D_2$ . The triplet of levels of  $^3P$  is  $^3P_2, ^3P_1$ , and  $^3P_0$ , and the singlet is  $^1P_1$ . For the  $^3S$  term there is only one level,  $^3S_1$  (because  $J = 1$  only), and the singlet term is  $^1S_0$ .

**Fig. 9.35** The correlation diagram for some of the states of a two-electron system. All atoms lie between the two extremes, but, the heavier the atom, the closer it lies to the pure  $jj$ -coupling case.

**Self-test 9.11** Write down the terms arising from the configurations (a)  $2s^1 2p^1$ , (b)  $2p^1 3d^1$ .

[(a)  $^3P_2, ^3P_1, ^3P_0, ^1P_1$ ; (b)  $^3F_4, ^3F_3, ^3F_2, ^1F_3, ^3D_3, ^3D_2, ^3D_1, ^1D_2, ^3P_2, ^3P_1, ^3P_0, ^1P_1$ ]

Russell–Saunders coupling fails when the spin–orbit coupling is large (in heavy atoms, those with high  $Z$ ). In that case, the individual spin and orbital momenta of the electrons are coupled into individual  $j$  values; then these momenta are combined into a grand total,  $J$ . This scheme is called  **$jj$ -coupling**. For example, in a  $p^2$  configuration, the individual values of  $j$  are  $\frac{3}{2}$  and  $\frac{1}{2}$  for each electron. If the spin and the orbital angular momentum of each electron are coupled together strongly, it is best to consider each electron as a particle with angular momentum  $j = \frac{3}{2}$  or  $\frac{1}{2}$ . These individual total momenta then couple as follows:

$$\begin{aligned} j_1 = \frac{3}{2} \quad \text{and} \quad j_2 = \frac{3}{2} \quad J = 3, 2, 1, 0 \\ j_1 = \frac{3}{2} \quad \text{and} \quad j_2 = \frac{1}{2} \quad J = 2, 1 \\ j_1 = \frac{1}{2} \quad \text{and} \quad j_2 = \frac{3}{2} \quad J = 2, 1 \\ j_1 = \frac{1}{2} \quad \text{and} \quad j_2 = \frac{1}{2} \quad J = 1, 0 \end{aligned}$$

For heavy atoms, in which  $jj$ -coupling is appropriate, it is best to discuss their energies using these quantum numbers.

Although  $jj$ -coupling should be used for assessing the energies of heavy atoms, the term symbols derived from Russell–Saunders coupling can still be used as labels. To see why this procedure is valid, we need to examine how the energies of the atomic states change as the spin–orbit coupling increases in strength. Such a **correlation diagram** is shown in Fig. 9.35. It shows that there is a correspondence between the low spin–orbit coupling (Russell–Saunders coupling) and high spin–orbit coupling ( $jj$ -coupling) schemes, so the labels derived by using the Russell–Saunders scheme can be used to label the states of the  $jj$ -coupling scheme.

#### (d) Selection rules

Any state of the atom, and any spectral transition, can be specified by using term symbols. For example, the transitions giving rise to the yellow sodium doublet (which were shown in Fig. 9.31) are

By convention, the upper term precedes the lower. The corresponding absorptions are therefore denoted

(The configurations have been omitted.)

We have seen that selection rules arise from the conservation of angular momentum during a transition and from the fact that a photon has a spin of 1. They can therefore be expressed in terms of the term symbols, because the latter carry information about angular momentum. A detailed analysis leads to the following rules:

$$\begin{aligned} \Delta S = 0 \quad \Delta L = 0, \pm 1 \quad \Delta l = \pm 1 \quad \Delta J = 0, \pm 1, \\ \text{but} \quad J = 0 \leftarrow | \rightarrow J = 0 \end{aligned}$$

Selection  
rules for  
atoms

 (9.46)

where the symbol  $\leftarrow | \rightarrow$  denotes a forbidden transition. The rule about  $\Delta S$  (no change of overall spin) stems from the fact that the light does not affect the spin directly. The

rules about  $\Delta L$  and  $\Delta l$  express the fact that the orbital angular momentum of an individual electron must change (so  $\Delta l = \pm 1$ ), but whether or not this results in an overall change of orbital momentum depends on the coupling.

The selection rules given above apply when Russell–Saunders coupling is valid (in light atoms, those of low  $Z$ ). If we insist on labelling the terms of heavy atoms with symbols like  $^3D$ , then we shall find that the selection rules progressively fail as the atomic number increases because the quantum numbers  $S$  and  $L$  become ill defined as  $jj$ -coupling becomes more appropriate. As explained above, Russell–Saunders term symbols are only a convenient way of labelling the terms of heavy atoms: they do not bear any direct relation to the actual angular momenta of the electrons in a heavy atom. For this reason, transitions between singlet and triplet states (for which  $\Delta S = \pm 1$ ), while forbidden in light atoms, are allowed in heavy atoms.

## IMPACT ON ASTROPHYSICS

### 19.1 Spectroscopy of stars

The bulk of stellar material consists of neutral and ionized forms of hydrogen and helium atoms, with helium being the product of ‘hydrogen burning’ by nuclear fusion. However, nuclear fusion also makes heavier elements. It is generally accepted that the outer layers of stars are composed of lighter elements, such as H, He, C, N, O, and Ne in both neutral and ionized forms. Heavier elements, including neutral and ionized forms of Si, Mg, Ca, S, and Ar, are found closer to the stellar core. The core itself contains the heaviest elements and  $^{56}\text{Fe}$  is particularly abundant because it is a very stable nuclide. All these elements are in the gas phase on account of the very high temperatures in stellar interiors. For example, the temperature is estimated to be 3.6 MK halfway to the centre of the Sun.

Astronomers use spectroscopic techniques to determine the chemical composition of stars because each element, and indeed each isotope of an element, has a characteristic spectral signature that is transmitted through space by the star’s light. To understand the spectra of stars, we must first know why they shine. Nuclear reactions in the dense stellar interior generate radiation that travels to less dense outer layers. Absorption and re-emission of photons by the atoms and ions in the interior give rise to a quasi-continuum of radiation energy that is emitted into space by a thin layer of gas called the *photosphere*. To a good approximation, the distribution of energy emitted from a star’s photosphere resembles the Planck distribution for a very hot black body (Section 7.1). For example, the energy distribution of our Sun’s photosphere may be modelled by a Planck distribution with an effective temperature of 5.8 kK. Superimposed on the black-body radiation continuum are sharp absorption and emission lines from neutral atoms and ions present in the photosphere. Analysis of stellar radiation with a spectrometer mounted on to a telescope yields the chemical composition of the star’s photosphere by comparison with known spectra of the elements. The data can also reveal the presence of small molecules, such as CN,  $\text{C}_2$ , TiO, and ZrO, in certain ‘cold’ stars, which are stars with relatively low effective temperatures.

The two outermost layers of a star are the *chromosphere*, a region just above the photosphere, and the *corona*, a region above the chromosphere that can be seen (with proper care) during eclipses. The photosphere, chromosphere, and corona comprise a star’s ‘atmosphere’. Our Sun’s chromosphere is much less dense than its photosphere and its temperature is much higher, rising to about 10 kK. The reasons for this increase in temperature are not fully understood. The temperature of our Sun’s corona is very high, rising up to 1.5 MK, so black-body emission is strong from the X-ray to the radiofrequency region of the spectrum. The spectrum of the Sun’s corona is dominated by emission lines from electronically excited species, such as neutral atoms and a number of highly ionized species. The most intense emission lines in the visible

range are from the  $\text{Fe}^{13+}$  ion at 530.3 nm, the  $\text{Fe}^{9+}$  ion at 637.4 nm, and the  $\text{Ca}^{4+}$  ion at 569.4 nm.

Because light from only the photosphere reaches our telescopes, the overall chemical composition of a star must be inferred from theoretical work on its interior and from spectral analysis of its atmosphere. Data on the Sun indicate that it is 92 per cent hydrogen and 7.8 per cent helium. The remaining 0.2 per cent is due to heavier elements, among which C, N, O, Ne, and Fe are the most abundant. More advanced analysis of spectra also permits the determination of other properties of stars, such as their relative speeds (Problem 9.29) and their effective temperatures (Problem 9.30).

# Checklist of key equations

| Property                                             | Equation                                                                                                  | Comment                                             |
|------------------------------------------------------|-----------------------------------------------------------------------------------------------------------|-----------------------------------------------------|
| Wavenumbers of the spectral lines of a hydrogen atom | $\tilde{\nu} = R_{\text{H}}\{1/n_1^2 - (1/n_2^2)\}$                                                       | $R_{\text{H}}$ is the Rydberg constant for hydrogen |
| Wavefunctions of hydrogenic atoms                    | $\psi(r, \theta, \phi) = R(r)Y(\theta, \phi)$                                                             | $Y$ are spherical harmonics                         |
| Energies of hydrogenic atoms                         | $E_n = -Z^2 \mu e^4 / 32 \pi^2 \epsilon_0^2 \hbar^2 n^2$                                                  |                                                     |
| Radial distribution function                         | $P(r) = r^2 R(r)^2$                                                                                       | $P(r) = 4\pi r^2 \psi^2$ for s orbitals             |

# Further information

## Further information 9.1 The separation of motion

### (a) The separation of internal and external motion

Consider a one-dimensional system in which the potential energy depends only on the separation of the two particles. The total energy is

$$E = \frac{p_1^2}{2m_1} + \frac{p_2^2}{2m_2} + V \quad (9.47)$$

Where  $p_1 = m_1 \dot{x}_1$  and  $p_2 = m_2 \dot{x}_2$ , the dot signifying differentiation with respect to time. The centre of mass (Fig. 9.36) is located at

**Fig. 9.36** The coordinates used for discussing the separation of the relative motion of two particles from the motion of the centre of mass.

$$X = \frac{m_1}{m} x_1 + \frac{m_2}{m} x_2 \quad m = m_1 + m_2 \quad (9.48)$$

and the separation of the particles is  $x = x_1 - x_2$ . It follows that

$$x_1 = X + \frac{m_2}{m} x \quad x_2 = X - \frac{m_1}{m} x \quad (9.49)$$

The linear momenta of the particles can be expressed in terms of the rates of change of  $x$  and  $X$ :

$$p_1 = m_1 \dot{x}_1 = m_1 \dot{X} + \frac{m_1 m_2}{m} \dot{x} \quad p_2 = m_2 \dot{x}_2 = m_2 \dot{X} - \frac{m_1 m_2}{m} \dot{x} \quad (9.50)$$

Then it follows that

$$\frac{p_1^2}{2m_1} + \frac{p_2^2}{2m_2} = \frac{1}{2} m \dot{X}^2 + \frac{1}{2} \mu \dot{x}^2 \quad (9.51)$$

where  $\mu$  is given in eqn 9.6. By writing  $P = m \dot{X}$  for the linear momentum of the system as a whole and defining  $p$  as  $\mu \dot{x}$ , we find

$$E = \frac{P^2}{2m} + \frac{p^2}{2\mu} + V \quad (9.52a)$$

The corresponding hamiltonian (generalized to three dimensions) is therefore

$$\hat{H} = -\frac{\hbar^2}{2m}\nabla_{\text{c.m.}}^2 - \frac{\hbar^2}{2\mu}\nabla^2 + V \quad (9.52b)$$

where the first term differentiates with respect to the centre of mass coordinates and the second with respect to the relative coordinates.

Now we write the overall wavefunction as the product  $\psi_{\text{total}} = \psi_{\text{c.m.}}\psi$ , where the first factor is a function of only the centre of mass coordinates and the second is a function of only the relative coordinates. The overall Schrödinger equation,  $\hat{H}\psi_{\text{total}} = E_{\text{total}}\psi_{\text{total}}$ , then separates by the argument that we have used in Sections 8.2a and 8.7, with  $E_{\text{total}} = E_{\text{c.m.}} + E$ .

### (b) The separation of angular and radial motion

The laplacian in three dimensions is given in eqn 8.51a. It follows that the Schrödinger equation in eqn 9.6 is

$$-\frac{\hbar^2}{2\mu}\left(\frac{\partial^2}{\partial r^2} + \frac{2}{r}\frac{\partial}{\partial r} + \frac{1}{r^2}\Lambda^2\right)RY + VRY = ERY \quad (9.53)$$

Because  $R$  depends only on  $r$  and  $Y$  depends only on the angular coordinates, this equation becomes

$$-\frac{\hbar^2}{2\mu}\left(Y\frac{d^2R}{dr^2} + \frac{2Y}{r}\frac{dR}{dr} + \frac{R}{r^2}\Lambda^2Y\right) + VRY = ERY \quad (9.54)$$

If we multiply through by  $r^2/R$ , we obtain

$$-\frac{\hbar^2}{2\mu R}\left(r^2\frac{d^2R}{dr^2} + 2r\frac{dR}{dr}\right) + Vr^2 - \frac{\hbar^2}{2\mu Y}\Lambda^2Y = Er^2 \quad (9.55)$$

At this point we employ the usual argument. The term in  $Y$  is the only one that depends on the angular variables, so it must be a constant. When we write this constant as  $\hbar^2l(l+1)/2\mu$ , eqn 9.8b follows immediately.

### Further information 9.2 The energy of spin-orbit interaction

The energy of a magnetic moment  $\mu$  in a magnetic field  $\mathcal{B}$  is equal to their scalar product  $-\mu \cdot \mathcal{B}$ . If the magnetic field arises from the orbital angular momentum of the electron, it is proportional to  $l$ ; if the magnetic moment  $\mu$  is that of the electron spin, then it is proportional to  $s$ . It then follows that the energy of interaction is proportional to the scalar product  $s \cdot l$ :

$$\text{Energy of interaction} = -\mu \cdot \mathcal{B} \propto s \cdot l$$

(For the various vector manipulations used in this section, see *Mathematical background 5* following this chapter.) Next, we note that the total angular momentum is the vector sum of the spin and orbital momenta:  $j = l + s$ . The magnitude of the vector  $j$  is calculated by evaluating

$$j \cdot j = (l + s) \cdot (l + s) = l \cdot l + s \cdot s + 2s \cdot l$$

so that

$$j^2 = l^2 + s^2 + 2s \cdot l$$

That is,

$$s \cdot l = \frac{1}{2}\{j^2 - l^2 - s^2\}$$

where we have used the fact that the scalar product of two vectors  $u$  and  $v$  is  $u \cdot v = uv \cos \theta$ , from which it follows that  $u \cdot u = u^2$ .

The preceding equation is a classical result. To make the transition to quantum mechanics, we treat all the quantities as operators, and write

$$\hat{s} \cdot \hat{l} = \frac{1}{2}\{j^2 - \hat{l}^2 - \hat{s}^2\}$$

At this point, we evaluate the expectation value:

$$\begin{aligned} \langle j, l, s | \hat{s} \cdot \hat{l} | j, l, s \rangle &= \frac{1}{2} \langle j, l, s | j^2 - \hat{l}^2 - \hat{s}^2 | j, l, s \rangle \\ &= \frac{1}{2} \{j(j+1) - l(l+1) - s(s+1)\} \hbar^2 \end{aligned} \quad (9.56)$$

Then, by inserting this expression into the formula for the energy of interaction ( $E \propto s \cdot l$ , and writing the constant of proportionality as  $hc\tilde{A}/\hbar^2$ , we obtain eqn 9.42.

## Discussion questions

**9.1** Discuss the origin of the series of lines in the emission spectra of hydrogen. What region of the electromagnetic spectrum is associated with each of the series shown in Fig. 9.1?

**9.2** Describe the separation of variables procedure as it is applied to simplify the description of a hydrogenic atom free to move through space.

**9.3** List and describe the significance of the quantum numbers needed to specify the internal state of a hydrogenic atom.

**9.4** Specify and account for the selection rules for transitions in hydrogenic atoms.

**9.5** Explain the significance of (a) a boundary surface and (b) the radial distribution function for hydrogenic orbitals.

**9.6** Outline the electron configurations of many-electron atoms in terms of their location in the periodic table.

**9.7** Describe and account for the variation of first ionization energies along Period 2 of the periodic table. Would you expect the same variation in Period 3?

**9.8** Describe the orbital approximation for the wavefunction of a many-electron atom. What are the limitations of the approximation?

**9.9** Explain the origin of spin-orbit coupling and how it affects the appearance of a spectrum.

**9.10** Describe the physical origins of linewidths in absorption and emission spectra. Do you expect the same contributions for species in condensed and gas phases?

## Exercises

- 9.1(a)** Determine the shortest and longest wavelength lines in the Lyman series.
- 9.1(b)** The Pfund series has  $n_1 = 5$ . Determine the shortest and longest wavelength lines in the Pfund series.
- 9.2(a)** Compute the wavelength, frequency, and wavenumber of the  $n = 2 \rightarrow n = 1$  transition in  $\text{He}^+$ .
- 9.2(b)** Compute the wavelength, frequency, and wavenumber of the  $n = 5 \rightarrow n = 4$  transition in  $\text{Li}^{+2}$ .
- 9.3(a)** When ultraviolet radiation of wavelength 58.4 nm from a helium lamp is directed on to a sample of krypton, electrons are ejected with a speed of  $1.59 \text{ Mm s}^{-1}$ . Calculate the ionization energy of krypton.
- 9.3(b)** When ultraviolet radiation of wavelength 58.4 nm from a helium lamp is directed on to a sample of xenon, electrons are ejected with a speed of  $1.79 \text{ Mm s}^{-1}$ . Calculate the ionization energy of xenon.
- 9.4(a)** State the orbital degeneracy of the levels in a hydrogen atom that have energy (a)  $-hcR_{\text{H}}$ ; (b)  $-\frac{1}{9}hcR_{\text{H}}$ ; (c)  $-\frac{1}{25}hcR_{\text{H}}$ .
- 9.4(b)** State the orbital degeneracy of the levels in a hydrogenic atom ( $Z$  in parentheses) that have energy (a)  $-4hcR_{\text{atom}}(2)$ ; (b)  $-\frac{1}{4}hcR_{\text{atom}}(4)$ , and (c)  $-hcR_{\text{atom}}(5)$ .
- 9.5(a)** The wavefunction for the ground state of a hydrogen atom is  $Ne^{-r/a_0}$ . Determine the normalization constant  $N$ .
- 9.5(b)** The wavefunction for the 2s orbital of a hydrogen atom is  $N(2 - r/a_0)e^{-r/2a_0}$ . Determine the normalization constant  $N$ .
- 9.6(a)** By differentiation of the 2s radial wavefunction, show that it has two extrema in its amplitude, and locate them.
- 9.6(b)** By differentiation of the 3s radial wavefunction, show that it has three extrema in its amplitude, and locate them.
- 9.7(a)** At what radius does the probability of finding an electron at a point in the H atom fall to 50 per cent of its maximum value?
- 9.7(b)** At what radius in the H atom does the radial distribution function of the ground state have (a) 50 per cent, (b) 75 per cent of its maximum value.
- 9.8(a)** Locate the radial nodes in the 3s orbital of an H atom.
- 9.8(b)** Locate the radial nodes in the 4p orbital of an H atom.
- 9.9(a)** Calculate the average kinetic and potential energies of an electron in the ground state of a hydrogen atom.
- 9.9(b)** Calculate the average kinetic and potential energies of a 2s electron in a hydrogenic atom of atomic number  $Z$ .
- 9.10(a)** Write down the expression for the radial distribution function of a 2s electron in a hydrogenic atom and determine the radius at which the electron is most likely to be found.
- 9.10(b)** Write down the expression for the radial distribution function of a 3s electron in a hydrogenic atom and determine the radius at which the electron is most likely to be found.
- 9.11(a)** Write down the expression for the radial distribution function of a 2p electron in a hydrogenic atom and determine the radius at which the electron is most likely to be found.
- 9.11(b)** Write down the expression for the radial distribution function of a 3p electron in a hydrogenic atom and determine the radius at which the electron is most likely to be found.
- 9.12(a)** What is the orbital angular momentum of an electron in the orbitals (a) 1s, (b) 3s, (c) 3d? Give the numbers of angular and radial nodes in each case.
- 9.12(b)** What is the orbital angular momentum of an electron in the orbitals (a) 4d, (b) 2p, (c) 3p? Give the numbers of angular and radial nodes in each case.
- 9.13(a)** Locate the angular nodes and nodal planes of each of the 2p orbitals of a hydrogenic atom of atomic number  $Z$ . To locate the angular nodes, give the angle that the plane makes with the  $z$ -axis.
- 9.13(b)** Locate the angular nodes and nodal planes of each of the 3d orbitals of a hydrogenic atom of atomic number  $Z$ . To locate the angular nodes, give the angle that the plane makes with the  $z$ -axis.
- 9.14(a)** Which of the following transitions are allowed in the normal electronic emission spectrum of an atom: (a)  $2s \rightarrow 1s$ , (b)  $2p \rightarrow 1s$ , (c)  $3d \rightarrow 2p$ ?
- 9.14(b)** Which of the following transitions are allowed in the normal electronic emission spectrum of an atom: (a)  $5d \rightarrow 2s$ , (b)  $5p \rightarrow 3s$ , (c)  $6p \rightarrow 4f$ ?
- 9.15(a)** What is the Doppler-shifted wavelength of a red (680 nm) traffic light approached at  $60 \text{ km h}^{-1}$ ?
- 9.15(b)** At what speed of approach would a red (680 nm) traffic light appear green (530 nm)?
- 9.16(a)** Estimate the lifetime of a state that gives rise to a line of width (a)  $0.20 \text{ cm}^{-1}$ , (b)  $2.0 \text{ cm}^{-1}$ .
- 9.16(b)** Estimate the lifetime of a state that gives rise to a line of width (a)  $200 \text{ MHz}$ , (b)  $2.45 \text{ cm}^{-1}$ .
- 9.17(a)** A molecule in a liquid undergoes about  $1.0 \times 10^{13}$  collisions in each second. Suppose that (a) every collision is effective in deactivating the molecule vibrationally and (b) that one collision in 100 is effective. Calculate the width (in  $\text{cm}^{-1}$ ) of vibrational transitions in the molecule.
- 9.17(b)** A molecule in a gas undergoes about  $1.0 \times 10^9$  collisions in each second. Suppose that (a) every collision is effective in deactivating the molecule rotationally and (b) that one collision in 10 is effective. Calculate the width (in hertz) of rotational transitions in the molecule.
- 9.18(a)** Write the ground-state electron configurations of the d-metals from scandium to zinc.
- 9.18(b)** Write the ground-state electron configurations of the d-metals from yttrium to cadmium.
- 9.19(a)** (a) Write the electronic configuration of the  $\text{Ni}^{2+}$  ion. (b) What are the possible values of the total spin quantum numbers  $S$  and  $M_S$  for this ion?
- 9.19(b)** (a) Write the electronic configuration of the  $\text{V}^{2+}$  ion. (b) What are the possible values of the total spin quantum numbers  $S$  and  $M_S$  for this ion?
- 9.20(a)** Calculate the permitted values of  $j$  for (a) a d electron, (b) an f electron.
- 9.20(b)** Calculate the permitted values of  $j$  for (a) a p electron, (b) an h electron.
- 9.21(a)** An electron in two different states of an atom is known to have  $j = \frac{3}{2}$  and  $\frac{1}{2}$ . What is its orbital angular momentum quantum number in each case?
- 9.21(b)** What are the allowed total angular momentum quantum numbers of a composite system in which  $j_1 = 5$  and  $j_2 = 3$ ?
- 9.22(a)** What information does the term symbol  $^1\text{D}_2$  provide about the angular momentum of an atom?
- 9.22(b)** What information does the term symbol  $^3\text{F}_4$  provide about the angular momentum of an atom?

**9.23(a)** Suppose that an atom has (a) 2, (b) 3 electrons in different orbitals. What are the possible values of the total spin quantum number  $S$ ? What is the multiplicity in each case?

**9.23(b)** Suppose that an atom has (a) 4, (b) 5, electrons in different orbitals. What are the possible values of the total spin quantum number  $S$ ? What is the multiplicity in each case?

**9.24(a)** What atomic terms are possible for the electron configuration  $ns^1nd^1$ ? Which term is likely to lie lowest in energy?

**9.24(b)** What atomic terms are possible for the electron configuration  $np^1nd^1$ ? Which term is likely to lie lowest in energy?

**9.25(a)** What values of  $J$  may occur in the terms (a)  $^1S$ , (b)  $^2P$ , (c)  $^3P$ ? How many states (distinguished by the quantum number  $M_J$ ) belong to each level?

**9.25(b)** What values of  $J$  may occur in the terms (a)  $^3D$ , (b)  $^4D$ , (c)  $^2G$ ? How many states (distinguished by the quantum number  $M_J$ ) belong to each level?

**9.26(a)** Give the possible term symbols for (a) Li [He]2s<sup>1</sup>, (b) Na [Ne]3p<sup>1</sup>.

**9.26(b)** Give the possible term symbols for (a) Sc [Ar]3d<sup>1</sup>4s<sup>2</sup>, (b) Br [Ar]3d<sup>10</sup>4s<sup>2</sup>4p<sup>5</sup>.

**9.27(a)** Which of the following transitions between terms are allowed in the normal electronic emission spectrum of a many-electron atom: (a)  $^3D_2 \rightarrow ^3P_1$ , (b)  $^3P_2 \rightarrow ^1S_0$ , (c)  $^3F_4 \rightarrow ^3D_3$ ?

**9.27(b)** Which of the following transitions between terms are allowed in the normal electronic emission spectrum of a many-electron atom: (a)  $^2P_{3/2} \rightarrow ^2S_{1/2}$ , (b)  $^3P_0 \rightarrow ^3S_1$ , (c)  $^3D_3 \rightarrow ^1P_1$ ?

## Problems\*

### Numerical problems

**9.1** The *Humphreys series* is a group of lines in the spectrum of atomic hydrogen. It begins at 12 368 nm and has been traced to 3281.4 nm. What are the transitions involved? What are the wavelengths of the intermediate transitions?

**9.2** A series of lines in the spectrum of atomic hydrogen lies at 656.46 nm, 486.27 nm, 434.17 nm, and 410.29 nm. What is the wavelength of the next line in the series? What is the ionization energy of the atom when it is in the lower state of the transitions?

**9.3** The  $\text{Li}^{2+}$  ion is hydrogenic and has a Lyman series at 740 747 cm<sup>-1</sup>, 877 924 cm<sup>-1</sup>, 925 933 cm<sup>-1</sup>, and beyond. Show that the energy levels are of the form  $-hcR/n^2$  and find the value of  $R$  for this ion. Go on to predict the wavenumbers of the two longest-wavelength transitions of the Balmer series of the ion and find the ionization energy of the ion.

**9.4** A series of lines in the spectrum of neutral Li atoms rise from combinations of  $1s^22p^1\ ^2P$  with  $1s^2nd^1\ ^2D$  and occur at 610.36 nm, 460.29 nm, and 413.23 nm. The d orbitals are hydrogenic. It is known that the  $^2P$  term lies at 670.78 nm above the ground state, which is  $1s^22s^1\ ^2S$ . Calculate the ionization energy of the ground-state atom.

**9.5‡** W.P. Wijesundera *et al.* (*Phys. Rev. A* 51, 278 (1995)) attempted to determine the electron configuration of the ground state of lawrencium, element 103. The two contending configurations are [Rn]5f<sup>14</sup>7s<sup>2</sup>7p<sup>1</sup> and [Rn]5f<sup>14</sup>6d7s<sup>2</sup>. Write down the term symbols for each of these configurations, and identify the lowest level within each configuration. Which level would be lowest according to a simple estimate of spin-orbit coupling?

**9.6** An emission line from K atoms is found to have two closely spaced components, one at 766.70 nm and the other at 770.11 nm. Account for this observation, and deduce what information you can.

**9.7** Calculate the mass of the deuteron given that the first line in the Lyman series of H lies at 82 259.098 cm<sup>-1</sup> whereas that of D lies at 82 281.476 cm<sup>-1</sup>. Calculate the ratio of the ionization energies of H and D.

**9.8** Positronium consists of an electron and a positron (same mass, opposite charge) orbiting round their common centre of mass. The broad features of

the spectrum are therefore expected to be hydrogen-like, the differences arising largely from the mass differences. Predict the wavenumbers of the first three lines of the Balmer series of positronium. What is the binding energy of the ground state of positronium?

**9.9** The *Zeeman effect* is the modification of an atomic spectrum by the application of a strong magnetic field. It arises from the interaction between applied magnetic fields and the magnetic moments due to orbital and spin angular momenta (recall the evidence provided for electron spin by the Stern–Gerlach experiment, Section 8.8). To gain some appreciation for the so-called *normal Zeeman effect*, which is observed in transitions involving singlet states, consider a p electron, with  $l = 1$  and  $m_l = 0, \pm 1$ . In the absence of a magnetic field, these three states are degenerate. When a field of magnitude  $\mathcal{B}$  is present, the degeneracy is removed and it is observed that the state with  $m_l = +1$  moves up in energy by  $\mu_B \mathcal{B}$ , the state with  $m_l = 0$  is unchanged, and the state with  $m_l = -1$  moves down in energy by  $\mu_B \mathcal{B}$ , where  $\mu_B = e\hbar/2m_e = 9.274 \times 10^{-24} \text{ J T}^{-1}$  is the Bohr magneton (see Section 13.1). Therefore, a transition between a  $^1S_0$  term and a  $^1P_1$  term consists of three spectral lines in the presence of a magnetic field where, in the absence of the magnetic field, there is only one. (a) Calculate the splitting in reciprocal centimetres between the three spectral lines of a transition between a  $^1S_0$  term and a  $^1P_1$  term in the presence of a magnetic field of 2 T (where  $1 \text{ T} = 1 \text{ kg s}^{-2} \text{ A}^{-1}$ ). (b) Compare the value you calculated in (a) with typical optical transition wavenumbers, such as those for the Balmer series of the H atom. Is the line splitting caused by the normal Zeeman effect relatively small or relatively large?

**9.10** In 1976 it was mistakenly believed that the first of the ‘superheavy’ elements had been discovered in a sample of mica. Its atomic number was believed to be 126. What is the most probable distance of the innermost electrons from the nucleus of an atom of this element? (In such elements, relativistic effects are very important, but ignore them here.)

**9.11** An electron in the ground-state  $\text{He}^+$  ion undergoes a transition to a state described by the wavefunction  $R_{4,1}(r)Y_{1,1}(\theta, \phi)$ . (a) Describe the transition using term symbols. (b) Compute the wavelength, frequency, and wavenumber of the transition. (c) By how much does the mean radius of the electron change due to the transition?

**9.12** The collision frequency  $z$  of a molecule of mass  $m$  in a gas at a pressure  $p$  is  $z = 4\sigma(kT/\pi m)^{1/2}p/kT$ , where  $\sigma$  is the collision cross-section. Find an

\* Problems denoted with the symbol ‡ were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

expression for the collision-limited lifetime of an excited state assuming that every collision is effective. Estimate the width of a rotational transition in HCl ( $\sigma = 0.30 \text{ nm}^2$ ) at  $25^\circ\text{C}$  and  $1.0 \text{ atm}$ . To what value must the pressure of the gas be reduced in order to ensure that collision broadening is less important than Doppler broadening?

### Theoretical problems

**9.13** What is the most probable point (not radius) at which a  $2p$  electron will be found in the hydrogen atom?

**9.14** Show by explicit integration that (a) hydrogenic  $1s$  and  $2s$  orbitals, (b)  $2p_x$  and  $2p_y$  orbitals are mutually orthogonal.

**9.15†** Explicit expressions for hydrogenic orbitals are given in Tables 9.1 and 8.2. (a) Verify both that the  $3p_x$  orbital is normalized (to 1) and that  $3p_x$  and  $3d_{xy}$  are mutually orthogonal. (b) Determine the positions of both the radial nodes and nodal planes of the  $3s$ ,  $3p_x$ , and  $3d_{xy}$  orbitals. (c) Determine the mean radius of the  $3s$  orbital. (d) Draw a graph of the radial distribution function for the three orbitals (of part (b)) and discuss the significance of the graphs for interpreting the properties of many-electron atoms. (e) Create both  $xy$ -plane polar plots and boundary surface plots for these orbitals. Construct the boundary plots so that the distance from the origin to the surface is the absolute value of the angular part of the wavefunction. Compare the  $s$ ,  $p$ , and  $d$  boundary surface plots with that of an  $f$  orbital, e.g.  $\psi_f \propto x(5z^2 - r^2) \propto \sin \theta (5 \cos^2 \theta - 1) \cos \phi$ .

**9.16** Determine whether the  $p_x$  and  $p_y$  orbitals are eigenfunctions of  $l_z$ . If not, does a linear combination exist that is an eigenfunction of  $l_z$ ?

**9.17** Show that  $l_x$  and  $l^2$  both commute with the hamiltonian for a hydrogen atom. What is the significance of this result?

**9.18** The ‘size’ of an atom is sometimes considered to be measured by the radius of a sphere that contains 90 per cent of the charge density of the electrons in the outermost occupied orbital. Calculate the ‘size’ of a hydrogen atom in its ground state according to this definition. Go on to explore how the ‘size’ varies as the definition is changed to other percentages, and plot your conclusion.

**9.19** Some atomic properties depend on the average value of  $1/r$  rather than the average value of  $r$  itself. Evaluate the expectation value of  $1/r$  for (a) a hydrogen  $1s$  orbital, (b) a hydrogenic  $2s$  orbital, (c) a hydrogenic  $2p$  orbital.

**9.20** One of the most famous of the obsolete theories of the hydrogen atom was proposed by Bohr. It has been replaced by quantum mechanics but, by a remarkable coincidence (not the only one where the Coulomb potential is concerned), the energies it predicts agree exactly with those obtained from the Schrödinger equation. In the Bohr atom, an electron travels in a circle around the nucleus. The Coulombic force of attraction ( $Ze^2/4\pi\epsilon_0 r^2$ ) is balanced by the centrifugal effect of the orbital motion. Bohr proposed that the angular momentum is limited to integral values of  $\hbar$ . When the two forces are balanced, the atom remains in a stationary state until it makes a spectral transition. Calculate the energies of a hydrogenic atom using the Bohr model.

**9.21** The Bohr model of the atom is specified in Problem 9.20. What features of it are untenable according to quantum mechanics? How does the Bohr ground state differ from the actual ground state. Is there an experimental distinction between the Bohr and quantum mechanical models of the ground state?

**9.22** Atomic units of length and energy may be based on the properties of a particular atom. The usual choice is that of a hydrogen atom, with the unit of length being the Bohr radius,  $a_0$ , and the unit of energy being the (negative of the) energy of the  $1s$  orbital. If the positronium atom ( $e^+$ ,  $e^-$ ) were used instead, with analogous definitions of units of length and energy, what would be the relation between these two sets of atomic units?

**9.23** Some of the selection rules for hydrogenic atoms were derived in *Justification 9.4*. Complete the derivation by considering the  $x$ - and  $y$ -components of the electric dipole moment operator.

**9.24†** Stern–Gerlach splittings of atomic beams are small and require either large magnetic field gradients or long magnets for their observation. For a beam of atoms with zero orbital angular momentum, such as H or Ag, the deflection is given by  $x = \pm(\mu_B L^2/4E_k)dB/dz$ , where  $\mu_B$  is the Bohr magneton (Problem 9.9),  $L$  is the length of the magnet,  $E_k$  is the average kinetic energy of the atoms in the beam, and  $dB/dz$  is the magnetic field gradient across the beam. (a) Use the Maxwell–Boltzmann velocity distribution to show that the average translational kinetic energy of the atoms emerging as a beam from a pinhole in an oven at temperature  $T$  is  $2kT$ . (b) Calculate the magnetic field gradient required to produce a splitting of  $1.00 \text{ mm}$  in a beam of Ag atoms from an oven at  $1000 \text{ K}$  with a magnet of length  $50 \text{ cm}$ .

**9.25** The wavefunction of a many-electron closed-shell atom can be expressed as a Slater determinant (Section 9.4b). A useful property of determinants is that interchanging any two rows or columns changes their sign and therefore, if any two rows or columns are identical, then the determinant vanishes. Use this property to show that (a) the wavefunction is antisymmetric under particle exchange, (b) no two electrons can occupy the same orbital with the same spin.

### Applications: to astrophysics and biochemistry

**9.26** Hydrogen is the most abundant element in all stars. However, neither absorption nor emission lines due to neutral hydrogen are found in the spectra of stars with effective temperatures higher than  $25\,000 \text{ K}$ . Account for this observation.

**9.27** The distribution of isotopes of an element may yield clues about the nuclear reactions that occur in the interior of a star. Show that it is possible to use spectroscopy to confirm the presence of both  $^4\text{He}^+$  and  $^3\text{He}^+$  in a star by calculating the wavenumbers of the  $n=3 \rightarrow n=2$  and of the  $n=2 \rightarrow n=1$  transitions for each isotope.

**9.28†** Highly excited atoms have electrons with large principal quantum numbers. Such *Rydberg atoms* have unique properties and are of interest to astrophysicists. For hydrogen atoms with large  $n$ , derive a relation for the separation of energy levels. Calculate this separation for  $n=100$ ; also calculate the average radius, the geometric cross-section, and the ionization energy. Could a thermal collision with another hydrogen atom ionize this Rydberg atom? What minimum velocity of the second atom is required? Could a normal-sized neutral H atom simply pass through the Rydberg atom leaving it undisturbed? What might the radial wavefunction for a  $100s$  orbital be like?

**9.29** The spectrum of a star is used to measure its *radial velocity* with respect to the Sun, the component of the star’s velocity vector that is parallel to a vector connecting the star’s centre to the centre of the Sun. The measurement relies on the Doppler effect. When a star emitting electromagnetic radiation of frequency  $\nu$  moves with a speed  $s$  relative to an observer, the observer detects radiation of frequency  $\nu_{\text{receding}} = \nu f$  or  $\nu_{\text{approaching}} = \nu/f$ , where  $f = \{(1 - s/c)/(1 + s/c)\}^{1/2}$  and  $c$  is the speed of light. It is easy to see that  $\nu_{\text{receding}} < \nu$  and a receding star is characterized by a *red shift* of its spectrum with respect to the spectrum of an identical, but stationary source. Furthermore,  $\nu_{\text{approaching}} > \nu$  and an approaching star is characterized by a *blue shift* of its spectrum with respect to the spectrum of an identical, but stationary source. In a typical experiment,  $\nu$  is the frequency of a spectral line of an element measured in a stationary Earth-bound laboratory from a calibration source, such as an arc lamp. Measurement of the same spectral line in a star gives  $\nu_{\text{star}}$  and the speed of recession or approach may be calculated from the value of  $\nu$  and the equations above. (a) Three Fe I lines of the star HDE 271 182, which belongs to the Large Magellanic Cloud,

occur at 438.882 nm, 441.000 nm, and 442.020 nm. The same lines occur at 438.392 nm, 440.510 nm, and 441.510 nm in the spectrum of an Earth-bound iron arc. Determine whether HDE 271 182 is receding from or approaching the Earth and estimate the star's radial speed with respect to the Earth. (b) What additional information would you need to calculate the radial velocity of HDE 271 182 with respect to the Sun?

**9.30** In Problem 9.29, we saw that Doppler shifts of atomic spectral lines are used to estimate the speed of recession or approach of a star. From the discussion in Section 9.6a, it can be inferred that Doppler broadening of an atomic spectral line depends on the temperature of the star that emits the radiation. A spectral line of  $^{48}\text{Ti}^{8+}$  (of mass  $47.95m_0$ ) in a distant star was found to be shifted from 654.2 nm to 706.5 nm and to be broadened to 61.8 pm. What is the speed of recession and the surface temperature of the star?

**9.31** The d-metals iron, copper, and manganese form cations with different oxidation states. For this reason, they are found in many oxidoreductases and in several proteins of oxidative phosphorylation and photosynthesis. Explain why many d-metals form cations with different oxidation states.

**9.32** Thallium, a neurotoxin, is the heaviest member of Group 13 of the periodic table and is found most usually in the +1 oxidation state. Aluminium, which causes anaemia and dementia, is also a member of the group but its chemical properties are dominated by the +3 oxidation state. Examine this issue by plotting the first, second, and third ionization energies for the Group 13 elements against atomic number. Explain the trends you observe. *Hints.* The third ionization energy,  $I_3$ , is the minimum energy needed to remove an electron from the doubly charged cation:  $\text{E}^{2+}(\text{g}) \rightarrow \text{E}^{3+}(\text{g}) + \text{e}^{-}(\text{g})$ ,  $I_3 = E(\text{E}^{3+}) - E(\text{E}^{2+})$ . For data, see the links to databases of atomic properties provided in the text's web site.

## MATHEMATICAL BACKGROUND 5

## Vectors

A vector quantity has both magnitude and direction. The vector shown in Fig. MB5.1 has components on the  $x$ ,  $y$ , and  $z$  axes with magnitudes  $v_x$ ,  $v_y$ , and  $v_z$ , respectively. The vector may be represented as

$$\mathbf{v} = v_x \mathbf{i} + v_y \mathbf{j} + v_z \mathbf{k} \quad (\text{MB5.1})$$

where  $\mathbf{i}$ ,  $\mathbf{j}$ , and  $\mathbf{k}$  are **unit vectors**, vectors of magnitude 1, pointing along the positive directions on the  $x$ -,  $y$ -, and  $z$ -axes. The magnitude of the vector is denoted  $v$  or  $|\mathbf{v}|$  and is given by

$$v = (v_x^2 + v_y^2 + v_z^2)^{1/2} \quad (\text{MB5.2})$$

## MB5.1 Addition and subtraction

If  $\mathbf{v} = v_x \mathbf{i} + v_y \mathbf{j} + v_z \mathbf{k}$  and  $\mathbf{u} = u_x \mathbf{i} + u_y \mathbf{j} + u_z \mathbf{k}$ , then

$$\mathbf{v} \pm \mathbf{u} = (v_x \pm u_x) \mathbf{i} + (v_y \pm u_y) \mathbf{j} + (v_z \pm u_z) \mathbf{k} \quad (\text{MB5.3})$$

A graphical method for adding and subtracting vectors is sometimes desirable. Consider two vectors  $\mathbf{v}$  and  $\mathbf{u}$  making an angle  $\theta$  (Fig. MB5.2a). The first step in the addition of  $\mathbf{v}$  to  $\mathbf{u}$  consists of joining the tail of  $\mathbf{v}$  to the head of  $\mathbf{u}$ , as shown in Fig. MB5.2b. In the second step, we draw a vector from the tail of  $\mathbf{u}$  to the head of  $\mathbf{v}$ , as shown in Fig. MB5.2c. Reversing the order of addition leads to the same result. That is, we obtain the same resultant whether we add  $\mathbf{u}$  to  $\mathbf{v}$  or  $\mathbf{v}$  to  $\mathbf{u}$  (Fig. MB5.3).

To calculate the magnitude of the resultant  $\mathbf{w} = \mathbf{u} + \mathbf{v}$  we note that  $\mathbf{v}$ ,  $\mathbf{u}$ , and  $\mathbf{w}$  form a triangle and that we know the magnitudes of two of its sides ( $u$  and  $v$ ) and of the angle between them ( $180^\circ - \theta$ ; see Fig. MB5.2c). To calculate the magnitude of the third side,  $w$ , we make use of the *law of cosines*, which states that:

For a triangle with sides  $a$ ,  $b$ , and  $c$ , and angle  $C$  facing side  $c$ :

$$c^2 = a^2 + b^2 - 2ab \cos C$$

**Fig. MB5.1** The vector  $\mathbf{v}$  has components  $v_x$ ,  $v_y$ , and  $v_z$  on the  $x$ -,  $y$ -, and  $z$ -axes, respectively. It has a magnitude  $v$ .

**Fig. MB5.2** (a) The vectors  $\mathbf{u}$  and  $\mathbf{v}$  make an angle  $\theta$ . (b) To add  $\mathbf{v}$  to  $\mathbf{u}$ , we first join the tail of  $\mathbf{v}$  to the head of  $\mathbf{u}$ , making sure that the angle  $\theta$  between the vectors remains unchanged. (c) To finish the process, we draw the resultant vector by joining the tail of  $\mathbf{u}$  to the head of  $\mathbf{v}$ .

**Fig. MB5.3** The addition of (a)  $\mathbf{v}$  to  $\mathbf{u}$  gives the same resultant as the addition of (b)  $\mathbf{u}$  to  $\mathbf{v}$ .

**Fig. MB5.4** The graphical representation of the law of cosines.

This law is summarized graphically in Fig. MB5.4 and its application to the case shown in Fig. MB5.2c leads to the expression

$$w^2 = u^2 + v^2 - 2uv \cos(180^\circ - \theta)$$

Because  $\cos(180^\circ - \theta) = -\cos \theta$ , it follows after taking the square-root of both sides of the preceding expression that

$$w = (u^2 + v^2 + 2uv \cos \theta)^{1/2} \quad (\text{MB5.4})$$

The subtraction of vectors follows the same principles outlined above for addition. Consider again the vectors shown in

**Fig. MB5.5** The graphical method for subtraction of the vector  $v$  from the vector  $u$  shown in (a) consists of (b) reversing the direction of  $v$  to form  $-v$ , (c) moving the origin of  $-v$  to the tip of  $u$ , and adding  $-v$  to  $u$ .

Fig. MB5.2a. We note that subtraction of  $v$  from  $u$  amounts to addition of  $-v$  to  $u$ . It follows that in the first step of subtraction we draw  $-v$  by reversing the direction of  $v$  (Fig. MB5.5). Then, the second step consists of adding the  $-v$  to  $u$  by using the same strategy as in Fig. MB5.2.

## MB5.2 Multiplication

There are two ways to multiply vectors. In one procedure, the **scalar product** (or **dot product**) of two vectors  $u$  and  $v$  is defined as

$$u \cdot v = uv \cos \theta \quad \text{Scalar product} \quad (\text{MB5.5})$$

As its name suggests, the scalar product of two vectors is a scalar.

### • A brief illustration

The energy of interaction between a magnetic moment  $\mu$  (which might be due to the orbital angular momentum,  $l$ , of an electron,  $\mu = \gamma l$ ) and a magnetic field  $B$  is  $E = -\mu \cdot B$ . Suppose the field is applied in the  $z$ -direction; then  $B = Bk$ . The energy of interaction is then

$$E = -\mu \cdot B = -\mu \cdot Bk = -\mu_z B = -\mu B \cos \theta$$

where  $\theta$  is the angle between the magnetic moment and the field direction. •

The second type of vector multiplication is the **vector product** (or **cross-product**) of two vectors  $u$  and  $v$  to give a vector  $w$ :

$$u \times v = w \quad \text{Vector product} \quad (\text{MB5.6})$$

where the length of  $w$  is  $uv \sin \theta$ , where  $\theta$  is the angle between  $u$  and  $v$ . The direction of  $w$  is determined by the 'right-hand rule' (Fig. MB5.6). An equivalent definition is

**Fig. MB5.6** The direction of the cross-products of two vectors  $u$  and  $v$  with an angle  $\theta$  between them: (a)  $u \times v$  and (b)  $v \times u$ . Note that the resultant vector  $w$  is perpendicular to both  $u$  and  $v$  but the direction depends on the order in which the product is taken.

$$u \times v = \begin{vmatrix} i & j & k \\ u_x & u_y & u_z \\ v_x & v_y & v_z \end{vmatrix} \quad \text{Vector product} \quad (\text{MB5.7})$$

$$= (u_y v_z - u_z v_y)i - (u_x v_z - u_z v_x)j + (u_x v_y - u_y v_x)k$$

where the structure in the middle is a determinant (see *Mathematical background 6* following Chapter 10).

### • A brief illustration

The angular momentum  $l$  is defined as the vector product of the position  $r = (x, y, z)$  and linear momentum:  $p = (p_x, p_y, p_z)$ :

$$r \times p = \begin{vmatrix} i & j & k \\ x & y & z \\ p_x & p_y & p_z \end{vmatrix} = (yp_z - zp_y)i - (xp_z - zp_x)j + (xp_y - yp_x)k$$

We can now pick out the  $x$ -component as  $l_x = yp_z - zp_y$ , and likewise for the remaining two components. •

## MB5.3 Differentiation

The derivative  $dv/dt$ , where the components  $v_x$ ,  $v_y$ , and  $v_z$  are themselves functions of  $t$ , is

$$\frac{dv}{dt} = \left( \frac{dv_x}{dt} \right) i + \left( \frac{dv_y}{dt} \right) j + \left( \frac{dv_z}{dt} \right) k \quad (\text{MB5.8})$$

The derivatives of scalar and vector products are obtained using the rules of differentiating a product:

$$\frac{d(u \cdot v)}{dt} = u \cdot \frac{dv}{dt} + v \cdot \frac{du}{dt} \quad (\text{MB5.9a})$$

$$\frac{d(u \times v)}{dt} = u \times \frac{dv}{dt} + \frac{du}{dt} \times v \quad (\text{MB5.9b})$$

In the latter, note the importance of preserving the order of vectors.

The **gradient** of a function  $f(x, y, z)$ , denoted  $\text{grad } f$  or  $\nabla f$ , is

$$\nabla f = \left( \frac{\partial f}{\partial x} \right) \mathbf{i} + \left( \frac{\partial f}{\partial y} \right) \mathbf{j} + \left( \frac{\partial f}{\partial z} \right) \mathbf{k} \quad \boxed{\text{Gradient}} \quad (\text{MB5.10})$$

where partial derivatives are treated in *Mathematical background 2*. Note that the gradient of a scalar function is a vector. We can treat  $\nabla$  as a vector operator (in the sense that it operates on a function and results in a vector), and write

$$\nabla = \mathbf{i} \frac{\partial}{\partial x} + \mathbf{j} \frac{\partial}{\partial y} + \mathbf{k} \frac{\partial}{\partial z} \quad (\text{MB5.11})$$

The scalar product of  $\nabla$  and  $\nabla f$ , using eqns MB5.10 and MB5.11, is

$$\begin{aligned} \nabla \cdot \nabla f &= \left\{ \mathbf{i} \frac{\partial}{\partial x} + \mathbf{j} \frac{\partial}{\partial y} + \mathbf{k} \frac{\partial}{\partial z} \right\} \cdot \left\{ \left( \frac{\partial f}{\partial x} \right) \mathbf{i} + \left( \frac{\partial f}{\partial y} \right) \mathbf{j} + \left( \frac{\partial f}{\partial z} \right) \mathbf{k} \right\} \\ &= \left( \frac{\partial^2 f}{\partial x^2} \right) + \left( \frac{\partial^2 f}{\partial y^2} \right) + \left( \frac{\partial^2 f}{\partial z^2} \right) \end{aligned} \quad (\text{MB5.12})$$

$\nabla \cdot \nabla f$  is normally denoted  $\nabla^2 f$  and read ‘del squared  $f$ ’. Its form in polar coordinates is given in Table 7.1.

# Molecular structure

# 10

The concepts developed in Chapter 9, particularly those of orbitals, can be extended to a description of the electronic structures of molecules. There are two principal quantum mechanical theories of molecular electronic structure. In valence-bond theory, the starting point is the concept of the shared electron pair. We see how to write the wavefunction for such a pair, and how it may be extended to account for the structures of a wide variety of molecules. The theory introduces the concepts of  $\sigma$  and  $\pi$  bonds, promotion, and hybridization that are used widely in chemistry. In molecular orbital theory (with which the bulk of the chapter is concerned), the concept of atomic orbital is extended to that of molecular orbital, which is a wavefunction that spreads over all the atoms in a molecule.

In this chapter we consider the origin of the strengths, numbers, and three-dimensional arrangement of chemical bonds between atoms. As we shall see, all chemical bonding can be traced to the interplay between the attraction of opposite charges, the repulsion of like charges, and the effect of changing kinetic energy as the electrons are confined to various regions when bonds form.

The quantum mechanical description of chemical bonding has become highly developed through the use of computers, and it is now possible to consider the structures of molecules of almost any complexity. We shall concentrate on the quantum mechanical description of the **covalent bond**, which was identified by G.N. Lewis (in 1916, before quantum mechanics was fully established) as an electron pair shared between two neighbouring atoms and denoted A–B. We shall see, however, that the other principal type of bond, an **ionic bond**, in which the cohesion arises from the Coulombic attraction between ions of opposite charge, is also captured as a limiting case of a covalent bond between dissimilar atoms.

There are two major approaches to the calculation of molecular structure, **valence-bond theory** (VB theory) and **molecular orbital theory** (MO theory). Almost all modern computational work makes use of MO theory, and we concentrate on that theory in this chapter. Valence-bond theory, though, has left its imprint on the language of chemistry, and it is important to know the significance of terms that chemists use every day. Therefore, our discussion is organized as follows. First, we set out the concepts common to all levels of description. Then we present VB theory, which gives us a simple qualitative understanding of bond formation and its associated language. Next, we present the basic ideas of MO theory. Finally, we see how computational techniques pervade all current discussions of molecular structure, including the prediction of chemical reactivity.

Problems

**Fig. 10.1** A molecular potential energy curve. The equilibrium bond length  $R_e$  corresponds to the energy minimum.

#### A brief comment

The dissociation energy differs from the depth of the well by an energy equal to the zero-point vibrational energy of the bonded atoms:  $D_0 = D_e - \frac{1}{2}h\nu$ , where  $\nu$  is the vibrational frequency of the bond (Section 12.8).

## The Born–Oppenheimer approximation

**Key point** The nuclei of atoms in a molecule are regarded as fixed at selected locations, and the Schrödinger equation is then solved for the wavefunction of the electrons alone.

All theories of molecular structure make the same simplification at the outset. Whereas the Schrödinger equation for a hydrogen atom can be solved exactly, an exact solution is not possible for any molecule because even the simplest molecule consists of three particles (two nuclei and one electron). We therefore adopt the **Born–Oppenheimer approximation** in which it is supposed that the nuclei, being so much heavier than an electron, move relatively slowly and may be treated as stationary while the electrons move in their field. That is, we think of the nuclei as fixed at arbitrary locations, and then solve the Schrödinger equation for the wavefunction of the electrons alone.

The approximation is quite good for ground-state molecules, for calculations suggest that the nuclei in  $H_2$  move through only about 1 pm while the electron speeds through 1000 pm, so even in this case the error of assuming that the nuclei are stationary is small. Exceptions to the approximation's validity include certain excited states of polyatomic molecules and the ground states of cations; both types of species are important when considering photoelectron spectroscopy (Section 10.4) and mass spectrometry.

The Born–Oppenheimer approximation allows us to select an internuclear separation in a diatomic molecule and then to solve the Schrödinger equation for the electrons at that nuclear separation. Then we choose a different separation and repeat the calculation, and so on. In this way we can explore how the energy of the molecule varies with bond length and obtain a **molecular potential energy curve** (Fig. 10.1). It is called a *potential energy curve* because the kinetic energy of the stationary nuclei is zero. Once the curve has been calculated or determined experimentally (by using the spectroscopic techniques described in Chapters 11 and 12), we can identify the **equilibrium bond length**,  $R_e$ , the internuclear separation at the minimum of the curve, and the **bond dissociation energy**,  $D_0$ , which is closely related to the depth,  $D_e$ , of the minimum below the energy of the infinitely widely separated and stationary atoms. When more than one molecular parameter is changed in a polyatomic molecule, such as its various bond lengths and angles, we obtain a potential energy *surface*; the overall equilibrium shape of the molecule corresponds to the global minimum of the surface.

## Valence-bond theory

Valence-bond theory was the first quantum mechanical theory of bonding to be developed. The language it introduced, which includes concepts such as spin pairing,  $\sigma$  and  $\pi$  bonds, and hybridization, is widely used throughout chemistry, especially in the description of the properties and reactions of organic compounds. Here we summarize essential topics of VB theory that should be familiar from introductory chemistry and set the stage for the development of MO theory.

### 10.1 Homonuclear diatomic molecules

**Key point** In VB theory, a bond forms when an electron in an atomic orbital on one atom pairs its spin with that of an electron in an atomic orbital on another atom.

We begin the account of VB theory by considering the simplest possible chemical bond, the one in molecular hydrogen,  $H_2$ . The spatial wavefunction for an electron on each of two widely separated H atoms is

$$\psi = \chi_{\text{H1s}_A}(r_1)\chi_{\text{H1s}_B}(r_2) \quad (10.1)$$

if electron 1 is on atom A and electron 2 is on atom B; in this chapter we use  $\chi$  (chi) to denote atomic orbitals. For simplicity, we shall write this wavefunction as  $\psi = A(1)B(2)$ . When the atoms are close, it is not possible to know whether it is electron 1 or electron 2 that is on A. An equally valid description is therefore  $\psi = A(2)B(1)$ , in which electron 2 is on A and electron 1 is on B. When two outcomes are equally probable, quantum mechanics instructs us to describe the true state of the system as a superposition of the wavefunctions for each possibility (Section 7.5e), so a better description of the molecule than either wavefunction alone is one of the (unnormalized) linear combinations  $\psi = A(1)B(2) \pm A(2)B(1)$ . The combination with lower energy is the one with a + sign, so the valence-bond wavefunction of the electrons in an  $\text{H}_2$  molecule is

$$\psi = A(1)B(2) + A(2)B(1) \quad (10.2)$$

A valence-bond wavefunction

The reason why this linear combination has a lower energy than either the separate atoms or the linear combination with a negative sign can be traced to the constructive interference between the wave patterns represented by the terms  $A(1)B(2)$  and  $A(2)B(1)$ , and the resulting enhancement of the probability density of the electrons in the internuclear region (Fig. 10.2).

The electron distribution described by the wavefunction in eqn 10.2 is called a  $\sigma$  bond. A  $\sigma$  bond has cylindrical symmetry around the internuclear axis, and is so called because, when viewed along the internuclear axis, it resembles a pair of electrons in an s orbital (and  $\sigma$  is the Greek equivalent of s).

A chemist's picture of a covalent bond is one in which the spins of two electrons pair as the atomic orbitals overlap. The origin of the role of spin, as we show in the following *Justification*, is that the wavefunction in eqn 10.2 can be formed only by a pair of spin-paired electrons. Spin pairing is not an end in itself: it is a means of achieving a wavefunction and the probability distribution implies that it corresponds to a low energy.

#### Justification 10.1 Electron pairing in VB theory

The Pauli principle requires the overall wavefunction of two electrons, the wavefunction including spin, to change sign when the labels of the electrons are interchanged (Section 9.4b). The overall VB wavefunction for two electrons is

$$\psi(1,2) = \{A(1)B(2) + A(2)B(1)\}\sigma(1,2)$$

where  $\sigma$  represents the spin component of the wavefunction. When the labels 1 and 2 are interchanged, this wavefunction becomes

$$\psi(2,1) = \{A(2)B(1) + A(1)B(2)\}\sigma(2,1) = \{A(1)B(2) + A(2)B(1)\}\sigma(2,1)$$

The Pauli principle requires that  $\psi(2,1) = -\psi(1,2)$ , which is satisfied only if  $\sigma(2,1) = -\sigma(1,2)$ . The combination of two spins that has this property is

$$\sigma_-(1,2) = (1/2^{1/2})\{\alpha(1)\beta(2) - \alpha(2)\beta(1)\}$$

which corresponds to paired electron spins (Section 9.8). Therefore, we conclude that the state of lower energy (and hence the formation of a chemical bond) is achieved if the electron spins are paired.

**Fig. 10.2** It is very difficult to represent valence-bond wavefunctions because they refer to two electrons simultaneously. However, this illustration is an attempt. The top illustration represents  $A(1)B(2)$ , and the middle illustration represents the contribution  $A(2)B(1)$ . When the two contributions are superimposed, there is interference between the various contributions, resulting in an enhanced (two-electron) density in the internuclear region.

The VB description of  $\text{H}_2$  can be applied to other homonuclear diatomic molecules. For  $\text{N}_2$ , for instance, we consider the valence electron configuration of each atom,

**Fig. 10.3** The orbital overlap and spin pairing between electrons in two collinear p orbitals that results in the formation of a  $\sigma$  bond.

**Fig. 10.4** A  $\pi$  bond results from orbital overlap and spin pairing between electrons in p orbitals with their axes perpendicular to the internuclear axis. The bond has two lobes of electron density separated by a nodal plane.

**Fig. 10.5** The structure of bonds in a nitrogen molecule: there is one  $\sigma$  bond and two  $\pi$  bonds. As explained later, the overall electron density has cylindrical symmetry around the internuclear axis.

which is  $2s^2 2p_x^1 2p_y^1 2p_z^1$ . It is conventional to take the z-axis to be the internuclear axis, so we can imagine each atom as having a  $2p_z$  orbital pointing towards a  $2p_z$  orbital on the other atom (Fig. 10.3), with the  $2p_x$  and  $2p_y$  orbitals perpendicular to the axis. A  $\sigma$  bond is then formed by spin pairing between the two electrons in the two  $2p_z$  orbitals. Its spatial wavefunction is given by eqn 10.2, but now A and B stand for the two  $2p_z$  orbitals.

The remaining N2p orbitals cannot merge to give  $\sigma$  bonds as they do not have cylindrical symmetry around the internuclear axis. Instead, they merge to form two  $\pi$  bonds. A  $\pi$  bond arises from the spin pairing of electrons in two p orbitals that approach side-by-side (Fig. 10.4). It is so called because, viewed along the internuclear axis, a  $\pi$  bond resembles a pair of electrons in a p orbital (and  $\pi$  is the Greek equivalent of p).

There are two  $\pi$  bonds in  $N_2$ , one formed by spin pairing in two neighbouring  $2p_x$  orbitals and the other by spin pairing in two neighbouring  $2p_y$  orbitals. The overall bonding pattern in  $N_2$  is therefore a  $\sigma$  bond plus two  $\pi$  bonds (Fig. 10.5), which is consistent with the Lewis structure  $:N \equiv N:$  for nitrogen.

## 10.2 Polyatomic molecules

**Key point** To accommodate the shapes of polyatomic molecules, VB theory introduces the concepts of promotion and hybridization.

Each  $\sigma$  bond in a polyatomic molecule is formed by the spin pairing of electrons in atomic orbitals with cylindrical symmetry around the relevant internuclear axis. Likewise,  $\pi$  bonds are formed by pairing electrons that occupy atomic orbitals of the appropriate symmetry.

The VB description of  $H_2O$  will make this clear. The valence-electron configuration of an O atom is  $2s^2 2p_x^2 2p_y^1 2p_z^1$ . The two unpaired electrons in the O2p orbitals can each pair with an electron in an H1s orbital, and each combination results in the formation of a  $\sigma$  bond (each bond has cylindrical symmetry about the respective O–H internuclear axis). Because the  $2p_y$  and  $2p_z$  orbitals lie at  $90^\circ$  to each other, the two  $\sigma$  bonds also lie at  $90^\circ$  to each other (Fig. 10.6). We can predict, therefore, that  $H_2O$  should be an angular molecule, which it is. However, the theory predicts a bond angle of  $90^\circ$ , whereas the actual bond angle is  $104.5^\circ$ .

**Self-test 10.1** Use VB theory to suggest a shape for the ammonia molecule,  $NH_3$ .  
[Trigonal pyramidal with HNH bond angle  $90^\circ$ ; experimental:  $107^\circ$ ]

Another deficiency of this initial formulation of VB theory is its inability to account for carbon's tetravalence (its ability to form four bonds). The ground-state configuration of C is  $2s^2 2p_x^1 2p_y^1$ , which suggests that a carbon atom should be capable of forming only two bonds, not four. This deficiency is overcome by allowing for **promotion**, the excitation of an electron to an orbital of higher energy. In carbon, for example, the promotion of a 2s electron to a 2p orbital can be thought of as leading to the configuration  $2s^1 2p_x^1 2p_y^1 2p_z^1$ , with four unpaired electrons in separate orbitals. These electrons may pair with four electrons in orbitals provided by four other atoms (such as four H1s orbitals if the molecule is  $CH_4$ ), and hence form four  $\sigma$  bonds. Although energy was required to promote the electron, it is more than recovered by the promoted atom's ability to form four bonds in place of the two bonds of the unpromoted atom. Promotion, and the formation of four bonds, is a characteristic feature of carbon because the promotion energy is quite small: the promoted electron leaves

a doubly occupied 2s orbital and enters a vacant 2p orbital, hence significantly relieving the electron–electron repulsion it experiences in the former. However, we need to remember that promotion is not a ‘real’ process in which an atom somehow becomes excited and then forms bonds: it is a notional contribution to the overall energy change that occurs when bonds form.

The description of the bonding in  $\text{CH}_4$  (and other alkanes) is still incomplete because it implies the presence of three  $\sigma$  bonds of one type (formed from  $\text{H}1s$  and  $\text{C}2p$  orbitals) and a fourth  $\sigma$  bond of a distinctly different character (formed from  $\text{H}1s$  and  $\text{C}2s$ ). This problem is overcome by realizing that the electron density distribution in the promoted atom is equivalent to the electron density in which each electron occupies a **hybrid orbital** formed by interference between the  $\text{C}2s$  and  $\text{C}2p$  orbitals of the same atom. The origin of the hybridization can be appreciated by thinking of the four atomic orbitals centred on a nucleus as waves that interfere destructively and constructively in different regions, and give rise to four new shapes.

As we show in the following *Justification*, the specific linear combinations that give rise to four equivalent hybrid orbitals are

$$\begin{aligned} h_1 &= s + p_x + p_y + p_z & h_2 &= s - p_x - p_y + p_z \\ h_3 &= s - p_x + p_y - p_z & h_4 &= s + p_x - p_y - p_z \end{aligned} \quad \boxed{\text{sp}^3 \text{ hybrid orbitals}} \quad (10.3)$$

As a result of the interference between the component orbitals, each hybrid orbital consists of a large lobe pointing in the direction of one corner of a regular tetrahedron (Fig. 10.7). The angle between the axes of the hybrid orbitals is the tetrahedral angle,  $\arccos(-1/3) = 109.47^\circ$ . Because each hybrid is built from one  $s$  orbital and three  $p$  orbitals, it is called an  **$\text{sp}^3$  hybrid orbital**.

#### Justification 10.2 Determining the form of tetrahedral hybrids

We begin by supposing that each hybrid can be written in the form  $h = as + b_x p_x + b_y p_y + b_z p_z$ . The hybrid  $h_1$  that points to the  $(1,1,1)$  corner of a cube (Fig. 10.8) must have equal contributions from all three  $p$  orbitals, so we can set the three  $b$  coefficients equal to each other and write  $h_1 = as + b(p_x + p_y + p_z)$ . The other three hybrids have the same composition (they are equivalent, apart from their direction in space), but are orthogonal to  $h_1$ . This orthogonality is achieved by choosing different signs for the  $p$  orbitals but the same overall composition. For instance, we might choose  $h_2 = as + b(-p_x - p_y + p_z)$ , in which case the orthogonality condition is

$$\begin{aligned} \int h_1 h_2 d\tau &= \int (as + b(p_x + p_y + p_z))(as + b(-p_x - p_y + p_z)) d\tau \\ &= a^2 \int s^2 d\tau - b^2 \int p_x^2 d\tau - b^2 \int p_y^2 d\tau + b^2 \int p_z^2 d\tau - ab \int sp_x d\tau - \dots - b^2 \int p_x p_y d\tau + \dots \\ &= a^2 - b^2 - b^2 + b^2 = a^2 - b^2 = 0 \end{aligned}$$

We conclude that a solution is  $a = b$  (the alternative solution,  $a = -b$ , simply corresponds to choosing different absolute phases for the  $p$ -orbitals) and the two hybrid orbitals are the  $h_1$  and  $h_2$  in eqn 10.3. A similar argument but with  $h_3 = as + b(-p_x + p_y - p_z)$  or  $h_4 = as + b(p_x - p_y - p_z)$  leads to the other two hybrids in eqn 10.3.

It is now easy to see how the valence-bond description of the  $\text{CH}_4$  molecule leads to a tetrahedral molecule containing four equivalent C–H bonds. Each hybrid orbital of the promoted C atom contains a single unpaired electron; an  $\text{H}1s$  electron can pair with each one, giving rise to a  $\sigma$  bond pointing in a tetrahedral direction. For example,

**Fig. 10.6** A first approximation to the valence-bond description of bonding in an  $\text{H}_2\text{O}$  molecule. Each  $\sigma$  bond arises from the overlap of an  $\text{H}1s$  orbital with one of the  $\text{O}2p$  orbitals. This model suggests that the bond angle should be  $90^\circ$ , which is significantly different from the experimental value.

**Fig. 10.7** An  $\text{sp}^3$  hybrid orbital formed from the superposition of  $s$  and  $p$  orbitals on the same atom. There are four such hybrids: each one points towards the corner of a regular tetrahedron. The overall electron density remains spherically symmetrical.

**Fig. 10.8** One  $\text{sp}^3$  hybrid is constructed by supposing that it points to the  $(1,1,1)$  corner of a cube: it has equal contributions from all three  $p$  orbitals.

the (unnormalized) wavefunction for the bond formed by the hybrid orbital  $h_1$  and the  $1s_A$  orbital (with wavefunction that we shall denote  $A$ ) is

$$\psi = h_1(1)A(2) + h_1(2)A(1) \quad (10.4)$$

As for  $H_2$ , to achieve this wavefunction, the two electrons it describes must be paired. Because each  $sp^3$  hybrid orbital has the same composition, all four  $\sigma$  bonds are identical apart from their orientation in space (Fig. 10.9).

A hybrid orbital has enhanced amplitude in the internuclear region, which arises from the constructive interference between the  $s$  orbital and the positive lobes of the  $p$  orbitals (Fig. 10.10). As a result, the bond strength is greater than for a bond formed from an  $s$  or  $p$  orbital alone. This increased bond strength is another factor that helps to repay the promotion energy.

Hybridization is used to describe the structure of an ethene molecule,  $H_2C=CH_2$ , and the torsional rigidity of double bonds. An ethene molecule is planar, with HCH and HCC bond angles close to  $120^\circ$ . To reproduce the  $\sigma$  bonding structure, we promote each C atom to a  $2s^1 2p^3$  configuration. However, instead of using all four orbitals to form hybrids, we form  $sp^2$  hybrid orbitals:

$$\begin{aligned} h_1 &= s + 2^{1/2}p_y \\ h_2 &= s + (\frac{3}{2})^{1/2}p_x - (\frac{1}{2})^{1/2}p_y \\ h_3 &= s - (\frac{3}{2})^{1/2}p_x - (\frac{1}{2})^{1/2}p_y \end{aligned} \quad \boxed{sp^2 \text{ hybrid orbitals}} \quad (10.5)$$

These hybrids lie in a plane and point towards the corners of an equilateral triangle at  $120^\circ$  to each other (Fig. 10.11 and Problem 10.17). The third  $2p$  orbital ( $2p_z$ ) is not included in the hybridization; its axis is perpendicular to the plane in which the hybrids lie. The different signs of the coefficients ensure that constructive interference takes place in different regions of space, so giving the patterns in the illustration. The  $sp^2$ -hybridized C atoms each form three  $\sigma$  bonds by spin pairing with either the  $h_1$

**Fig. 10.9** Each  $sp^3$  hybrid orbital forms a  $\sigma$  bond by overlap with an  $H1s$  orbital located at the corner of the tetrahedron. This model accounts for the equivalence of the four bonds in  $CH_4$ .

**Fig. 10.10** A more detailed representation of the formation of an  $sp^3$  hybrid by interference between wavefunctions centred on the same atomic nucleus. (To simplify the representation, we have ignored the radial node of the  $2s$  orbital.)

**Fig. 10.11** (a) An  $s$  orbital and two  $p$  orbitals can be hybridized to form three equivalent orbitals that point towards the corners of an equilateral triangle. (b) The remaining unhybridized  $p$  orbital is perpendicular to the plane.

hybrid of the other C atom or with H1s orbitals. The  $\sigma$  framework therefore consists of C–H and C–C  $\sigma$  bonds at  $120^\circ$  to each other. When the two  $\text{CH}_2$  groups lie in the same plane, the two electrons in the unhybridized p orbitals can pair and form a  $\pi$  bond (Fig. 10.12). The formation of this  $\pi$  bond locks the framework into the planar arrangement, for any rotation of one  $\text{CH}_2$  group relative to the other leads to a weakening of the  $\pi$  bond (and consequently an increase in energy of the molecule).

A similar description applies to ethyne,  $\text{HC}\equiv\text{CH}$ , a linear molecule. Now the C atoms are **sp hybridized**, and the  $\sigma$  bonds are formed using hybrid atomic orbitals of the form

$$h_1 = s + p_z \quad h_2 = s - p_z \quad \boxed{\text{sp hybrid orbitals}} \quad (10.6)$$

These two hybrids lie along the internuclear axis. The electrons in them pair either with an electron in the corresponding hybrid orbital on the other C atom or with an electron in one of the H1s orbitals. Electrons in the two remaining p orbitals on each atom, which are perpendicular to the molecular axis, pair to form two perpendicular  $\pi$  bonds (Fig. 10.13).

**Self-test 10.2** Hybrid orbitals do not always form bonds: they may also contain lone pairs of electrons. Use VB theory to suggest possible shapes for the hydrogen peroxide molecule,  $\text{H}_2\text{O}_2$ .

[Each H–O–O bond angle is predicted to be approximately  $109^\circ$  (experimental:  $94.8^\circ$ ); rotation around the O–O bond is possible, so the molecule is conformationally mobile]

Other hybridization schemes, particularly those involving d orbitals, are often invoked in elementary descriptions of molecular structure to be consistent with other molecular geometries (Table 10.1). The hybridization of  $N$  atomic orbitals always results in the formation of  $N$  hybrid orbitals, which may either form bonds or may contain lone pairs of electrons. For example,  $\text{sp}^3\text{d}^2$  hybridization results in six equivalent hybrid orbitals pointing towards the corners of a regular octahedron; it is sometimes invoked to account for the structure of octahedral molecules, such as  $\text{SF}_6$ .

**Fig. 10.12** A representation of the structure of a double bond in ethene; only the  $\pi$  bond is shown explicitly.

**Fig. 10.13** A representation of the structure of a triple bond in ethyne; only the  $\pi$  bonds are shown explicitly. The overall electron density has cylindrical symmetry around the axis of the molecule.

**Table 10.1\*** Some hybridization schemes

| Coordination number | Arrangement            | Composition                                                                      |

## Molecular orbital theory

In MO theory, electrons do not belong to particular bonds but spread throughout the entire molecule. This theory has been more fully developed than VB theory and provides the language that is widely used in modern discussions of bonding. To introduce it, we follow the same strategy as in Chapter 9, where the one-electron H atom was taken as the fundamental species for discussing atomic structure and then developed into a description of many-electron atoms. In this chapter we use the simplest molecular species of all, the hydrogen molecule-ion,  $\text{H}_2^+$ , to introduce the essential features of bonding and then use it to describe the structures of more complex systems.

### 10.3 The hydrogen molecule-ion

**Key points** (a) A molecular orbital is constructed as a linear combination of atomic orbitals. (b) A bonding orbital arises from the constructive overlap of neighbouring atomic orbitals. (c) An antibonding orbital arises from the destructive overlap of neighbouring atomic orbitals.

The hamiltonian for the single electron in  $\text{H}_2^+$  is

$$\hat{H} = -\frac{\hbar^2}{2m_e} \nabla^2 + V \quad V = -\frac{e^2}{4\pi\epsilon_0} \left( \frac{1}{r_{A1}} + \frac{1}{r_{B1}} - \frac{1}{R} \right) \quad (10.7)$$

where  $r_{A1}$  and  $r_{B1}$  are the distances of the electron from the two nuclei A and B (1) and  $R$  is the distance between the two nuclei. In the expression for  $V$ , the first two terms in parentheses are the attractive contribution from the interaction between the electron and the nuclei; the remaining term is the repulsive interaction between the nuclei. The collection of fundamental constants  $e^2/4\pi\epsilon_0$  occurs widely throughout this chapter, and we shall denote it  $j_0$ .

The one-electron wavefunctions obtained by solving the Schrödinger equation  $\hat{H}\psi = E\psi$  are called **molecular orbitals** (MO). A molecular orbital  $\psi$  gives, through the value of  $|\psi|^2$ , the distribution of the electron in the molecule. A molecular orbital is like an atomic orbital, but spreads throughout the molecule.

The Schrödinger equation can be solved analytically for  $\text{H}_2^+$  (within the Born–Oppenheimer approximation), but the wavefunctions are very complicated functions; moreover, the solution cannot be extended to polyatomic systems. Therefore, we adopt a simpler procedure that, while more approximate, can be extended readily to other molecules.

#### (a) Linear combinations of atomic orbitals

If an electron can be found in an atomic orbital belonging to atom A and also in an atomic orbital belonging to atom B, then the overall wavefunction is a superposition of the two atomic orbitals:

$$\psi_{\pm} = N(A \pm B) \quad \text{Linear combination of atomic orbitals} \quad (10.8)$$

where, for  $\text{H}_2^+$ ,  $A$  denotes  $\chi_{\text{H}1s}$ ,  $B$  denotes  $\chi_{\text{H}1s}$ , and  $N$  is a normalization factor. The technical term for the superposition in eqn 10.8 is a **linear combination of atomic orbitals** (LCAO). An approximate molecular orbital formed from a linear combination of atomic orbitals is called an **LCAO-MO**. A molecular orbital that has cylindrical symmetry around the internuclear axis, such as the one we are discussing, is called a  **$\sigma$  orbital** because it resembles an s orbital when viewed along the axis and, more precisely, because it has zero orbital angular momentum around the internuclear axis.

**Example 10.1** Normalizing a molecular orbital

Normalize the molecular orbital  $\psi_+$  in eqn 10.8.

**Method** We need to find the factor  $N$  such that  $\int \psi^* \psi d\tau = 1$ . To proceed, substitute the LCAO into this integral, and make use of the fact that the atomic orbitals are individually normalized.

**Answer** Substitution of the wavefunction gives

$$\int \psi^* \psi d\tau = N^2 \left\{ \int A^2 d\tau + \int B^2 d\tau + 2 \int AB d\tau \right\} = N^2(1 + 1 + 2S)$$

where  $S = \int AB d\tau$  and has a value that depends on the nuclear separation (this ‘overlap integral’ will play a significant role later). For the integral to be equal to 1, we require

$$N = \frac{1}{\{2(1 + S)\}^{1/2}}$$

In  $\text{H}_2^+$ ,  $S \approx 0.59$ , so  $N = 0.56$ .

**Self-test 10.3** Normalize the orbital  $\psi_-$  in eqn 10.8.

$$[N = 1/\{2(1 - S)\}^{1/2}, \text{ so } N = 1.10]$$

Figure 10.14 shows the contours of constant amplitude for the molecular orbital  $\psi_+$  in eqn 10.8, and Fig. 10.15 shows its boundary surface. Plots like these are readily obtained using commercially available software. The calculation is quite straightforward, because all we need do is feed in the mathematical forms of the two atomic orbitals and then let the program do the rest. In this case, we use

$$A = \frac{e^{-r_A/a_0}}{(\pi a_0^3)^{1/2}} \quad B = \frac{e^{-r_B/a_0}}{(\pi a_0^3)^{1/2}} \quad (10.9)$$

and note that  $r_A$  and  $r_B$  are not independent (2), but related by

$$r_B = \{r_A^2 + R^2 - 2r_A R \cos \theta\}^{1/2} \quad (10.10)$$

**(b) Bonding orbitals**

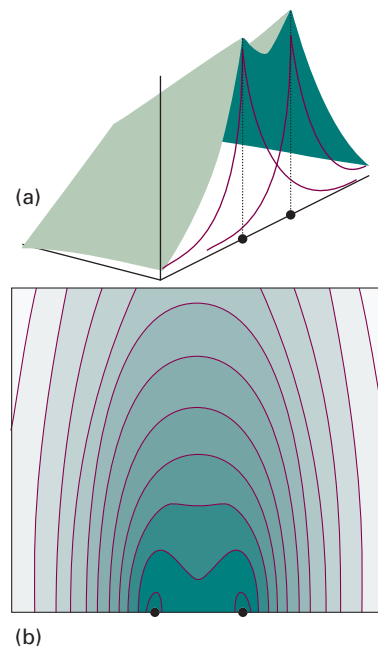

According to the Born interpretation, the probability density of the electron at each point in  $\text{H}_2^+$  is proportional to the square modulus of its wavefunction at that point. The probability density corresponding to the (real) wavefunction  $\psi_+$  in eqn 10.8 is

$$\psi_+^2 = N^2(A^2 + B^2 + 2AB) \quad (10.11)$$

This probability density is plotted in Fig. 10.16 and an important feature becomes apparent when we examine the internuclear region, where both atomic orbitals have similar amplitudes. According to eqn 10.11, the total probability density is proportional to the sum of:

- $A^2$ , the probability density if the electron were confined to the atomic orbital  $A$ .
- $B^2$ , the probability density if the electron were confined to the atomic orbital  $B$ .
- $2AB$ , an extra contribution to the density from both atomic orbitals.

This last contribution, the **overlap density**, is crucial, because it represents an enhancement of the probability of finding the electron in the internuclear region. The

**Fig. 10.14** (a) The amplitude of the bonding molecular orbital in a hydrogen molecule-ion in a plane containing the two nuclei and (b) a contour representation of the amplitude. To make this plot, we have taken  $N^2 = 0.31$  (Example 10.1).

**interActivity** Plot the  $1\sigma$  orbital for different values of the internuclear distance. Point to the features of the  $1\sigma$  orbital that lead to bonding.

**Fig. 10.15** A general indication of the shape of the boundary surface of a  $\sigma$  orbital.

**Fig. 10.16** The electron density calculated by forming the square of the wavefunction used to construct Fig. 10.14. Note the accumulation of electron density in the internuclear region.

enhancement can be traced to the constructive interference of the two atomic orbitals: each has a positive amplitude in the internuclear region, so the total amplitude is greater there than if the electron were confined to a single atomic orbital.

We shall frequently make use of the observation that *bonds form when electrons accumulate in regions where atomic orbitals overlap and interfere constructively*. The conventional explanation of this observation is based on the notion that accumulation of electron density between the nuclei puts the electron in a position where it interacts strongly with both nuclei. Hence, the energy of the molecule is lower than that of the separate atoms, where each electron can interact strongly with only one nucleus. This conventional explanation, however, has been called into question, because shifting an electron away from a nucleus into the internuclear region *raises* its potential energy. The modern (and still controversial) explanation does not emerge from the simple LCAO treatment given here. It seems that, at the same time as the electron shifts into the internuclear region, the atomic orbitals shrink. This orbital shrinkage improves the electron–nucleus attraction more than it is decreased by the migration to the internuclear region, so there is a net lowering of potential energy. The kinetic energy of the electron is also modified because the curvature of the wavefunction is changed, but the change in kinetic energy is dominated by the change in potential energy. Throughout the following discussion we ascribe the strength of chemical bonds to the accumulation of electron density in the internuclear region. We leave open the question whether in molecules more complicated than  $\text{H}_2^+$  the true source of energy lowering is that accumulation itself or some indirect but related effect.

The  $\sigma$  orbital we have described is an example of a **bonding orbital**, an orbital which, if occupied, helps to bind two atoms together. Specifically, we label it  $1\sigma$  as it is the  $\sigma$  orbital of lowest energy. An electron that occupies a  $\sigma$  orbital is called a  **$\sigma$  electron** and, if that is the only electron present in the molecule (as in the ground state of  $\text{H}_2^+$ ), then we report the configuration of the molecule as  $1\sigma^1$ .

The energy  $E_{1\sigma}$  of the  $1\sigma$  orbital is (see Problem 10.18):

$$E_{1\sigma} = E_{\text{H}1s} + \frac{j_0}{R} - \frac{j+k}{1+S} \quad (10.12)$$

where  $E_{\text{H}1s}$  is the energy of a  $\text{H}1s$  orbital,  $j_0/R$  is the potential energy of repulsion between the two nuclei, and

$$S = \int AB \, d\tau = \left\{ 1 + \frac{R}{a_0} + \frac{1}{3} \left( \frac{R}{a_0} \right)^2 \right\} e^{-R/a_0} \quad (10.13a)$$

$$j = j_0 \int \frac{A^2}{r_B} \, d\tau = \frac{j_0}{R} \left\{ 1 - \left( 1 + \frac{R}{a_0} \right) e^{-2R/a_0} \right\} \quad (10.13b)$$

$$k = j_0 \int \frac{AB}{r_B} \, d\tau = \frac{j_0}{a_0} \left( 1 + \frac{R}{a_0} \right) e^{-R/a_0} \quad (10.13c)$$

We can interpret these three integrals as follows:

- All three integrals are positive and decline towards zero at large internuclear separations ( $S$  and  $k$  on account of the exponential term;  $j$  on account of the factor  $1/R$ ). The integral  $S$  is discussed in more detail in Section 10.4c.
- The integral  $j$  is a measure of the interaction between a nucleus and the electron density centred on the other nucleus.
- The integral  $k$  is a measure of the interaction between a nucleus and the excess electron density in the internuclear region arising from overlap.

**Fig. 10.17** The calculated and experimental molecular potential energy curves for a hydrogen molecule-ion showing the variation of the energy of the molecule as the bond length is changed. The alternative g,u notation is introduced in Section 10.3c.

Figure 10.17 is a plot of  $E_{1\sigma}$  against  $R$  relative to the energy of the separated atoms. The energy of the  $1\sigma$  orbital decreases as the internuclear separation decreases from large values because electron density accumulates in the internuclear region as the constructive interference between the atomic orbitals increases (Fig. 10.18). However, at small separations there is too little space between the nuclei for significant accumulation of electron density there. In addition, the nucleus–nucleus repulsion (which is proportional to  $1/R$ ) becomes large. As a result, the energy of the molecule rises at short distances, and there is a minimum in the potential energy curve. Calculations on  $\text{H}_2^+$  give  $R_e = 130$  pm and  $D_e = 1.77$  eV ( $171 \text{ kJ mol}^{-1}$ ); the experimental values are 106 pm and 2.6 eV, so this simple LCAO-MO description of the molecule, while inaccurate, is not absurdly wrong.

### (c) Antibonding orbitals

The linear combination  $\psi_-$  in eqn 10.8 corresponds to a higher energy than that of  $\psi_+$ . Because it is also a  $\sigma$  orbital we label it  $2\sigma$ . This orbital has an internuclear nodal plane where  $A$  and  $B$  cancel exactly (Figs. 10.19 and 10.20). The probability density is

$$\psi_-^2 = N^2(A^2 + B^2 - 2AB) \quad (10.14)$$

There is a reduction in probability density between the nuclei due to the  $-2AB$  term (Fig. 10.21); in physical terms, there is destructive interference where the two atomic orbitals overlap. The  $2\sigma$  orbital is an example of an **antibonding orbital**, an orbital that, if occupied, contributes to a reduction in the cohesion between two atoms and helps to raise the energy of the molecule relative to the separated atoms.

The energy  $E_{2\sigma}$  of the  $2\sigma$  antibonding orbital is given by (see Problem 10.18)

$$E_{2\sigma} = E_{\text{H}1s} + \frac{j_0}{R} - \frac{j-k}{1-S} \quad (10.15)$$

where the integrals  $S$ ,  $j$ , and  $k$  are the same as before (eqn 10.13). The variation of  $E_{2\sigma}$  with  $R$  is shown in Fig. 10.17, where we see the destabilizing effect of an antibonding

**Fig. 10.18** A representation of the constructive interference that occurs when two  $\text{H}1s$  orbitals overlap and form a bonding  $\sigma$  orbital.

**Fig. 10.19** A representation of the destructive interference that occurs when two  $\text{H}1s$  orbitals overlap and form an antibonding  $2\sigma$  orbital.

**Fig. 10.20** (a) The amplitude of the antibonding molecular orbital in a hydrogen molecule-ion in a plane containing the two nuclei and (b) a contour representation of the amplitude. Note the internuclear node.

**interActivity** Plot the  $2\sigma$  orbital for different values of the internuclear distance. Point to the features of the  $2\sigma$  orbital that lead to antibonding.

**Fig. 10.21** The electron density calculated by forming the square of the wavefunction used to construct Fig. 10.20. Note the elimination of electron density from the internuclear region.

**Fig. 10.22** A partial explanation of the origin of bonding and antibonding effects. (a) In a bonding orbital, the nuclei are attracted to the accumulation of electron density in the internuclear region. (b) In an antibonding orbital, the nuclei are attracted to an accumulation of electron density outside the internuclear region.

**Fig. 10.23** The parity of an orbital is even (g) if its wavefunction is unchanged under inversion through the centre of symmetry of the molecule, but odd (u) if the wavefunction changes sign. Heteronuclear diatomic molecules do not have a centre of inversion, so for them the g, u classification is irrelevant.

electron. The effect is partly due to the fact that an antibonding electron is excluded from the internuclear region and hence is distributed largely outside the bonding region. In effect, whereas a bonding electron pulls two nuclei together, an antibonding electron pulls the nuclei apart (Fig. 10.22). Figure 10.17 also shows another feature that we draw on later:  $|E_- - E_{\text{HIs}}| > |E_+ - E_{\text{HIs}}|$ , which indicates that *the antibonding orbital is more antibonding than the bonding orbital is bonding*. This important conclusion stems in part from the presence of the nucleus–nucleus repulsion ( $j_0/R$ ): this contribution raises the energy of both molecular orbitals. Antibonding orbitals are often labelled with an asterisk (\*), so the  $2\sigma$  orbital could also be denoted  $2\sigma^*$  (and read ‘2 sigma star’).

For homonuclear diatomic molecules (molecules consisting of two atoms of the same element, such as  $\text{N}_2$ ), it proves helpful to label a molecular orbital according to its **inversion symmetry**, the behaviour of the wavefunction when it is inverted through the centre (more formally, the centre of inversion) of the molecule. Thus, if we consider any point on the bonding  $\sigma$  orbital, and then project it through the centre of the molecule and out an equal distance on the other side, then we arrive at an identical value of the wavefunction (Fig. 10.23). This so-called **gerade symmetry** (from the German word for ‘even’) is denoted by a subscript g, as in  $\sigma_g$ . The same procedure applied to the antibonding  $2\sigma$  orbital results in the same amplitude but opposite sign of the wavefunction. This **ungerade symmetry** (‘odd symmetry’) is denoted by a subscript u, as in  $\sigma_u$ . This inversion symmetry classification is not applicable to heteronuclear diatomic molecules (diatomic molecules formed by atoms from two different elements, such as CO) because these molecules do not have a centre of inversion. When using the g, u notation, each set of orbitals of the same inversion symmetry are labelled separately so, whereas  $1\sigma$  becomes  $1\sigma_g$ , its antibonding partner, which so far we have called  $2\sigma$ , is the first orbital of a different symmetry, and is denoted  $1\sigma_u$ . The general rule is that *each set of orbitals of the same symmetry designation is labelled separately*.

## 10.4 Homonuclear diatomic molecules

**Key points** Electrons are added to available molecular orbitals in a manner that achieves the lowest overall energy. (a) As a first approximation,  $\sigma$  orbitals are constructed separately from valence s and p orbitals. (b)  $\pi$  Orbitals are constructed from the side-by-side overlap of p orbitals of the appropriate symmetry. (c) The overlap integral is a measure of the extent of orbital overlap. (d) The ground-state electron configurations of diatomic molecules are predicted by using the building up principle, and the bond order is a measure of the resulting net bonding character. (e) Photoelectron spectroscopy is a technique for determining the energies of electrons in molecular orbitals.

In Chapter 9 we used the hydrogenic atomic orbitals and the building-up principle to deduce the ground electronic configurations of many-electron atoms. We now do the same for many-electron diatomic molecules by using the  $\text{H}_2^+$  molecular orbitals as a basis for their discussion. The general procedure is to construct molecular orbitals by combining the available atomic orbitals:

1. The electrons supplied by the atoms are accommodated in the orbitals so as to achieve the lowest overall energy subject to the constraint of the Pauli exclusion principle, that no more than two electrons may occupy a single orbital (and then must be paired).
2. If several degenerate molecular orbitals are available, electrons are added singly to each individual orbital before doubly occupying any one orbital (because that minimizes electron–electron repulsions).

Building-up  
principle for  
molecules

3. According to Hund's maximum multiplicity rule (Section 9.4d), if two electrons do occupy different degenerate orbitals, then a lower energy is obtained if they do so with parallel spins.

### (a) $\sigma$ Orbitals

Consider  $\text{H}_2$ , the simplest many-electron diatomic molecule. Each H atom contributes a  $1s$  orbital (as in  $\text{H}_2^+$ ), so we can form the  $1\sigma_g$  and  $1\sigma_u$  orbitals from them, as we have seen already. At the experimental internuclear separation these orbitals will have the energies shown in Fig. 10.24, which is called a **molecular orbital energy level diagram**. Note that from two atomic orbitals we can build two molecular orbitals. In general, from  $N$  atomic orbitals we can build  $N$  molecular orbitals.

There are two electrons to accommodate, and both can enter  $1\sigma_g$  by pairing their spins, as required by the Pauli principle (just as for atoms, Section 9.4b). The ground-state configuration is therefore  $1\sigma_g^2$  and the atoms are joined by a bond consisting of an electron pair in a bonding  $\sigma$  orbital. This approach shows that an electron pair, which was the focus of Lewis's account of chemical bonding, represents the maximum number of electrons that can enter a bonding molecular orbital.

The same argument explains why He does not form diatomic molecules. Each He atom contributes a  $1s$  orbital, so  $1\sigma_g$  and  $1\sigma_u$  molecular orbitals can be constructed. Although these orbitals differ in detail from those in  $\text{H}_2$ , their general shapes are the same and we can use the same qualitative energy level diagram in the discussion. There are four electrons to accommodate. Two can enter the  $1\sigma_g$  orbital, but then it is full, and the next two must enter the  $1\sigma_u$  orbital (Fig. 10.25). The ground electronic configuration of  $\text{He}_2$  is therefore  $1\sigma_g^2 1\sigma_u^2$ . We see that there is one bond and one antibond. Because  $1\sigma_u$  is raised in energy relative to the separate atoms more than  $1\sigma_g$  is lowered, an  $\text{He}_2$  molecule has a higher energy than the separated atoms, so it is unstable relative to them.

We shall now see how the concepts we have introduced apply to homonuclear diatomic molecules in general. In elementary treatments, only the orbitals of the valence shell are used to form molecular orbitals so, for molecules formed with atoms from Period 2 elements, only the  $2s$  and  $2p$  atomic orbitals are considered. We shall make that approximation here too.

A general principle of molecular orbital theory is that *all orbitals of the appropriate symmetry* contribute to a molecular orbital. Thus, to build  $\sigma$  orbitals, we form linear combinations of all atomic orbitals that have cylindrical symmetry about the internuclear axis. These orbitals include the  $2s$  orbitals on each atom and the  $2p_z$  orbitals on the two atoms (Fig. 10.26). The general form of the  $\sigma$  orbitals that may be formed is therefore

$$\psi = c_{A2s}\chi_{A2s} + c_{B2s}\chi_{B2s} + c_{A2p_z}\chi_{A2p_z} + c_{B2p_z}\chi_{B2p_z} \quad (10.16)$$

From these four atomic orbitals we can form four molecular orbitals of  $\sigma$  symmetry by an appropriate choice of the coefficients  $c$ .

The procedure for calculating the coefficients will be described in Section 10.6. At this stage we adopt a simpler route, and suppose that, because the  $2s$  and  $2p_z$  orbitals have distinctly different energies, they may be treated separately. That is, the four  $\sigma$  orbitals fall approximately into two sets, one consisting of two molecular orbitals of the form

$$\psi = c_{A2s}\chi_{A2s} + c_{B2s}\chi_{B2s} \quad (10.17a)$$

and another consisting of two orbitals of the form

$$\psi = c_{A2p_z}\chi_{A2p_z} + c_{B2p_z}\chi_{B2p_z} \quad (10.17b)$$

**Fig. 10.24** A molecular orbital energy level diagram for orbitals constructed from the overlap of  $1s$  orbitals; the separation of the levels corresponds to that found at the equilibrium bond length. The ground electronic configuration of  $\text{H}_2$  is obtained by accommodating the two electrons in the lowest available orbital (the bonding orbital).

**Fig. 10.25** The ground electronic configuration of the hypothetical four-electron molecule  $\text{He}_2$  has two bonding electrons and two antibonding electrons. It has a higher energy than the separated atoms, and so is unstable.

**Fig. 10.26** According to molecular orbital theory,  $\sigma$  orbitals are built from all orbitals that have the appropriate symmetry. In homonuclear diatomic molecules of Period 2, that means that two  $2s$  and two  $2p_z$  orbitals should be used. From these four orbitals, four molecular orbitals can be built.

**A brief comment**

We number only the molecular orbitals formed from atomic orbitals in the valence shell. In an alternative system of notation,  $1\sigma_g$  and  $1\sigma_u$  are used to designate the molecular orbitals formed from the core  $1s$  orbitals of the atoms; the orbitals we are considering would then be labelled starting from 2.

**Fig. 10.27** A representation of the composition of bonding and antibonding  $\sigma$  orbitals built from the overlap of  $p$  orbitals. These illustrations are schematic.

**Fig. 10.28** A schematic representation of the structure of  $\pi$  bonding and antibonding molecular orbitals. The figure also shows that the bonding  $\pi$  orbital has odd parity, whereas the antibonding  $\pi$  orbital has even parity.

Because atoms A and B are identical, the energies of their  $2s$  orbitals are the same, so the coefficients are equal (apart from a possible difference in sign); the same is true of the  $2p_z$  orbitals. Therefore, the two sets of orbitals have the form  $\chi_{A2s} \pm \chi_{B2s}$  and  $\chi_{A2p_z} \pm \chi_{B2p_z}$ .

The  $2s$  orbitals on the two atoms overlap to give a bonding and an antibonding  $\sigma$  orbital ( $1\sigma_g$  and  $1\sigma_u$ , respectively) in exactly the same way as we have already seen for  $1s$  orbitals. The two  $2p_z$  orbitals directed along the internuclear axis overlap strongly. They may interfere either constructively or destructively, and give a bonding or antibonding  $\sigma$  orbital (Fig. 10.27). These two  $\sigma$  orbitals are labelled  $2\sigma_g$  and  $2\sigma_u$ , respectively. In general, note how the numbering follows the order of increasing energy.

**(b)  $\pi$  Orbitals**

Now consider the  $2p_x$  and  $2p_y$  orbitals of each atom. These orbitals are perpendicular to the internuclear axis and may overlap broadside-on. This overlap may be constructive or destructive and results in a bonding or an antibonding  $\pi$  orbital (Fig. 10.28). The notation  $\pi$  is the analogue of  $p$  in atoms, for when viewed along the axis of the molecule, a  $\pi$  orbital looks like a  $p$  orbital and has one unit of orbital angular momentum around the internuclear axis. The two neighbouring  $2p_x$  orbitals overlap to give a bonding and antibonding  $\pi_x$  orbital, and the two  $2p_y$  orbitals overlap to give two  $\pi_y$  orbitals. The  $\pi_x$  and  $\pi_y$  bonding orbitals are degenerate; so too are their antibonding partners. We also see from Fig. 10.28 that a bonding  $\pi$  orbital has odd parity and is denoted  $\pi_u$  and an antibonding  $\pi$  orbital has even parity, denoted  $\pi_g$ .

**(c) The overlap integral**

The extent to which two atomic orbitals on different atoms overlap is measured by the overlap integral,  $S$ :

$$S = \int \chi_A^* \chi_B d\tau \quad \text{Definition of overlap integral} \quad [10.18]$$

We have already met this integral (in Example 10.1 and eqn 10.13). If the atomic orbital  $\chi_A$  on A is small wherever the orbital  $\chi_B$  on B is large, or vice versa, then the product of their amplitudes is everywhere small and the integral—the sum of these products—is small (Fig. 10.29). If  $\chi_A$  and  $\chi_B$  are both large in some region of space, then  $S$  may be large. If the two normalized atomic orbitals are identical (for instance,  $1s$  orbitals on the same nucleus), then  $S = 1$ . In some cases, simple formulas can be given for overlap integrals. For instance, the variation of  $S$  with internuclear separation for hydrogenic  $1s$  orbitals on atoms of atomic number  $Z$  is given by

$$S(1s, 1s) = \left\{ 1 + \frac{ZR}{a_0} + \frac{1}{3} \left( \frac{ZR}{a_0} \right)^2 \right\} e^{-ZR/a_0} \quad (10.19)$$

and is plotted in Fig. 10.30 (eqn 10.19 is a generalization of eqn 10.13a, which was for  $H1s$  orbitals). It follows that  $S = 0.59$  (an unusually large value) for two  $H1s$  orbitals at the equilibrium bond length in  $H_2^+$ . Typical values of  $S$  for orbitals with  $n = 2$  are in the range 0.2 to 0.3.

Now consider the arrangement in which an  $s$  orbital is superimposed on a  $p_x$  orbital of a different atom (Fig. 10.31). The integral over the region where the product of orbitals is positive exactly cancels the integral over the region where the product of orbitals is negative, so overall  $S = 0$  exactly. Therefore, there is no net overlap between the  $s$  and  $p$  orbitals in this arrangement.

**Fig. 10.29** (a) When two orbitals are on atoms that are far apart, the wavefunctions are small where they overlap, so  $S$  is small. (b) When the atoms are closer, both orbitals have significant amplitudes where they overlap, and  $S$  may approach 1. Note that  $S$  will decrease again as the two atoms approach more closely than shown here, because the region of negative amplitude of the p orbital starts to overlap the positive overlap of the s orbital. When the centres of the atoms coincide,  $S = 0$ .

**Fig. 10.30** The overlap integral,  $S$ , between two H1s orbitals as a function of their separation,  $R$ .

**Fig. 10.31** A p orbital in the orientation shown here has zero net overlap ( $S = 0$ ) with the s orbital at all internuclear separations.

#### (d) The electronic structures of homonuclear diatomic molecules

To construct the molecular orbital energy level diagram for Period 2 homonuclear diatomic molecules, we form eight molecular orbitals from the eight valence shell orbitals (four from each atom). In some cases,  $\pi$  orbitals are less strongly bonding than  $\sigma$  orbitals because their maximum overlap occurs off-axis. This relative weakness suggests that the molecular orbital energy level diagram ought to be as shown in Fig. 10.32. However, we must remember that we have assumed that  $2s$  and  $2p_z$  orbitals contribute to different sets of molecular orbitals, whereas in fact all four atomic orbitals have the same symmetry around the internuclear axis and contribute jointly to the four  $\sigma$  orbitals. Hence, there is no guarantee that this order of energies should prevail, and it is found experimentally (by spectroscopy) and by detailed calculation that the order varies along Period 2 (Fig. 10.33). The order shown in Fig. 10.34 is

**Fig. 10.32** The molecular orbital energy level diagram for homonuclear diatomic molecules. The lines in the middle are an indication of the energies of the molecular orbitals that can be formed by overlap of atomic orbitals. As remarked in the text, this diagram should be used for  $O_2$  (the configuration shown) and  $F_2$ .

**Fig. 10.33** The variation of the orbital energies as calculated for Period 2 homonuclear diatomics.

**Fig. 10.34** An alternative molecular orbital energy level diagram for homonuclear diatomic molecules. As remarked in the text, this diagram should be used for diatomics up to and including  $N_2$  (the configuration shown).

#### A brief comment

Bond dissociation energies are commonly used in thermodynamic cycles, where bond enthalpies,  $\Delta_{\text{bond}}H^\circ$ , should be used instead. It follows from the same kind of argument used in *Justification 9.7* concerning ionization enthalpies that

To derive this relation, we have supposed that the molar constant-pressure heat capacity of  $X_2$  is  $\frac{7}{2}R$  (Section 2.4 and eqn 2.26), for there is a contribution from two rotational modes as well as three translational modes.

appropriate as far as  $N_2$ , and Fig. 10.32 is appropriate for  $O_2$  and  $F_2$ . The relative order is controlled by the separation of the 2s and 2p orbitals in the atoms, which increases across the group. The consequent switch in order occurs at about  $N_2$ .

With the molecular orbital energy level diagram established, we can deduce the probable ground configurations of the molecules by adding the appropriate number of electrons to the orbitals and following the building-up rules. Anionic species (such as the peroxide ion,  $O_2^{2-}$ ) need more electrons than the parent neutral molecules; cationic species (such as  $O_2^+$ ) need fewer.

Consider  $N_2$ , which has 10 valence electrons. Two electrons pair, occupy, and fill the  $1\sigma_g$  orbital; the next two occupy and fill the  $1\sigma_u$  orbital. Six electrons remain. There are two  $1\pi_u$  orbitals, so four electrons can be accommodated in them. The last two enter the  $2\sigma_g$  orbital. Therefore, the ground-state configuration of  $N_2$  is  $1\sigma_g^2 1\sigma_u^2 1\pi_u^4 2\sigma_g^2$ . It is sometimes helpful to include an asterisk to denote an antibonding orbital, in which case this configuration would be denoted  $1\sigma_g^2 1\sigma_u^{*2} 1\pi_u^4 2\sigma_g^2$ .

A measure of the net bonding in a diatomic molecule is its **bond order**,  $b$ :

$$b = \frac{1}{2}(N - N^*)$$

Definition of  
bond order

[10.20]

where  $N$  is the number of electrons in bonding orbitals and  $N^*$  is the number of electrons in antibonding orbitals. Thus, each electron pair in a bonding orbital increases the bond order by 1 and each pair in an antibonding orbital decreases  $b$  by 1. For  $H_2$ ,  $b = 1$ , corresponding to a single bond,  $H-H$ , between the two atoms. In  $He_2$ ,  $b = 0$ , and there is no bond. In  $N_2$ ,  $b = \frac{1}{2}(8 - 2) = 3$ . This bond order accords with the Lewis structure of the molecule ( $:N \equiv N:$ ).

The ground-state electron configuration of  $O_2$ , with 12 valence electrons, is based on Fig. 10.32, and is  $1\sigma_g^2 1\sigma_u^2 2\sigma_g^2 1\pi_u^4 1\pi_g^2$  (or  $1\sigma_g^2 1\sigma_u^{*2} 2\sigma_g^2 1\pi_u^4 1\pi_g^{*2}$ ). Its bond order is 2. According to the building-up principle, however, the two  $1\pi_g$  electrons occupy different orbitals: one will enter  $1\pi_{g,x}$  and the other will enter  $1\pi_{g,y}$ . Because the electrons are in different orbitals, they will have parallel spins. Therefore, we can predict that an  $O_2$  molecule will have a net spin angular momentum  $S = 1$  and, in the language introduced in Section 9.8, be in a triplet state. As electron spin is the source of a magnetic moment, we can go on to predict that oxygen should be paramagnetic, a substance that tends to move into a magnetic field (see Chapter 19). This prediction, which VB theory does not make, is confirmed by experiment.

An  $F_2$  molecule has two more electrons than an  $O_2$  molecule. Its configuration is therefore  $1\sigma_g^2 1\sigma_u^{*2} 2\sigma_g^2 1\pi_u^4 1\pi_g^{*4}$  and  $b = 1$ . We conclude that  $F_2$  is a singly bonded molecule, in agreement with its Lewis structure. The hypothetical molecule dineon,  $Ne_2$ , has two additional electrons: its configuration is  $1\sigma_g^2 1\sigma_u^{*2} 2\sigma_g^2 1\pi_u^4 1\pi_g^{*4} 2\sigma_u^{*2}$  and  $b = 0$ . The zero bond order is consistent with the monatomic nature of Ne.

The bond order is a useful parameter for discussing the characteristics of bonds, because it correlates with bond length and bond strength. For bonds between atoms of a given pair of elements:

- The greater the bond order, the shorter the bond.
- The greater the bond order, the greater the bond strength.

Table 10.2 lists some typical bond lengths in diatomic and polyatomic molecules. The strength of a bond is measured by its bond dissociation energy,  $D_0$ , the energy required to separate the atoms to infinity or by the well depth  $D_e$ , with  $D_0 = D_e - \frac{1}{2}\hbar\omega$  (see the first *brief comment* in this chapter;  $\omega = 2\pi\nu$ ). Table 10.3 lists some experimental values of  $D_0$ .

**Example 10.2** Judging the relative bond strengths of molecules and ions

Predict whether  $\text{N}_2^+$  is likely to have a larger or smaller dissociation energy than  $\text{N}_2$ .

**Method** Because the molecule with the higher bond order is likely to have the higher dissociation energy, compare their electronic configurations and assess their bond orders.

**Answer** From Fig. 10.34, the electron configurations and bond orders are

$$\text{N}_2 \quad 1\sigma_g^2 1\sigma_u^{*2} 1\pi_u^4 2\sigma_g^2 \quad b = 3$$

$$\text{N}_2^+ \quad 1\sigma_g^2 1\sigma_u^{*2} 1\pi_u^4 2\sigma_g^1 \quad b = 2\frac{1}{2}$$

Because the cation has the smaller bond order, we expect it to have the smaller dissociation energy. The experimental dissociation energies are  $945 \text{ kJ mol}^{-1}$  for  $\text{N}_2$  and  $842 \text{ kJ mol}^{-1}$  for  $\text{N}_2^+$ .

**Self-test 10.4** Which can be expected to have the higher dissociation energy,  $\text{F}_2$  or  $\text{F}_2^+$ ?

**(e) Photoelectron spectroscopy**

So far we have treated molecular orbitals as purely theoretical constructs, but is there experimental evidence for their existence? **Photoelectron spectroscopy** (PES) measures the ionization energies of molecules when electrons are ejected from different orbitals by absorption of a photon of known energy, and uses the information to infer the energies of molecular orbitals. The technique is also used to study solids, and in Chapter 22 we shall see the important information that it gives about species at or on surfaces.

Because energy is conserved when a photon ionizes a sample, the sum of the ionization energy,  $I$ , of the sample and the kinetic energy of the **photoelectron**, the ejected electron, must be equal to the energy of the incident photon  $h\nu$  (Fig. 10.35):

$$h\nu = \frac{1}{2}m_e v^2 + I \quad (10.21a)$$

This equation (which is like the one used for the photoelectric effect, eqn 7.15) can be refined in two ways. First, photoelectrons may originate from one of a number of different orbitals, and each one has a different ionization energy. Hence, a series of different kinetic energies of the photoelectrons will be obtained, each one satisfying

$$h\nu = \frac{1}{2}m_e v^2 + I_i \quad (10.21b)$$

where  $I_i$  is the ionization energy for ejection of an electron from an orbital  $i$ . Therefore, by measuring the kinetic energies of the photoelectrons, and knowing  $v$ , these ionization energies can be determined. Photoelectron spectra are interpreted in terms of an approximation called **Koopmans' theorem**, which states that the ionization energy  $I_i$  is equal to the orbital energy of the ejected electron (formally:  $I_i = -\epsilon_i$ ). That is, we can identify the ionization energy with the energy of the orbital from which it is ejected. The theorem is only an approximation because it ignores the fact that the remaining electrons adjust their distributions when ionization occurs.

The ionization energies of molecules are several electronvolts even for valence electrons, so it is essential to work in at least the ultraviolet region of the spectrum and with wavelengths of less than about 200 nm. Much work has been done with radiation generated by a discharge through helium: the  $\text{He(I)}$  line ( $1s^1 2p^1 \rightarrow 1s^2$ ) lies at 58.43 nm, corresponding to a photon energy of 21.22 eV. Its use gives rise to the technique of **ultraviolet photoelectron spectroscopy** (UPS). When core electrons are being studied,

**Table 10.2\*** Bond lengths

| Bond | Order | $R_e/\text{pm}$ |

**Fig. 10.35** An incoming photon carries an energy  $h\nu$ ; an energy  $I_i$  is needed to remove an electron from an orbital  $i$ , and the difference appears as the kinetic energy of the electron.

**Fig. 10.36** A photoelectron spectrometer consists of a source of ionizing radiation (such as a helium discharge lamp for UPS and an X-ray source for XPS), an electrostatic analyser, and an electron detector. The deflection of the electron path caused by the analyser depends on their speed.

**Fig. 10.37** The UV photoelectron spectrum of  $N_2$ .

photons of even higher energy are needed to expel them: X-rays are used, and the technique is denoted XPS.

The kinetic energies of the photoelectrons are measured using an electrostatic deflector that produces different deflections in the paths of the photoelectrons as they pass between charged plates (Fig. 10.36). As the field strength is increased, electrons of different speeds, and therefore kinetic energies, reach the detector. The electron flux can be recorded and plotted against kinetic energy to obtain the photoelectron spectrum.

#### • A brief illustration

Photoelectrons ejected from  $N_2$  with He(I) radiation have kinetic energies of 5.63 eV ( $1 \text{ eV} = 8065.5 \text{ cm}^{-1}$ , Fig. 10.37). Helium(I) radiation of wavelength 58.43 nm has wavenumber  $1.711 \times 10^5 \text{ cm}^{-1}$  and therefore corresponds to an energy of 21.22 eV. Then, from eqn 10.21,  $21.22 \text{ eV} = 5.63 \text{ eV} + I_i$ , so  $I_i = 15.59 \text{ eV}$ . This ionization energy is the energy needed to remove an electron from the occupied molecular orbital with the highest energy of the  $N_2$  molecule, the  $2\sigma_g$  bonding orbital. •

**Self-test 10.5** Under the same circumstances, photoelectrons are also detected at 4.53 eV. To what ionization energy does that correspond? Suggest an origin.

[16.7 eV,  $1\pi_u$ ]

It is often observed that photoejection results in cations that are excited vibrationally. Because different energies are needed to excite different vibrational states of the ion, the photoelectrons appear with different kinetic energies. The result is **vibrational fine structure**, a progression of lines with a frequency spacing that corresponds to the vibrational frequency of the molecule. Figure 10.38 shows an example of vibrational fine structure in the photoelectron spectrum of  $Br_2$ .

## 10.5 Heteronuclear diatomic molecules

**Key points** (a) A polar bond can be regarded as arising from a molecular orbital that is concentrated more on one atom than its partner. (b) The electronegativity of an element is a measure of the power of an atom to attract electrons to itself when it is part of a compound. (c) The variation principle provides a criterion of acceptability of an approximate wavefunction.

The electron distribution in a covalent bond in a heteronuclear diatomic molecule is not shared equally by the atoms because it is energetically favourable for the electron pair to be found closer to one atom than the other. This imbalance results in a **polar bond**, a covalent bond in which the electron pair is shared unequally by the two atoms. The bond in HF, for instance, is polar, with the electron pair closer to the F atom. The accumulation of the electron pair near the F atom results in that atom having a net negative charge, which is called a **partial negative charge** and denoted  $\delta^-$ . There is a matching **partial positive charge**,  $\delta^+$ , on the H atom.

### (a) Polar bonds

A polar bond consists of two electrons in a bonding molecular orbital of the form

$$\psi = c_A A + c_B B$$

Form of wavefunction  
of a polar bond

(10.22)

with unequal coefficients. The proportion of the atomic orbital  $A$  in the bond is  $|c_A|^2$  and that of  $B$  is  $|c_B|^2$ . A nonpolar bond has  $|c_A|^2 = |c_B|^2$  and a pure ionic bond has one coefficient zero (so the species  $A^+B^-$  would have  $c_A = 0$  and  $c_B = 1$ ). The atomic orbital

with the lower energy makes the larger contribution to the bonding molecular orbital. The opposite is true of the antibonding orbital, for which the dominant component comes from the atomic orbital with higher energy.

These points can be illustrated by considering HF, and judging the energies of the atomic orbitals from the ionization energies of the atoms. The general form of the molecular orbitals is

$$\psi = c_H \chi_H + c_F \chi_F \quad (10.23)$$

where  $\chi_H$  is an H1s orbital and  $\chi_F$  is an F2p<sub>z</sub> orbital (with *z* along the internuclear axis, the convention for linear molecules). The H1s orbital lies 13.6 eV below the zero of energy (the separated proton and electron) and the F2p<sub>z</sub> orbital lies at 17.4 eV (Fig. 10.39). Hence, the bonding  $\sigma$  orbital in HF is mainly F2p<sub>z</sub> and the antibonding  $\sigma$  orbital is mainly H1s orbital in character. The two electrons in the bonding orbital are most likely to be found in the F2p<sub>z</sub> orbital, so there is a partial negative charge on the F atom and a partial positive charge on the H atom.

### (b) Electronegativity

The charge distribution in bonds is commonly discussed in terms of the **electronegativity**,  $\chi$  (chi), of the elements involved (there should be little danger of confusing this use of  $\chi$  with its use to denote an atomic orbital, which is another common convention). The electronegativity is a parameter introduced by Linus Pauling as a measure of the power of an atom to attract electrons to itself when it is part of a compound. Pauling used valence-bond arguments to suggest that an appropriate numerical scale of electronegativities could be defined in terms of bond dissociation energies,  $D_0$ , and proposed that the difference in electronegativities could be expressed as

$$|\chi_A - \chi_B| = \{D_0(AB) - \frac{1}{2}[D_0(AA) + D_0(BB)]\}^{1/2} \quad \text{Definition of Pauling electronegativity} \quad [10.24]$$

where  $D_0(AA)$  and  $D_0(BB)$  are the dissociation energies of A–A and B–B bonds and  $D_0(AB)$  is the dissociation energy of an A–B bond, all in electronvolts. (In later work Pauling used the geometrical mean of dissociation energies in place of the arithmetic mean.) This expression gives differences of electronegativities; to establish an absolute scale Pauling chose individual values that gave the best match to the values obtained from eqn 10.24. Electronegativities based on this definition are called **Pauling electronegativities** (Table 10.4). The most electronegative elements are those close to F (excluding the noble gases); the least are those close to Cs. It is found that the greater the difference in electronegativities, the greater the polar character of the bond. The difference for HF, for instance, is 1.78; a C–H bond, which is commonly regarded as almost nonpolar, has an electronegativity difference of 0.35.

The spectroscopist Robert Mulliken proposed an alternative definition of electronegativity. He argued that an element is likely to be highly electronegative if it has a high ionization energy (so it will not release electrons readily) and a high electron affinity (so it is energetically favorable to acquire electrons). The **Mulliken electronegativity scale** is therefore based on the definition

$$\chi_M = \frac{1}{2}(I + E_{\text{ea}}) \quad \text{Definition of Mulliken electronegativity} \quad [10.25]$$

where  $I$  is the ionization energy of the element and  $E_{\text{ea}}$  is its electron affinity (both in electronvolts). The Mulliken and Pauling scales are approximately in line with each other. A reasonably reliable conversion between the two is

$$\chi_P = 1.35\chi_M^{1/2} - 1.37 \quad (10.26)$$

Fig. 10.38 The UV photoelectron spectrum of Br<sub>2</sub>.

Fig. 10.39 The molecular orbital energy level diagram for HF showing the energy levels calculated for the basis H1s and F2p<sub>z</sub>. The energies are shown relative to the ionization limit.

Table 10.4\* Pauling electronegativities

| Element | $\chi_P$ |
|---------|----------|
| H       | 2.2      |
| C       | 2.6      |
| N       | 3.0      |
| O       | 3.4      |
| F       | 4.0      |
| Cl      | 3.2      |
| Cs      | 0.79     |

\* More values will be found in the Data section.

**(c) The variation principle**

A more systematic way of discussing bond polarity and finding the coefficients in the linear combinations used to build molecular orbitals is provided by the **variation principle**:

If an arbitrary wavefunction is used to calculate the energy,  
the value calculated is never less than the true energy.

 Variation  
principle

This principle is the basis of all modern molecular structure calculations (Section 10.7). The arbitrary wavefunction is called the **trial wavefunction**. The principle implies that, if we vary the coefficients in the trial wavefunction until the lowest energy is achieved (by evaluating the expectation value of the hamiltonian for each wavefunction), then those coefficients will be the best. We might get a lower energy if we use a more complicated wavefunction (for example, by taking a linear combination of several atomic orbitals on each atom), but we shall have the optimum (minimum energy) molecular orbital that can be built from the chosen **basis set**, the given set of atomic orbitals.

The method can be illustrated by the trial wavefunction in eqn 10.23. We show in the following *Justification* that the coefficients are given by the solutions of the two secular equations

$$(\alpha_A - E)c_A + (\beta - ES)c_B = 0 \quad (10.27a)$$

$$(\beta - ES)c_A + (\alpha_B - E)c_B = 0 \quad (10.27b)$$

The parameter  $\alpha$  is called a **Coulomb integral**. It is negative and can be interpreted as the energy of the electron when it occupies  $A$  (for  $\alpha_A$ ) or  $B$  (for  $\alpha_B$ ). In a homonuclear diatomic molecule,  $\alpha_A = \alpha_B$ . The parameter  $\beta$  is called a **resonance integral** (for classical reasons). It vanishes when the orbitals do not overlap, and at equilibrium bond lengths it is normally negative.

**A brief comment**

The name 'secular' is derived from the Latin word for age or generation. The term comes from astronomy, where the same equations appear in connection with slowly accumulating modifications of planetary orbits.

**Justification 10.3** *The variation principle applied to a heteronuclear diatomic molecule*

The trial wavefunction in eqn 10.23 is real but not normalized because at this stage the coefficients can take arbitrary values. Therefore, we can write  $\psi^* = \psi$  but do not assume that  $\int \psi^2 d\tau = 1$ . When a wavefunction is not normalized, we replace the expression

$$\langle \hat{\Omega} \rangle = \int \psi^* \hat{\Omega} \psi d\tau$$

by

$$\langle \hat{\Omega} \rangle = \frac{\int (N\psi^* \hat{\Omega} N\psi) d\tau}{\int \psi^* \psi d\tau} = \frac{\int \psi^* \hat{\Omega} \psi d\tau}{\int \psi^* \psi d\tau}$$

(For the second equality, we have used eqn 7.19 for each  $N$ .) In this case, the energy of the trial wavefunction is the expectation value of the energy operator (the hamiltonian,  $\hat{H}$ ) and we write:

$$E = \frac{\int \psi^* \hat{H} \psi d\tau}{\int \psi^* \psi d\tau} \quad (10.28)$$

We now search for values of the coefficients in the trial function that minimize the value of  $E$ . This is a standard problem in calculus, and is solved by finding the coefficients for which

$$\frac{\partial E}{\partial c_A} = 0 \quad \frac{\partial E}{\partial c_B} = 0$$

The first step is to express the two integrals in eqn 10.28 in terms of the coefficients. The denominator is

$$\begin{aligned} \int \psi^2 d\tau &= \int (c_A A + c_B B)^2 d\tau = c_A^2 \int A^2 d\tau + c_B^2 \int B^2 d\tau + 2c_A c_B \int AB d\tau \\ &= c_A^2 + c_B^2 + 2c_A c_B S \end{aligned}$$

because the individual atomic orbitals are normalized and the third integral is the overlap integral  $S$  (eqn 10.18). The numerator is

$$\begin{aligned} \int \psi \hat{H} \psi d\tau &= \int (c_A A + c_B B) \hat{H} (c_A A + c_B B) d\tau \\ &= c_A^2 \int A \hat{H} A d\tau + c_B^2 \int B \hat{H} B d\tau + c_A c_B \int A \hat{H} B d\tau + c_A c_B \int B \hat{H} A d\tau \end{aligned}$$

There are some complicated integrals in this expression, but we can combine them all into the parameters

$$\alpha_A = \int A \hat{H} A d\tau \quad \alpha_B = \int B \hat{H} B d\tau \quad [10.29]$$

$$\beta = \int A \hat{H} B d\tau = \int B \hat{H} A d\tau \text{ (by the hermiticity of } \hat{H} \text{)}$$

Then

$$\int \psi \hat{H} \psi d\tau = c_A^2 \alpha_A + c_B^2 \alpha_B + 2c_A c_B \beta$$

The complete expression for  $E$  is

$$E = \frac{c_A^2 \alpha_A + c_B^2 \alpha_B + 2c_A c_B \beta}{c_A^2 + c_B^2 + 2c_A c_B S} \quad (10.30)$$

Its minimum is found by differentiation with respect to the two coefficients and setting the results equal to 0. After some straightforward work we obtain

$$\begin{aligned} \frac{\partial E}{\partial c_A} &= \frac{2 \times (c_A \alpha_A - c_A E + c_B \beta - c_B S E)}{c_A^2 + c_B^2 + 2c_A c_B S} \\ \frac{\partial E}{\partial c_B} &= \frac{2 \times (c_B \alpha_B - c_B E + c_A \beta - c_A S E)}{c_A^2 + c_B^2 + 2c_A c_B S} \end{aligned}$$

For the derivatives to be equal to 0, the numerators of these expressions must vanish. That is, we must find values of  $c_A$  and  $c_B$  that satisfy the conditions

$$\begin{aligned} c_A \alpha_A - c_A E + c_B \beta - c_B S E &= (\alpha_A - E) c_A + (\beta - ES) c_B = 0 \\ c_A \beta - c_A S E + c_B \alpha_B - c_B E &= (\beta - ES) c_A + (\alpha_B - E) c_B = 0 \end{aligned}$$

which are the secular equations (eqn 10.27).

To solve the secular equations for the coefficients we need to know the energy  $E$  of the orbital. As for any set of simultaneous equations, the secular equations have a solution if the **secular determinant**, the determinant of the coefficients, is zero; that is, if

$$\begin{vmatrix} \alpha_A - E & \beta - ES \\ \beta - ES & \alpha_B - E \end{vmatrix} = (\alpha_A - E)(\alpha_B - E) - (\beta - ES)^2 = 0 \quad (10.31)$$

This quadratic equation, which expands to

$$(1 - S^2)E^2 + \{2\beta S - (\alpha_A + \alpha_B)\}E + (\alpha_A\alpha_B - \beta^2) = 0$$

has two roots that give the energies of the bonding and antibonding molecular orbitals formed from the atomic orbitals:

$$E_{\pm} = \frac{\alpha_A + \alpha_B - 2\beta S \pm \{(\alpha_A + \alpha_B - 2\beta S)^2 - 4(1 - S^2)(\alpha_A\alpha_B - \beta^2)\}^{1/2}}{2(1 - S^2)} \quad (10.32a)$$

This expression becomes more transparent in two cases. For a *homonuclear diatomic molecule* we can set  $\alpha_A = \alpha_B = \alpha$  and obtain

$$E_+ = \frac{\alpha + \beta}{1 + S} \quad E_- = \frac{\alpha - \beta}{1 - S} \quad \text{Homonuclear diatomic molecules} \quad (10.32b)$$

For  $\beta < 0$ ,  $E_+$  is the lower energy solution. For *heteronuclear diatomic molecules* we can make the approximation that  $S = 0$  (simply to get a more transparent expression), and find

$$E_{\pm} = \frac{1}{2}(\alpha_A + \alpha_B) \pm \frac{1}{2}(\alpha_A - \alpha_B) \left\{ 1 + \left( \frac{2\beta}{\alpha_A - \alpha_B} \right)^2 \right\}^{1/2} \quad \text{Zero overlap approximation} \quad (10.32c)$$

#### • A brief illustration

The ionization energies of H1s and F2p electrons are 13.6 eV and 17.4 eV, respectively. Therefore, to calculate the energies of the bonding and antibonding orbitals in HF (using H1s and F2p<sub>z</sub> orbitals as a basis) we set  $\alpha_H = -13.6$  eV and  $\alpha_F = -17.4$  eV. We take  $\beta = -1.0$  eV as a typical value and  $S = 0$ . Substituting these values into eqn 10.32c gives  $E_+ = -17.6$  eV and  $E_- = -13.4$  eV (as shown in Fig. 10.39). Had we used  $S = 0.2$  (another typical value), then eqn 10.32a would have given  $E_+ = -18.9$  eV and  $E_- = -13.0$  eV. •

**Fig. 10.40** The variation of the energies of molecular orbitals with the energy separation of the contributing atomic orbitals.

**Self-test 10.6** The ionization energy of Cl is 13.1 eV; find the energies of the  $\sigma$  orbitals in the HCl molecule using  $\beta = -1.0$  eV and  $S = 0$ .

[ $E_- = -12.3$  eV,  $E_+ = -14.4$  eV]

An important feature of eqn 10.32c is that as the energy difference  $|\alpha_A - \alpha_B|$  between the interacting atomic orbitals increases, the bonding and antibonding effects decrease (Fig. 10.40). Thus, when  $|\alpha_B - \alpha_A| \gg 2|\beta|$  we can make the approximation  $(1 + x)^{1/2} \approx 1 + \frac{1}{2}x$  and obtain

$$E_+ \approx \alpha_A + \frac{\beta^2}{\alpha_A - \alpha_B} \quad E_- \approx \alpha_B - \frac{\beta^2}{\alpha_A - \alpha_B} \quad (10.33)$$

As these expressions show, and as can be seen from the graph, when the energy difference is very large, the energies of the resulting molecular orbitals differ only slightly from those of the atomic orbitals, which implies in turn that the bonding and antibonding effects are small. That is:

The strongest bonding and antibonding effects are obtained when the two contributing orbitals have closely similar energies.

Orbital  
contribution  
criterion

The difference in energy between core and valence orbitals is the justification for neglecting the contribution of core orbitals to bonding. The core orbitals of one atom have a similar energy to the core orbitals of the other atom; but core–core interaction is largely negligible because the overlap between them (and hence the value of  $\beta$ ) is so small.

The values of the coefficients in the linear combination in eqn 10.22 are obtained by solving the secular equations using the two energies obtained from the secular determinant. The lower energy,  $E_+$ , gives the coefficients for the bonding molecular orbital, the upper energy,  $E_-$ , the coefficients for the antibonding molecular orbital. The secular equations give expressions for the ratio of the coefficients. Thus, the first of the two secular equations in eqn 10.27a,  $(\alpha_A - E)c_A + (\beta - ES)c_B = 0$ , gives

$$c_B = -\left(\frac{\alpha_A - E}{\beta - ES}\right)c_A \quad (10.34)$$

The wavefunction should also be normalized. This condition means that we must also ensure that

$$\begin{aligned} \int \psi^2 d\tau &= \int (c_A A + c_B B)^2 d\tau = c_A^2 \int A^2 d\tau + c_B^2 \int B^2 d\tau + 2c_A c_B \int AB d\tau \\ &= c_A^2 + c_B^2 + 2c_A c_B S = 1 \end{aligned} \quad (10.35)$$

When the preceding relation is substituted into this expression, we find

$$c_A = \frac{1}{\left\{1 + \left(\frac{\alpha_A - E}{\beta - ES}\right)^2 - 2S\left(\frac{\alpha_A - E}{\beta - ES}\right)\right\}^{1/2}} \quad (10.36)$$

which, together with eqn 10.32a, gives explicit expressions for the coefficients once we substitute the appropriate values of  $E = E_{\pm}$  found previously. As before, this expression becomes more transparent in two cases. First, for a homonuclear diatomic molecule, with  $\alpha_A = \alpha_B = \alpha$  and  $E_{\pm}$  given in eqn 10.32b we find

$$E_+ = \frac{\alpha + \beta}{1 + S} \quad c_A = \frac{1}{\{2(1 + S)\}^{1/2}} \quad c_B = c_A \quad \text{Homonuclear diatomic molecule} \quad (10.37a)$$

$$E_- = \frac{\alpha - \beta}{1 - S} \quad c_A = \frac{1}{\{2(1 - S)\}^{1/2}} \quad c_B = -c_A \quad (10.37b)$$

For a heteronuclear diatomic molecule with  $S = 0$ , the coefficients are given by

$$c_A = \frac{1}{\left\{1 + \left(\frac{\alpha_A - E}{\beta}\right)^2\right\}^{1/2}} \quad c_B = -\left(\frac{\alpha_A - E}{\beta}\right)c_A \quad \text{Zero overlap approximation} \quad (10.38)$$

with the appropriate values of  $E = E_{\pm}$  taken from eqn 10.32c.

### • A brief illustration

Here we continue the previous *brief illustration* using HF. With  $\alpha_{\text{H}} = -13.6$  eV,  $\alpha_{\text{F}} = -17.4$  eV,  $\beta = -1.0$  eV, and  $S = 0$  the two orbital energies were found to be  $E_+ = -17.6$  eV and  $E_- = -13.4$  eV. When these values are substituted into eqn 10.37 we find the following coefficients:

$$\begin{aligned} E_- &= -13.4 \text{ eV} & \psi_- &= 0.97\chi_{\text{H}} - 0.24\chi_{\text{F}} \\ E_+ &= -17.6 \text{ eV} & \psi_+ &= 0.24\chi_{\text{H}} + 0.97\chi_{\text{F}} \end{aligned}$$

Notice how the lower energy orbital (the one with energy  $-17.6$  eV) has a composition that is more F2p orbital than H1s, and that the opposite is true of the higher energy, antibonding orbital. Had we taken  $S = 0.2$ , then we would have found

$$\begin{aligned} E_- &= -13.0 \text{ eV} & \psi_- &= 0.88\chi_{\text{H}} + 0.32\chi_{\text{F}} \\ E_+ &= -18.9 \text{ eV} & \psi_+ &= 0.51\chi_{\text{H}} - 0.97\chi_{\text{F}} \end{aligned}$$

It is no longer possible to interpret the coefficients as occupation probabilities of individual atomic orbitals or even their relative signs because now the basis orbitals are not orthogonal. •

**Self-test 10.7** The ionization energy of Cl is 13.1 eV; find the form of the  $\sigma$  orbitals in the HCl molecule using  $\beta = -1.0$  eV and  $S = 0$ .

$$[\psi_- = -0.62\chi_{\text{H}} + 0.79\chi_{\text{Cl}}; \psi_+ = 0.79\chi_{\text{H}} + 0.62\chi_{\text{Cl}}]$$

### IMPACT ON BIOCHEMISTRY

#### I10.1 The biochemical reactivity of O<sub>2</sub>, N<sub>2</sub>, and NO

We can now see how some of these concepts are applied to diatomic molecules that play a vital biochemical role. At sea level, air contains approximately 23.1 per cent O<sub>2</sub> and 75.5 per cent N<sub>2</sub> by mass. Molecular orbital theory predicts correctly that O<sub>2</sub> has unpaired electron spins. It is a reactive component of the Earth's atmosphere; its most important biological role is as an oxidizing agent. By contrast N<sub>2</sub>, the major component of the air we breathe, is so stable (on account of the triple bond connecting the atoms) and unreactive that *nitrogen fixation*, the reduction of atmospheric N<sub>2</sub> to NH<sub>3</sub>, is among the most thermodynamically demanding of biochemical reactions, in the sense that it requires a great deal of energy derived from metabolism. So taxing is the process that only certain bacteria and archaea are capable of carrying it out, making nitrogen available first to plants and other micro-organisms in the form of ammonia. Only after incorporation into amino acids by plants does nitrogen adopt a chemical form that, when consumed, can be used by animals in the synthesis of proteins and other molecules that contain nitrogen.

The reactivity of O<sub>2</sub>, while important for biological energy conversion, also poses serious physiological problems. During the course of metabolism, some electrons reduce O<sub>2</sub> to superoxide ion, O<sub>2</sub><sup>•−</sup>, which must be scavenged to prevent damage to cellular components. There is growing evidence for the involvement of the damage caused by reactive oxygen species (ROS), such as O<sub>2</sub><sup>•−</sup>, H<sub>2</sub>O<sub>2</sub>, and •OH (the hydroxyl radical), in the mechanism of ageing and in the development of cardiovascular disease, cancer, stroke, inflammatory disease, and other conditions. For this reason, much effort has been expended on studies of the biochemistry of *antioxidants*, substances that can either deactivate ROS directly or halt the progress of cellular damage through reactions with radicals formed by processes initiated by ROS. Important

examples of antioxidants are vitamin C (ascorbic acid), vitamin E ( $\alpha$ -tocopherol), and uric acid.

Nitric oxide (nitrogen monoxide, NO) is a small molecule that diffuses quickly between cells, carrying chemical messages that help initiate a variety of processes, such as regulation of blood pressure, inhibition of platelet aggregation, and defence against inflammation and attacks to the immune system. Figure 10.41 shows the bonding scheme in NO and illustrates a number of points we have made about heteronuclear diatomic molecules. The ground configuration is  $1\sigma^2 2\sigma^2 3\sigma^2 1\pi^4 2\pi^1$ . The  $3\sigma$  and  $1\pi$  orbitals are predominantly of O character as that is the more electronegative element. The highest-energy occupied orbital is  $2\pi$ ; it is occupied by one electron and has more N character than O character. It follows that NO is a radical with an unpaired electron that can be regarded as localized more on the N atom than on the O atom. The lowest-energy unoccupied orbital is  $4\sigma$ , which is also localized predominantly on N. Because NO is a radical, we expect it to be reactive. Its half-life is estimated as 1–5 s, so it needs to be synthesized often in the cell. As we saw above, there is a biochemical price to be paid for the reactivity of biological radicals.

Fig. 10.41 The molecular orbital energy level diagram for NO.

## Molecular orbitals for polyatomic systems

The molecular orbitals of polyatomic molecules are built in the same way as in diatomic molecules, the only difference being that we use more atomic orbitals to construct them. As for diatomic molecules, polyatomic molecular orbitals spread over the entire molecule. A molecular orbital has the general form

$$\psi = \sum_o c_o \chi_o \quad \text{General form of LCAO} \quad (10.39)$$

where  $\chi_o$  is an atomic orbital and the sum extends over all the valence orbitals of all the atoms in the molecule. To find the coefficients, we set up the secular equations and the secular determinant, just as for diatomic molecules, solve the latter for the energies, and then use these energies in the secular equations to find the coefficients of the atomic orbitals for each molecular orbital.

The principal difference between diatomic and polyatomic molecules lies in the greater range of shapes that are possible: a diatomic molecule is necessarily linear, but a triatomic molecule, for instance, may be either linear or angular (bent) with a characteristic bond angle. The shape of a polyatomic molecule—the specification of its bond lengths and its bond angles—can be predicted by calculating the total energy of the molecule for a variety of nuclear positions, and then identifying the conformation that corresponds to the lowest energy.

### 10.6 The Hückel approximation

**Key points** (a) The Hückel method neglects overlap and interactions between atoms that are not neighbours. (b) It may be expressed in a compact manner by introducing matrices. (c) The strength of  $\pi$  bonding in conjugated systems is expressed by the  $\pi$ -binding energy, the delocalization energy, and the  $\pi$ -bond formation energy. (d) The stability of benzene arises from the geometry of the ring and the high delocalization energy.

Molecular orbital theory takes large molecules and extended aggregates of atoms, such as solid materials, in its stride. First we consider conjugated molecules, in which there is an alternation of single and double bonds along a chain of carbon atoms.

Although the classification of an orbital as  $\sigma$  or  $\pi$  is strictly valid only in linear molecules, as will be familiar from introductory chemistry courses, it is also used to denote the local symmetry with respect to a given A–B bond axis.

The  $\pi$  molecular orbital energy level diagrams of conjugated molecules can be constructed using a set of approximations suggested by Erich Hückel in 1931. In his approach, the  $\pi$  orbitals are treated separately from the  $\sigma$  orbitals, and the latter form a rigid framework that determines the general shape of the molecule. All the C atoms are treated identically, so all the Coulomb integrals  $\alpha$  for the atomic orbitals that contribute to the  $\pi$  orbitals are set equal. For example, in ethene, we take the  $\sigma$  bonds as fixed, and concentrate on finding the energies of the single  $\pi$  bond and its companion antibond.

### (a) Ethene and frontier orbitals

We express the  $\pi$  orbitals as LCAOs of the C2p orbitals that lie perpendicular to the molecular plane. In ethene, for instance, we would write

$$\psi = c_A A + c_B B \quad (10.40)$$

where the  $A$  is a C2p orbital on atom A, and so on. Next, the optimum coefficients and energies are found by the variation principle as explained in Section 10.5. That is, we solve the secular determinant, which in the case of ethene is eqn 10.31 with  $\alpha_A = \alpha_B = \alpha$ :

$$\begin{vmatrix} \alpha - E & \beta - ES \\ \beta - ES & \alpha - E \end{vmatrix} = 0 \quad (10.41)$$

The roots of this determinant were given in eqn 10.32b. In a modern computation all the resonance integrals and overlap integrals would be included, but an indication of the molecular orbital energy level diagram can be obtained very readily if we make the following additional **Hückel approximations**:

1. All overlap integrals are set equal to zero.
2. All resonance integrals between non-neighbours are set equal to zero.
3. All remaining resonance integrals are set equal (to  $\beta$ ).

Hückel  
approximations

These approximations are obviously very severe, but they let us calculate at least a general picture of the molecular orbital energy levels with very little work. The assumptions result in the following structure of the secular determinant:

1. All diagonal elements:  $\alpha - E$ .
2. Off-diagonal elements between neighbouring atoms:  $\beta$ .
3. All other elements: 0.

These approximations convert eqn 10.41 to

$$\begin{vmatrix} \alpha - E & \beta \\ \beta & \alpha - E \end{vmatrix} = (\alpha - E)^2 - \beta^2 = 0 \quad (10.42)$$

The roots of the equation are

$$E_{\pm} = \alpha \pm \beta \quad (10.43)$$

The + sign corresponds to the bonding combination ( $\beta$  is negative) and the – sign corresponds to the antibonding combination (Fig. 10.42). We see the effect of neglecting overlap by comparing this result with eqn 10.32b.

**Fig. 10.42** The Hückel molecular orbital energy level diagram for the  $\pi$  orbitals of ethene. Two electrons occupy the lower  $\pi$  orbital.

The building-up principle leads to the configuration  $1\pi^2$ , because each carbon atom supplies one electron to the  $\pi$  system. The **highest occupied molecular orbital** in ethene, its HOMO, is the  $1\pi$  orbital; the **lowest unoccupied molecular orbital**, its LUMO, is the  $2\pi$  orbital (or, as it is sometimes denoted, the  $2\pi^*$  orbital). These two orbitals jointly form the **frontier orbitals** of the molecule. The frontier orbitals are important because they are largely responsible for many of the chemical and spectroscopic properties of the molecule. For example, we can estimate that  $2|\beta|$  is the  $\pi^* \leftarrow \pi$  excitation energy of ethene, the energy required to excite an electron from the  $1\pi$  to the  $2\pi$  orbital. The constant  $\beta$  is often left as an adjustable parameter; an approximate value for  $\pi$  bonds formed from overlap of two C2p atomic orbitals is about  $-2.4$  eV ( $-230$  kJ mol $^{-1}$ ).

### (b) The matrix formulation of the Hückel method

In preparation for making Hückel theory more sophisticated and readily applicable to bigger molecules, we need to reformulate it in terms of matrices and vectors (see *Mathematical background 6* following this chapter). We have seen that the secular equations that we have to solve for a two-atom system have the form

$$(H_{AA} - E_i S_{AA})c_{i,A} + (H_{AB} - E_i S_{AB})c_{i,B} = 0 \quad (10.44a)$$

$$(H_{BA} - E_i S_{BA})c_{i,A} + (H_{BB} - E_i S_{BB})c_{i,B} = 0 \quad (10.44b)$$

where the eigenvalue  $E_i$  corresponds to a wavefunction of the form  $\psi_i = c_{i,A}A + c_{i,B}B$ . (These expressions generalize eqn 10.27.) There are two atomic orbitals, two eigenvalues, and two wavefunctions, so there are two pairs of secular equations, with the first corresponding to  $E_1$  and  $\psi_1$ :

$$(H_{AA} - E_1 S_{AA})c_{1,A} + (H_{AB} - E_1 S_{AB})c_{1,B} = 0 \quad (10.45a)$$

$$(H_{BA} - E_1 S_{BA})c_{1,A} + (H_{BB} - E_1 S_{BB})c_{1,B} = 0 \quad (10.45b)$$

and another pair corresponding to  $E_2$  and  $\psi_2$ :

$$(H_{AA} - E_2 S_{AA})c_{2,A} + (H_{AB} - E_2 S_{AB})c_{2,B} = 0 \quad (10.45c)$$

$$(H_{BA} - E_2 S_{BA})c_{2,A} + (H_{BB} - E_2 S_{BB})c_{2,B} = 0 \quad (10.45d)$$

If we introduce the following matrices and column vectors

$$H = \begin{pmatrix} H_{AA} & H_{AB} \\ H_{BA} & H_{BB} \end{pmatrix} \quad S = \begin{pmatrix} S_{AA} & S_{AB} \\ S_{BA} & S_{BB} \end{pmatrix} \quad c_i = \begin{pmatrix} c_{i,A} \\ c_{i,B} \end{pmatrix} \quad (10.46)$$

then each pair of equations may be written more succinctly as

$$(H - E_i S)c_i = 0 \quad \text{or} \quad Hc_i = Sc_i E_i \quad (10.47)$$

The two sets of equations like these (with  $i = 1$  and  $2$ ) can be combined into a single matrix equation by introducing the matrices

$$c = (c_1 \quad c_2) = \begin{pmatrix} c_{1,A} & c_{2,A} \\ c_{1,B} & c_{2,B} \end{pmatrix} \quad E = \begin{pmatrix} E_1 & 0 \\ 0 & E_2 \end{pmatrix} \quad (10.48)$$

for then all four equations in eqn 10.45 are summarized by the single expression

$$Hc = ScE \quad (10.49)$$

**Self-test 10.8** Show by carrying out the necessary matrix operations that eqn 10.49 is a representation of all four equations in eqn 10.45.

In the Hückel approximation,  $H_{AA} = H_{BB} = \alpha$ ,  $H_{AB} = H_{BA} = \beta$ , and we neglect overlap, setting  $S = 1$ , the unit matrix (with 1 on the diagonal and 0 elsewhere). Then

$$Hc = cE$$

At this point, we multiply from the left by the inverse matrix  $c^{-1}$ , use  $c^{-1}c = 1$ , and find

$$c^{-1}Hc = E \quad (10.50)$$

In other words, to find the eigenvalues  $E_i$ , we have to find a transformation of  $H$  that makes it diagonal. This procedure is called **matrix diagonalization**. The diagonal elements then correspond to the eigenvalues  $E_i$  and the columns of the matrix  $c$  that brings about this diagonalization are the coefficients of the members of the **basis set**, the set of atomic orbitals used in the calculation, and hence give us the composition of the molecular orbitals.

3 Butadiene

### Example 10.3 Finding molecular orbitals by matrix diagonalization

Set up and solve the matrix equations within the Hückel approximation for the  $\pi$  orbitals of butadiene (3).

**Method** The matrices will be four-dimensional for this four-atom system. Ignore overlap, and construct the matrix  $H$  by using the Hückel approximation and the parameters  $\alpha$  and  $\beta$ . Find the matrix  $c$  that diagonalizes  $H$ : for this step, use mathematical software. Full details are given in *Mathematical background 6*.

**Answer**

$$H = \begin{pmatrix} H_{11} & H_{12} & H_{13} & H_{14} \\ H_{21} & H_{22} & H_{23} & H_{24} \\ H_{31} & H_{32} & H_{33} & H_{34} \\ H_{41} & H_{42} & H_{43} & H_{44} \end{pmatrix} \stackrel{\text{Hückel approximation}}{=} \begin{pmatrix} \alpha & \beta & 0 & 0 \\ \beta & \alpha & \beta & 0 \\ 0 & \beta & \alpha & \beta \\ 0 & 0 & \beta & \alpha \end{pmatrix}$$

We write this matrix as

$$H = \alpha 1 + \beta \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}$$

because most mathematical software can deal only with numerical matrices. The diagonalized form of the second matrix is

$$\beta \begin{pmatrix} +1.62 & 0 & 0 & 0 \\ 0 & +0.62 & 0 & 0 \\ 0 & 0 & -0.62 & 0 \\ 0 & 0 & 0 & -1.62 \end{pmatrix}$$

so we can infer that the diagonalized Hamiltonian matrix is

$$E = \begin{pmatrix} \alpha + 1.62\beta & 0 & 0 & 0 \\ 0 & \alpha + 0.62\beta & 0 & 0 \\ 0 & 0 & \alpha - 0.62\beta & 0 \\ 0 & 0 & 0 & \alpha - 1.62\beta \end{pmatrix}$$

The matrix that achieves the diagonalization is

$$\mathbf{c} = \begin{pmatrix} 0.372 & 0.602 & 0.602 & -0.372 \\ 0.602 & 0.372 & -0.372 & 0.602 \\ 0.602 & -0.372 & -0.372 & -0.602 \\ 0.372 & -0.602 & 0.602 & 0.372 \end{pmatrix}$$

with each column giving the coefficients of the atomic orbitals for the corresponding molecular orbital. We can conclude that the energies and molecular orbitals are

$$\begin{aligned} E_1 &= \alpha + 1.62\beta & \psi_1 &= 0.372\chi_A + 0.602\chi_B + 0.602\chi_C + 0.372\chi_D \\ E_2 &= \alpha + 0.62\beta & \psi_2 &= 0.602\chi_A + 0.372\chi_B - 0.372\chi_C - 0.602\chi_D \\ E_3 &= \alpha - 0.62\beta & \psi_3 &= 0.602\chi_A - 0.372\chi_B - 0.372\chi_C + 0.602\chi_D \\ E_4 &= \alpha - 1.62\beta & \psi_4 &= -0.372\chi_A + 0.602\chi_B - 0.602\chi_C + 0.372\chi_D \end{aligned}$$

where the C2p atomic orbitals are denoted by  $\chi_A, \dots, \chi_D$ . Note that the molecular orbitals are mutually orthogonal and, with overlap neglected, normalized.

**Self-test 10.9** Repeat the exercise for the allyl radical,  $\cdot\text{CH}_2\text{--CH=CH}_2$ .

$$\begin{aligned} [E &= \alpha + 1.41\beta, \alpha, \alpha - 1.41\beta; \psi_1 = 0.500\chi_A + 0.707\chi_B + 0.500\chi_C, \\ \psi_2 &= 0.707\chi_A - 0.707\chi_C, \psi_3 = 0.500\chi_A - 0.707\chi_B + 0.500\chi_C] \end{aligned}$$

### (c) Butadiene and $\pi$ -electron binding energy

As we saw in Example 10.3, the energies of the four LCAO-MOs for butadiene are

$$E = \alpha \pm 1.62\beta, \quad \alpha \pm 0.62\beta \quad (10.51)$$

These orbitals and their energies are drawn in Fig. 10.43. Note that the greater the number of internuclear nodes, the higher the energy of the orbital. There are four electrons to accommodate, so the ground-state configuration is  $1\pi^2 2\pi^2$ . The frontier orbitals of butadiene are the  $2\pi$  orbital (the HOMO, which is largely bonding) and the  $3\pi$  orbital (the LUMO, which is largely antibonding). ‘Largely’ bonding means that an orbital has both bonding and antibonding interactions between various neighbours, but the bonding effects dominate. ‘Largely antibonding’ indicates that the antibonding effects dominate.

An important point emerges when we calculate the total  $\pi$ -electron binding energy,  $E_\pi$ , the sum of the energies of each  $\pi$  electron, and compare it with what we find in ethene. In ethene the total energy is

$$E_\pi = 2(\alpha + \beta) = 2\alpha + 2\beta$$

In butadiene it is

$$E_\pi = 2(\alpha + 1.62\beta) + 2(\alpha + 0.62\beta) = 4\alpha + 4.48\beta$$

Therefore, the energy of the butadiene molecule lies lower by  $0.48\beta$  (about  $110 \text{ kJ mol}^{-1}$ ) than the sum of two individual  $\pi$  bonds. This extra stabilization of a conjugated system compared with a set of localized  $\pi$  bonds is called the **delocalization energy** of the molecule.

A closely related quantity is the  $\pi$ -bond formation energy,  $E_{\text{bf}}$ , the energy released when a  $\pi$  bond is formed. Because the contribution of  $\alpha$  is the same in the molecule as in the atoms, we can find the  $\pi$ -bond formation energy from the  $\pi$ -electron binding energy by writing

$$E_{\text{bf}} = E_\pi - N_C \alpha$$

Definition of  $\pi$ -bond formation energy

[10.52]

**Fig. 10.43** The Hückel molecular orbital energy levels of butadiene and the top view of the corresponding  $\pi$  orbitals. The four p electrons (one supplied by each C) occupy the two lower  $\pi$  orbitals. Note that the orbitals are delocalized.

where  $N_C$  is the number of carbon atoms in the molecule. The  $\pi$ -bond formation energy in butadiene, for instance, is  $4.48\beta$ .

**Example 10.4** Estimating the delocalization energy

Use the Hückel approximation to find the energies of the  $\pi$  orbitals of cyclobutadiene, and estimate the delocalization energy.

**Method** Set up the secular determinant using the same basis as for butadiene, but note that atoms A and D are also now neighbours. Then solve for the roots of the secular equation and assess the total  $\pi$ -electron binding energy. For the delocalization energy, subtract from the total  $\pi$ -bond energy the energy of two  $\pi$  bonds.

**Answer** The hamiltonian matrix is

$$H = \begin{pmatrix} \alpha & \beta & 0 & \beta \\ \beta & \alpha & \beta & 0 \\ 0 & \beta & \alpha & \beta \\ \beta & 0 & \beta & \alpha \end{pmatrix}$$

Diagonalization gives the energies of the orbitals as

$$E = \alpha + 2\beta, \quad \alpha, \quad \alpha, \quad \alpha - 2\beta$$

Four electrons must be accommodated. Two occupy the lowest orbital (of energy  $\alpha + 2\beta$ ), and two occupy the doubly degenerate orbitals (of energy  $\alpha$ ). The total energy is therefore  $4\alpha + 4\beta$ . Two isolated  $\pi$  bonds would have an energy  $4\alpha + 4\beta$ ; therefore, in this case, the delocalization energy is zero.

**Self-test 10.10** Repeat the calculation for benzene (use software!).

[See next subsection]

**Fig. 10.44** The  $\sigma$  framework of benzene is formed by the overlap of  $Csp^2$  hybrids, which fit without strain into a hexagonal arrangement.

**(d) Benzene and aromatic stability**

The most notable example of delocalization conferring extra stability is benzene and the aromatic molecules based on its structure. Benzene is often expressed in a mixture of valence-bond and molecular orbital terms, with typically valence-bond language used for its  $\sigma$  framework and molecular orbital language used to describe its  $\pi$  electrons.

First, the valence-bond component. The six C atoms are regarded as  $sp^2$  hybridized, with a single unhybridized perpendicular  $2p$  orbital. One H atom is bonded by ( $Csp^2, H1s$ ) overlap to each C carbon, and the remaining hybrids overlap to give a regular hexagon of atoms (Fig. 10.44). The internal angle of a regular hexagon is  $120^\circ$ , so  $sp^2$  hybridization is ideally suited for forming  $\sigma$  bonds. We see that the hexagonal shape of benzene permits strain-free  $\sigma$  bonding.

Now consider the molecular orbital component of the description. The six  $C2p$  orbitals overlap to give six  $\pi$  orbitals that spread all round the ring. Their energies are calculated within the Hückel approximation by diagonalizing the hamiltonian matrix

$$H = \begin{pmatrix} \alpha & \beta & 0 & 0 & 0 & \beta \\ \beta & \alpha & \beta & 0 & 0 & 0 \\ 0 & \beta & \alpha & \beta & 0 & 0 \\ 0 & 0 & \beta & \alpha & \beta & 0 \\ 0 & 0 & 0 & \beta & \alpha & \beta \\ \beta & 0 & 0 & 0 & \beta & \alpha \end{pmatrix} = \alpha 1 + \beta \begin{pmatrix} 0 & 1 & 0 & 0 & 0 & 1 \\ 1 & 0 & 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 1 \\ 1 & 0 & 0 & 0 & 1 & 0 \end{pmatrix}$$

The MO energies, the eigenvalues of this matrix, are simply

$$E = \alpha \pm 2\beta, \alpha \pm \beta, \alpha \pm \beta \quad (10.53)$$

as shown in Fig. 10.45. The orbitals there have been given symmetry labels that we explain in Chapter 11. Note that the lowest energy orbital is bonding between all neighbouring atoms, the highest energy orbital is antibonding between each pair of neighbours, and the intermediate orbitals are a mixture of bonding, non-bonding, and antibonding character between adjacent atoms.

We now apply the building-up principle to the  $\pi$  system. There are six electrons to accommodate (one from each C atom), so the three lowest orbitals ( $a_{2u}$  and the doubly degenerate pair  $e_{1g}$ ) are fully occupied, giving the ground-state configuration  $a_{2u}^2 e_{1g}^4$ . A significant point is that the only molecular orbitals occupied are those with net bonding character.

The  $\pi$ -electron energy of benzene is

$$E_\pi = 2(\alpha + 2\beta) + 4(\alpha + \beta) = 6\alpha + 8\beta$$

If we ignored delocalization and thought of the molecule as having three isolated  $\pi$  bonds, it would be ascribed a  $\pi$ -electron energy of only  $3(2\alpha + 2\beta) = 6\alpha + 6\beta$ . The delocalization energy is therefore  $2\beta \approx -460 \text{ kJ mol}^{-1}$ , which is considerably more than for butadiene. The  $\pi$ -bond formation energy in benzene is  $8\beta$ .

This discussion suggests that aromatic stability can be traced to two main contributions. First, the shape of the regular hexagon is ideal for the formation of strong  $\sigma$  bonds: the  $\sigma$  framework is relaxed and without strain. Second, the  $\pi$  orbitals are such as to be able to accommodate all the electrons in bonding orbitals, and the delocalization energy is large.

## 10.7 Computational chemistry

**Key points** (a) The Hartree–Fock equations are versions of the Schrödinger equation based on the occupation of individual molecular orbitals by electrons. The Roothaan equations are versions of these equations that are based on the molecular orbitals being expressed as linear combinations of molecular orbitals. (b) Semi-empirical calculations approximate integrals by estimating integrals using empirical data; *ab initio* methods evaluate all integrals numerically. (c) Density functional theories develop equations based on the electron density rather than the wavefunction itself.

The severe assumptions of the Hückel method are now easy to avoid by using a variety of software packages that can be used not only to calculate the shapes and energies of molecular orbitals but also predict with reasonable accuracy the structure and reactivity of molecules. The full treatment of molecular electronic structure has received an enormous amount of attention by chemists and has become a keystone of modern chemical research.

### (a) The Hartree–Fock equations

The starting point is to write down the many-electron wavefunction as a product of one-electron wavefunctions:

$$\Psi = \psi_a^\alpha(1) \psi_a^\beta(2) \dots \psi_z^\beta(N_e)$$

This is the wavefunction for an  $N_e$ -electron closed-shell molecule in which electron 1 occupies molecular orbital  $\psi_a$  with spin  $\alpha$ , electron 2 occupies molecular orbital  $\psi_a$  with spin  $\beta$ , and so on. We shall consider only closed-shell species. The wavefunction must satisfy the Pauli principle and change sign under the permutation of any

### A brief comment

The simple form of the eigenvalues in eqn 10.53 suggests that there is a more direct way of determining them than by using mathematical software. That is in fact the case, for symmetry arguments of the kind described in Chapter 11 show that the  $6 \times 6$  matrix can be factorized into two  $1 \times 1$  matrices and two  $2 \times 2$  matrices, which are very easy to deal with.

**Fig. 10.45** The Hückel orbitals of benzene and the corresponding energy levels. The symmetry labels are explained in Chapter 11. The bonding and antibonding character of the delocalized orbitals reflects the numbers of nodes between the atoms. In the ground state, only the bonding orbitals are occupied.

### A brief comment

The following sections provide a brief introduction. A more complete account with detailed examples will be found in Chapter 6 of our *Quanta, matter, and change* (2009). That chapter is also available in the online resource centre for this book.

pair of electrons. To achieve this behaviour, we write the wavefunction as a sum of all possible permutations with the appropriate sign:

$$\Psi = \psi_a^\alpha(1)\psi_a^\beta(2) \dots \psi_z^\beta(N_e) - \psi_a^\alpha(2)\psi_a^\beta(1) \dots \psi_z^\beta(N_e) + \dots$$

There are  $N_e!$  terms in this sum, and the entire sum can be written as a Slater determinant like that used in the description of many-electron atoms (Section 9.4b):

$$\Psi = \frac{1}{\sqrt{N_e!}} \begin{vmatrix} \psi_a^\alpha(1) & \psi_a^\beta(1) & \dots & \dots & \psi_z^\beta(1) \\ \psi_a^\alpha(2) & \psi_a^\beta(2) & \dots & \dots & \psi_z^\beta(2) \\ \vdots & \vdots & & & \vdots \\ \vdots & \vdots & & & \vdots \\ \psi_a^\alpha(N_e) & \psi_a^\beta(N_e) & \dots & \dots & \psi_z^\beta(N_e) \end{vmatrix} \quad \begin{array}{l} \text{A Slater} \\ \text{determinant} \end{array} \quad (10.54)$$

where the initial factor ensures that the wavefunction is normalized if the component molecular orbitals are normalized.

When the determinantal wavefunction is combined with the variation principle (Section 10.5c), the optimum wavefunctions, in the sense of corresponding to the lowest total energy, must satisfy a modified version of the Schrödinger equation, which is written as a set of **Hartree–Fock equations**:

$$f_1 \psi_m(1) = \varepsilon_m \psi_m(1) \quad \begin{array}{l} \text{Hartree–Fock} \\ \text{equations} \end{array} \quad (10.55)$$

for each molecular orbital  $\psi_m$ . The **Fock operator**  $f_1$  has terms that express mathematically (see *Further information 10.1*):

- the kinetic energy of the electron in  $\psi_m$ ;
- the potential energy of interaction between the electron in  $\psi_m$  and the nuclei in the molecule;
- repulsive interactions between the electron in  $\psi_m$  and other electrons in the molecule;
- the effects of spin correlation between electrons in the molecule.

Because the Fock operator includes the effects of all the other electrons on electron 1, its detailed form depends on the wavefunctions of those electrons. To proceed, we have to guess the initial form of those wavefunctions, use them in the definition of the Fock operator, and solve the Hartree–Fock equations. That process is then continued using the newly found wavefunctions until each cycle of calculation leaves the energies and wavefunctions unchanged to within a chosen criterion. This is the origin of the term **self-consistent field** (SCF) for this type of procedure.

To solve the Hartree–Fock equations the molecular orbitals are expressed as linear combinations of  $N_b$  atomic orbitals  $\chi_o$  (that is,  $N_b$  is the size of the basis set), which for simplicity we shall take to be real, and write

$$\psi_m = \sum_{o=1}^{N_b} c_{om} \chi_o \quad \begin{array}{l} \text{A general LCAO} \end{array} \quad (10.56)$$

For a given basis set, ‘solving the Hartree–Fock equations for  $\psi_m$ ’ now corresponds to determining the values of the coefficients  $c_{om}$ . As we show in *Further information 10.1* the use of a linear combination like this leads to a set of equations that can be expressed in a matrix form known as the **Roothaan equations**:

$$Fc = ScE \quad \begin{array}{l} \text{Roothaan equations} \end{array} \quad (10.57)$$

where  $F$  is a matrix formed from the Fock operator with elements  $F_{ab} = \int \chi_a(1) f_1 \chi_b(1) d\tau_1$ ,  $S$  is the matrix of overlap integrals with elements  $S_{ab} = \int \chi_a(1) \chi_b(1) d\tau_1$ , and  $c$  and  $\epsilon$  are matrices formed from the orbital coefficients  $c_{om}$  and molecular orbital energies  $\epsilon_m$ , respectively. The resemblance of eqn 10.57 to eqn 10.49 ( $Hc = ScE$ ) should be noted.

### (b) Semi-empirical and *ab initio* methods

There are two main strategies for continuing the calculation from this point. In the **semi-empirical methods**, many of the integrals are estimated by appealing to spectroscopic data or physical properties such as ionization energies, and using a series of rules to set certain integrals equal to zero. We saw this procedure in a primitive form when we identified the integral  $\alpha$  in eqn 10.32 with the negative of the ionization energy of an atom (see the *brief illustration* following that equation). In the ***ab initio* methods**, an attempt is made to calculate all the integrals that appear in the Fock and overlap matrices. Both procedures employ a great deal of computational effort and, along with cryptanalysts and meteorologists, theoretical chemists are among the heaviest users of the fastest computers.

We show in *Further information 10.1* that the Fock matrix includes integrals of the form

$$(AB|CD) = \int_0 \int_0 A(1)B(1) \frac{1}{r_{12}} C(2)D(2) d\tau_1 d\tau_2 \quad (10.58)$$

where  $A$ ,  $B$ ,  $C$ , and  $D$  are atomic orbitals that in general may be centred on different nuclei. It can be appreciated that, if there are several dozen atomic orbitals used to build the molecular orbitals, then there will be tens of thousands of integrals of this form to evaluate (the number of integrals increases as the fourth power of the number of atomic orbitals in the basis). Some kind of approximation scheme is necessary.

One severe approximation used in the early days of computational chemistry was called **complete neglect of differential overlap** (CNDO), in which all integrals are set to zero unless  $A$  and  $B$  are the same orbitals centred on the same nucleus, and likewise for  $C$  and  $D$ . The surviving integrals are then adjusted until the energy levels are in good agreement with experiment or the computed enthalpy of formation of the compound is in agreement with experiment. More recent semi-empirical methods make less draconian decisions about which integrals are to be ignored, but they are all descendants of the early CNDO technique. These procedures are now readily available in commercial software packages and can be used with very little detailed knowledge of their mode of calculation. The packages also have sophisticated graphical output procedures, which enable one to analyse the shapes of orbitals and the distribution of electric charge in molecules. The latter is important when assessing, for instance, the likelihood that a given molecule will bind to an active site in an enzyme.

Commercial packages are also available for *ab initio* calculations. Here the problem is to evaluate as efficiently as possible thousands of integrals of the form  $(AB|CD)$ . This task is greatly facilitated by expressing the atomic orbitals used in the LCAOs as linear combinations of Gaussian orbitals. A **Gaussian type orbital** (GTO) is a function of the form  $e^{-\zeta r^2}$ . The advantage of GTOs over the correct orbitals (which for hydrogenic systems are proportional to  $e^{-\zeta r}$ ) is that the product of two Gaussian functions is itself a Gaussian function that lies between the centres of the two contributing functions (Fig. 10.46). In this way, the four-centre integrals like that in eqn 10.58 become two-centre integrals of the form

$$(AB|CD) = \int_0 \int_0 X(1) \frac{1}{r_{12}} Y(2) d\tau_1 d\tau_2 \quad (10.59)$$

**Fig. 10.46** The product of two Gaussian functions (the purple curves) is itself a Gaussian function located between the two contributing Gaussians.

where  $X$  is the Gaussian corresponding to the product  $AB$  and  $Y$  is the corresponding Gaussian from  $CD$ . Integrals of this form are much easier and faster to evaluate numerically than the original four-centre integrals. Although more GTOs have to be used to simulate the atomic orbitals, there is an overall increase in speed of computation.

#### • A brief illustration

Suppose we consider a one-dimensional ‘homonuclear’ system, with Gaussians of the form  $e^{-ax^2}$  located at 0 and  $R$ . Then one of the integrals that would have to be evaluated would include the term

$$\chi_A(1)\chi_B(1) = e^{-ax^2}e^{-a(x-R)^2} = e^{-2ax^2+2axR-aR^2}$$

Next we note that  $-2a(x - \frac{1}{2}R)^2 = -2ax^2 + 2axR - \frac{1}{2}aR^2$ , so we can write

$$\chi_A(1)\chi_B(1) = e^{-2a(x-\frac{1}{2}R)^2-\frac{1}{2}aR^2} = e^{-2a(x-\frac{1}{2}R)^2}e^{-\frac{1}{2}aR^2}$$

which is proportional to a single Gaussian centred on the midpoint of the internuclear distance. •

### (c) Density functional theory

A technique that has gained considerable ground in recent years to become one of the most widely used techniques for the calculation of molecular structure is **density functional theory** (DFT). Its advantages include less demanding computational effort, less computer time, and—in some cases (particularly d-metal complexes)—better agreement with experimental values than is obtained from Hartree–Fock procedures.

The central focus of DFT is the electron density,  $\rho$ , rather than the wavefunction  $\psi$ . The ‘functional’ part of the name comes from the fact that the energy of the molecule is a function of the electron density, written  $E[\rho]$ , and the electron density is itself a function of position,  $\rho(r)$ , and in mathematics a function of a function is called a *functional*. The occupied orbitals are used to construct the electron density from

$$\rho(r) = \sum_m |\psi_m(r)|^2 \quad \text{Electron probability density} \quad (10.60)$$

and are calculated from the **Kohn–Sham equations**, which are like the Hartree–Fock equations except for a term  $V_{\text{XC}}$ , called the **exchange–correlation potential**:

$$\left\{ h_1 + j_0 \int \frac{\rho(2)}{r_{12}} d\tau_2 + V_{\text{XC}}(1) \right\} \psi_m(1) = \epsilon_m \psi_m(1) \quad \text{Kohn–Sham equations} \quad (10.61)$$

The first term on the left is the usual one-electron kinetic and potential energy contribution and the second term is the potential energy of repulsion between electrons 1 and 2. The challenge in DFT is to construct the exchange–correlation potential and computational chemists use several approximate expressions for  $V_{\text{XC}}$ .

The Kohn–Sham equations are solved iteratively and self-consistently. First, we guess the electron density. For this step it is common to use a superposition of atomic electron densities. Next, the Kohn–Sham equations are solved to obtain an initial set of orbitals. This set of orbitals is used to obtain a better approximation to the electron density and the process is repeated until the density and the exchange–correlation energy are constant to within some tolerance.

## 10.8 The prediction of molecular properties

**Key points** (a) Graphical techniques plot a variety of surfaces based on electronic structure calculations. (b) Computational techniques are used to estimate enthalpies of formation and standard potentials. Electronic absorption spectra of conjugated systems correlate with the HOMO–LUMO energy gap.

The results of molecular orbital calculations are only approximate, with deviations from experimental values increasing with the size of the molecule. Therefore, one goal of computational chemistry is to gain insight into trends in properties of molecules, without necessarily striving for ultimate accuracy. In the next sections we give a brief summary of strategies used by computational chemists for the prediction of molecular properties.

### (a) Electron density and the electrostatic potential surfaces

One of the most significant developments in computational chemistry has been the introduction of graphical representations of molecular orbitals and electron densities. The raw output of a molecular structure calculation is a list of the coefficients of the atomic orbitals in each molecular orbital and the energies of these orbitals. The graphical representation of a molecular orbital uses stylized shapes to represent the basis set, and then scales their size to indicate the coefficient in the linear combination. Different signs of the wavefunctions are represented by different colours.

Once the coefficients are known, it is possible to construct a representation of the electron density in the molecule by noting which orbitals are occupied and then forming the squares of those orbitals. The total electron density at any point is then the sum of the squares of the wavefunctions evaluated at that point. The outcome is commonly represented by an **isodensity surface**, a surface of constant total electron density (Fig. 10.47). As shown in the illustration, there are several styles of representing an isodensity surface, as a solid form, as a transparent form with a ball-and-stick representation of the molecule within, or as a mesh. A related representation is a **solvent-accessible surface** in which the shape represents the shape of the molecule by imagining a sphere representing a solvent molecule rolling across the surface and plotting the locations of the centre of that sphere.

One of the most important aspects of a molecule other than its geometrical shape is the distribution of charge over its surface. The net charge at each point on an isodensity surface can be calculated by subtracting the charge due to the electron density at that point from the charge due to the nuclei: the result is an **electrostatic potential surface** (an ‘elpot surface’) in which net positive charge is shown in one colour and net negative charge is shown in another, with intermediate gradations of colour (Fig. 10.48).

Representations such as those we have illustrated are of critical importance in a number of fields. For instance, they may be used to identify an electron-poor region of a molecule that is susceptible to association with or chemical attack by an electron-rich region of another molecule. Such considerations are important for assessing the pharmacological activity of potential drugs.

### (b) Thermodynamic and spectroscopic properties

We saw in Section 2.8b that computational chemistry is commonly used to estimate standard enthalpies of formation of molecules with complex three-dimensional structures. The computational approach also makes it possible to gain insight into the effect of solvation on the enthalpy of formation without conducting experiments. A calculation performed in the absence of solvent molecules estimates the properties of the molecule of interest in the gas phase. Computational methods are available that

**Fig. 10.47** Various representations of an isodensity surface of ethanol (a) solid surface, (b) transparent surface, and (c) mesh surface.

**Fig. 10.48** An elpot diagram of ethanol; the molecule has the same orientation as in Fig. 10.47. Red denotes regions of relative negative potential and blue regions of relative positive potential (as in  $\delta^-$ -O- $\text{H}^{\delta+}$ ).

allow for the inclusion of several solvent molecules around a solute molecule, thereby taking into account the effect of molecular interactions with the solvent on the enthalpy of formation of the solute. Again, the numerical results are only estimates and the primary purpose of the calculation is to predict whether interactions with the solvent increase or decrease the enthalpy of formation. As an example, consider the amino acid glycine, which can exist in a neutral (4) or zwitterionic (5) form, in which the amino group is protonated and the carboxyl group is deprotonated. It is possible to show computationally that in the gas phase the neutral form has a lower enthalpy of formation than the zwitterionic form. However, in water the opposite is true because of strong interactions between the polar solvent and the charges in the zwitterion.

Molecular orbital calculations can also be used to predict trends in electrochemical properties, such as standard potentials (Chapter 6). Several experimental and computational studies of aromatic hydrocarbons indicate that decreasing the energy of the LUMO enhances the ability of a molecule to accept an electron into the LUMO, with an attendant increase in the value of the standard potential of the molecule. The effect is also observed in quinones and flavins, which are co-factors involved in biological electron transfer reactions. For example, stepwise substitution of the hydrogen atoms in *p*-benzoquinone by methyl groups ( $-\text{CH}_3$ ) results in a systematic increase in the energy of the LUMO and a decrease in the standard potential for formation of the semiquinone radical (6).

The standard potentials of naturally occurring quinones are also modified by the presence of different substituents, a strategy that imparts specific functions to specific quinones. For example, the substituents in coenzyme Q are largely responsible for positioning its standard potential so that the molecule can function as an electron shuttle between specific electroactive proteins in the respiratory chain (*Impact 16.1*).

Calculations based on semi-empirical, *ab initio*, and DFT methods are used to correlate the HOMO–LUMO energy gaps with the wavelengths of spectroscopic absorptions. For example, consider the linear polyenes shown in Table 10.5: ethene ( $\text{C}_2\text{H}_4$ ), butadiene ( $\text{C}_4\text{H}_6$ ), hexatriene ( $\text{C}_6\text{H}_8$ ), and octatetraene ( $\text{C}_8\text{H}_{10}$ ), all of which absorb in the ultraviolet region of the spectrum. The table also shows that, as expected, the wavelength of the lowest-energy electronic transition decreases as the energy separation between the HOMO and LUMO increases. We also see that the smallest HOMO–LUMO gap and longest transition wavelength correspond to octatetraene, the longest polyene in the group. It follows that the wavelength of the transition increases with increasing number of conjugated double bonds in linear polyenes.

**Table 10.5** *Ab initio* calculations and spectroscopic data

| Polyene                                                                                                            | $\{E(\text{HOMO}) - E(\text{LUMO})\}/\text{eV}$ | $\lambda/\text{nm}$ |
|--------------------------------------------------------------------------------------------------------------------|-------------------------------------------------|---------------------|
|  (C <sub>2</sub> H <sub>4</sub> ) | 18.1                                            | 163                 |
|                                   | 14.5                                            | 217                 |
|                                   | 12.7                                            | 252                 |
|                                   | 11.8                                            | 304                 |

Extrapolation of the trend suggests that a sufficiently long linear polyene should absorb light in the visible region of the electromagnetic spectrum. This is indeed the case for  $\beta$ -carotene (7), which absorbs light with  $\lambda \approx 450$  nm. The ability of  $\beta$ -carotene to absorb visible light is part of the strategy employed by plants to harvest solar energy for use in photosynthesis (Chapter 22).

**7**  $\beta$ -Carotene

## Checklist of key equations

| Property                              | Equation                               | Comment                                           |
|---------------------------------------|----------------------------------------|---------------------------------------------------|
| Valence-bond wavefunction             | $\psi = A(1)B(2) + A(2)B(1)$           |                                                   |
| Linear combination of atomic orbitals | $\psi_{\pm} = N(A \pm B)$              | Homonuclear diatomic molecule                     |
| Overlap integral                      | $S = \int \chi_A^* \chi_B d\tau$       |                                                   |
| Bond order                            | $b = \frac{1}{2}(N - N^*)$             |                                                   |
| Photoelectron spectroscopy            | $h\nu = \frac{1}{2}m_e v^2 + I_i$      | $I_i$ is the ionization energy from orbital $i$ . |
| Linear combination of atomic orbitals | $\psi = \sum_i c_i \chi_i$             | General case                                      |
| Hückel equations                      | $Hc = ScE$                             |                                                   |
| $\pi$ -Bond formation energy          | $E_{\text{bf}} = E_{\pi} - N_C \alpha$ |                                                   |
| Hartree–Fock equation                 | $f_1 \psi_m(1) = \epsilon_m \psi_m(1)$ |                                                   |
| Roothaan equations                    | $Fc = Sc\epsilon$                      |                                                   |

## Further information

### Further information 10.1 Details of the Hartree–Fock method

The Fock operator has the form

$$f_1 = h_1 + \sum_m \{2J_m(1) - K_m(1)\} \quad (10.62)$$

where the sum is over all occupied orbitals and  $h$ ,  $J$ , and  $K$  are all operators. The first of the three terms in this expression is the **core Hamiltonian**

$$h_1 = -\frac{\hbar^2}{2m_e} \nabla_1^2 - j_0 \sum_I \frac{Z_I}{r_{1I}} \quad \text{Core hamiltonian} \quad (10.63a)$$

where  $I$  labels the nuclei in the molecule and  $j_0 = e^2/4\pi\epsilon_0$  (as in Section 10.3). The **Coulomb operator**,  $J$ , is

$$J_m(1)\psi_a(1) = j_0 \int \psi_m(1) \frac{1}{r_{12}} \psi_m^*(2) \psi_m(2) d\tau_2 \quad \text{Coulomb operator} \quad (10.63b)$$

and represents the repulsion experienced by electron 1 in orbital  $\psi_a$  from electron 2 in orbital  $\psi_m$ . The **exchange operator**,  $K$ , is

$$K_m(1)\psi_a(1) = j_0 \int \psi_m(1) \frac{1}{r_{12}} \psi_m^*(2) \psi_a(2) d\tau_2 \quad \text{Exchange operator} \quad (10.63c)$$

This integral represents the modification of the electron–electron repulsion that is due to spin correlation (Section 9.4d).

To construct the Roothaan equations we substitute the linear combination of atomic orbitals into the Hartree–Fock equations (eqn 10.55,  $f_1\psi_m(1) = \epsilon_m\psi_m(1)$ ), which gives

$$f_1 \sum_{o=1}^{N_b} c_{oa} \chi_o(1) = \epsilon_a \sum_{o=1}^{N_b} c_{oa} \chi_o(1)$$

Now multiply from the left by  $\chi_{o'}(1)$  and integrate over the coordinates of electron 1:

$$\sum_{o=1}^{N_b} c_{oa} \int \chi_{o'}(1) f(1) \chi_o(1) d\tau_1 = \epsilon_a \sum_{o=1}^{N_b} c_{oa} \int \chi_{o'}(1) \chi_o(1) d\tau_1$$

That is,

$$\sum_{o=1}^{N_b} F_{o'o} c_{oa} = \epsilon_a \sum_{o=1}^{N_b} S_{o'o} c_{oa}$$

This expression has the form of a relation between matrix elements of the product matrices  $FC$  and  $Sc$ :

$$(Fc)_{o'a} = (Sc)_{o'a} \epsilon_a$$

If we now introduce the diagonal matrix  $\epsilon$  with the values of  $\epsilon_a$  along its diagonal, this relation can be written as the matrix equality  $Fc = Sc\epsilon$ , as in eqn 10.57.

### • A brief illustration

To set up the Roothaan equations for the HF molecule using the  $N_b = 2$  basis set H1s ( $\chi_A$ ) and F2p<sub>z</sub> ( $\chi_B$ ) we write the two molecular orbitals ( $m = a, b$ ) as

$$\psi_a = c_{Aa} \chi_A + c_{Ba} \chi_B \quad \psi_b = c_{Ab} \chi_A + c_{Bb} \chi_B$$

The matrix  $c$  is then  $c = \begin{pmatrix} c_{Aa} & c_{Ab} \\ c_{Ba} & c_{Bb} \end{pmatrix}$  and the overlap matrix is

$$S = \begin{pmatrix} 1 & S \\ S & 1 \end{pmatrix}. \text{ The Fock matrix is}$$

$$F = \begin{pmatrix} F_{AA} & F_{AB} \\ F_{BA} & F_{BB} \end{pmatrix} \quad \text{with} \quad F_{o'o} = \int \chi_{o'} f_1 \chi_o d\tau_1$$

Then the Roothaan equations ( $Fc = Sc\epsilon$ ) are

$$\begin{pmatrix} F_{AA} & F_{AB} \\ F_{BA} & F_{BB} \end{pmatrix} \begin{pmatrix} c_{Aa} & c_{Ab} \\ c_{Ba} & c_{Bb} \end{pmatrix} = \begin{pmatrix} 1 & S \\ S & 1 \end{pmatrix} \begin{pmatrix} c_{Aa} & c_{Ab} \\ c_{Ba} & c_{Bb} \end{pmatrix} \begin{pmatrix} \epsilon_a & 0 \\ 0 & \epsilon_b \end{pmatrix}$$

This matrix equation expands to four individual equations, one of which is

$$F_{AA}c_{Aa} + F_{AB}c_{Ba} = \epsilon_a c_{Aa} + S\epsilon_a c_{Ba}$$

and which constitute four simultaneous equations for the coefficients  $c$  just like the secular equations developed earlier (such as in eqns 10.27 or 10.44). One major difference, though, is that, because  $f_1$  is defined in terms of the molecular orbitals, the  $F$  factors depend on the coefficients we are trying to find. We develop this expression below. •

A quick look at the form of the Fock matrix gives us an idea of the magnitude of the challenges associated with implementation of the Hartree–Fock method. It follows from eqn 10.62 that

$$F_{o'o} = \int \chi_{o'}(1) \left\{ h_1 + \sum_m [2J_m(1) - K_m(1)] \right\} \chi_o(1) d\tau_1$$

Suppose we focus on the term involving  $K$ ; then from eqn 10.63 it follows that one contribution to  $F$  is

$$\begin{aligned} j_0 \int \chi_{o'}(1) \left\{ \int \psi_m(1) \frac{1}{r_{12}} \psi_m(2) \chi_o(2) d\tau_2 \right\} d\tau_1 \\ = j_0 \int \chi_{o'}(1) \psi_m(1) \frac{1}{r_{12}} \psi_m(2) \chi_o(2) d\tau_1 d\tau_2 \end{aligned}$$

where to get the term on the right we have simply rearranged some factors. Each molecular orbital  $\psi$  is a linear combination of atomic orbitals  $\chi$ , so even this single contribution is a sum of terms that have the form

$$(AB|CD) = j_0 \int A(1)B(1) \frac{1}{r_{12}} C(2)D(2) d\tau_1 d\tau_2$$

where  $A, B, C$ , and  $D$  are atomic orbitals, as we encountered in eqn 10.58.

### • A brief illustration

The term  $F_{AB}$  in the hydrogen fluoride calculation that we have been developing is

$$F_{AB} = \int \chi_A(1) h_1 \chi_B(1) d\tau_1 + 2 \int \chi_A(1) J_a(1) \chi_B(1) d\tau_1 - \int \chi_A(1) K_a(1) \chi_B(1) d\tau_1$$

because only  $\psi_a$  is occupied, so only  $m = a$  contributes to the sum over  $m$ . We use the definition of  $J_m$  in eqn 10.63b to write the second term on the right as follows:

$$\begin{aligned} \int \chi_A(1) J_a(1) \chi_B(1) d\tau_1 &= j_0 \int \chi_A(1) \left[ \chi_B(1) \frac{1}{r_{12}} (c_{Aa} \chi_A(2) + c_{Ba} \chi_B(2)) \right] d\tau_2 d\tau_1 \\ &= j_0 c_{Aa}^2 \int \chi_A(1) \chi_B(1) \frac{1}{r_{12}} \chi_A(2) \chi_A(2) d\tau_1 d\tau_2 + \dots \\ &= j_0 c_{Aa}^2 (AB|AA) + \dots \end{aligned}$$

There are four such terms, and four more from  $K$ . We now see how the coefficients  $c$  also appear in the  $F$ s that appear in the Roothaan equations, which makes them so difficult to solve and forces us to use self-consistent numerical methods. •

## Discussion questions

**10.1** Compare the approximations built into valence-bond theory and molecular orbital theory.

**10.2** Discuss the steps involved in the construction of  $sp^3$ ,  $sp^2$ , and  $sp$  hybrid orbitals.

**10.3** Distinguish between the Pauling and Mulliken electronegativity scales.

**10.4** Why is spin-pairing associated with bond formation? Discuss the concept in the context of valence-bond and molecular-orbital methods.

**10.5** Discuss the approximations built into the Hückel method.

**10.6** Distinguish between delocalization energy,  $\pi$ -electron binding energy, and  $\pi$ -bond formation energy.

**10.7** Use concepts of molecular orbital theory to describe the biochemical reactivity of  $O_2$ ,  $N_2$ , and  $NO$ .

**10.8** Outline the steps involved in the Hartree–Fock method for the calculation of molecular electronic structure.

**10.9** Why are self-consistent field procedures used in computational chemistry?

## Exercises

**10.1(a)** Write the VB spatial wavefunction for the bonds in  $H_2O$  using the basis  $H1s$  and  $O2p$ .

**10.1(b)** Write the VB spatial wavefunction for the bonds in  $H_2O_2$  using the basis  $H1s$  and  $O2p$ .

**10.2(a)** Write the total VB wavefunction (including spin) for the bond in  $OH^-$  using the basis  $H1s$  and  $O2p_z$ .

**10.2(b)** Write the total VB wavefunction (including spin) for the bond in  $HF$  using the basis  $H1s$  and  $F2p_z$ .

**10.3(a)** Write the VB wavefunction for a  $CH_4$  molecule using the  $sp^3$  hybrid orbitals  $h$  on C and the four  $H1s$  orbitals.

**10.3(b)** Write the VB wavefunction for a  $BF_3$  molecule using the  $sp^2$  hybrid orbitals  $h$  on B and the three  $F2p$  orbitals.

**10.4(a)** Show that the  $sp^3$  hybrid orbitals  $h_3$  and  $h_4$  in eqn 10.3 are mutually orthogonal.

**10.4(b)** Show that the  $sp^2$  hybrid orbitals  $h_2$  and  $h_3$  in eqn 10.5 are mutually orthogonal.

**10.5(a)** Give the ground-state electron configurations and bond orders of (a)  $Li_2$ , (b)  $Be_2$ , and (c)  $C_2$ .

**10.5(b)** Give the ground-state electron configurations of (a)  $H_2^+$ , (b)  $N_2$ , and (c)  $O_2$ .

**10.6(a)** Give the ground-state electron configurations of (a)  $CO$ , (b)  $NO$ , and (c)  $CN^-$ .

**10.6(b)** Give the ground-state electron configurations of (a)  $ClF$ , (b)  $CS$ , and (c)  $O_2^-$ .

**10.7(a)** From the ground-state electron configurations of  $B_2$  and  $C_2$ , predict which molecule should have the greater bond dissociation energy.

**10.7(b)** Which of the molecules  $N_2$ ,  $NO$ ,  $O_2$ ,  $C_2$ ,  $F_2$ , and  $CN$  would you expect to be stabilized by (a) the addition of an electron to form  $AB^-$ , (b) the removal of an electron to form  $AB^+$ ?

**10.8(a)** Sketch the molecular orbital energy level diagram for  $XeF$  and deduce its ground-state electron configurations. Is  $XeF$  likely to have a shorter bond length than  $XeF^+$ ?

**10.8(b)** Sketch the molecular orbital energy level diagrams for  $BrCl$  and deduce its ground-state electron configurations. Is  $BrCl$  likely to have a shorter bond length than  $BrCl^-$ ?

**10.9(a)** Use the electron configurations of  $NO$  and  $N_2$  to predict which is likely to have the shorter bond length.

**10.9(b)** Arrange the species  $O_2^+$ ,  $O_2$ ,  $O_2^-$ ,  $O_2^{2-}$  in order of increasing bond length.

**10.10(a)** Show that a molecular orbital of the form  $A \sin \theta + B \cos \theta$  is normalized to 1 if the orbitals  $A$  and  $B$  are each normalized to 1 and  $S = 0$ . What linear combination of  $A$  and  $B$  is orthogonal to this combination?

**10.10(b)** Normalize the molecular orbital  $\psi_A + \lambda\psi_B$  in terms of the parameter  $\lambda$  and the overlap integral  $S$ .

**10.11(a)** Confirm that the bonding and antibonding combinations  $\psi_A \pm \psi_B$  are mutually orthogonal in the sense that their mutual overlap is zero.

**10.11(b)** Suppose that a molecular orbital has the form  $N(0.145A + 0.844B)$ . Find a linear combination of the orbitals  $A$  and  $B$  that is orthogonal to this combination.

**10.12(a)** What is the energy of an electron that has been ejected from an orbital of ionization energy 11.0 eV by a photon of radiation of wavelength 100 nm?

**10.12(b)** What is the energy of an electron that has been ejected from an orbital of ionization energy 4.69 eV by a photon of radiation of wavelength 584 pm?

**10.13(a)** An electron ejected from an orbital of a diatomic molecule by 21.22 eV radiation was found to have a speed of  $1.90 \text{ Mm s}^{-1}$ . To what ionization energy does that correspond?

**10.13(b)** An electron ejected from an orbital of a diatomic molecule by He(I) radiation was found to have a speed of 0.501 per cent the speed of light,  $c$ . To what ionization energy does that correspond?

**10.14(a)** The ionization energy of Xe5p and F2p electrons are 12.1 eV and 17.4 eV, respectively. Calculate the energies and composition of the bonding and antibonding orbitals of XeF. Use  $\beta = -1.5 \text{ eV}$  and  $S = 0$ .

**10.14(b)** The ionization energy of Xe5p and O2p electrons are 12.1 eV and 13.6 eV, respectively. Calculate the energies and composition of the bonding and antibonding orbitals of XeO. Use  $\beta = -1.2 \text{ eV}$  and  $S = 0$ .

**10.15(a)** Repeat Exercise 10.14a but with  $S = 0.20$ .

**10.15(b)** Repeat Exercise 10.14b but with  $S = 0.20$ .

**10.16(a)** Construct the molecular orbital energy level diagrams of ethene on the basis that the molecule is formed from the appropriately hybridized  $\text{CH}_2$  or CH fragments.

**10.16(b)** Construct the molecular orbital energy level diagrams of ethyne (acetylene) on the basis that the molecule is formed from the appropriately hybridized  $\text{CH}_2$  or CH fragments.

**10.17(a)** Write down the secular determinants for (a) linear  $\text{H}_3$ , (b) cyclic  $\text{H}_3$  within the Hückel approximation. Estimate the binding energy in each case.

**10.17(b)** Write down the secular determinant for the allyl radical,  $\text{CH}_2=\text{CH}-\text{CH}_2$  and estimate the  $\pi$ -binding energy.

**10.18(a)** Predict the electronic configurations of (a) the benzene anion, (b) the benzene cation. Estimate the  $\pi$ -electron binding energy in each case within the Hückel approximation. *Hint.* Use mathematical software.

**10.18(b)** Predict the electronic configurations of (a) the naphthalene anion, (b) the naphthalene cation. Estimate the  $\pi$ -electron binding energy in each case within the Hückel approximation. *Hint.* Use mathematical software.

**10.19(a)** Use mathematical software to estimate the  $\pi$ -electron binding energy of (a) anthracene (8), (b) phenanthrene (9) within the Hückel approximation.

8 Anthracene

9 Phenanthrene

**10.19(b)** Use mathematical software to estimate the  $\pi$ -electron binding energy of azulene (10) within the Hückel approximation.

10 Azulene

## Problems\*

### Numerical and graphical problems

**10.1** Show graphically that, if a wave  $\cos kx$  centred on A (so that  $x$  is measured from A) interferes with a similar wave  $\cos k'x$  centred on B (with  $x$  measured from B) a distance  $R$  away, then constructive interference occurs in the intermediate region when  $k = k' = \pi/2R$  and destructive interference if  $kR = \frac{1}{2}\pi$  and  $k'R = \frac{3}{2}\pi$ .

**10.2** Before doing the calculation below, sketch how the overlap between a 1s orbital and a 2p orbital can be expected to depend on their separation. The overlap integral between an H1s orbital and an H2p orbital on nuclei separated by a distance  $R$  and forming a  $\sigma$  orbital is  $S = \frac{1}{2}(R/a_0)\{1 + (R/a_0) + \frac{1}{3}(R/a_0)^2\}e^{-R/a_0}$ . Plot this function, and find the separation for which the overlap is a maximum.

**10.3** Calculate the total amplitude of the normalized bonding and antibonding LCAO-MOs that may be formed from two H1s orbitals at

a separation of 106 pm. Plot the two amplitudes for positions along the molecular axis both inside and outside the internuclear region.

**10.4** Repeat the calculation in Problem 10.3 but plot the probability densities of the two orbitals. Then form the difference density, the difference between  $\psi^2$  and  $\frac{1}{2}\{\psi_A^2 + \psi_B^2\}$ .

**10.5†** Use the  $2p_x$  and  $2p_z$  hydrogenic atomic orbitals to construct simple LCAO descriptions of  $2p\sigma$  and  $2p\pi$  molecular orbitals. (a) Make a probability density plot, and both surface and contour plots of the  $xz$ -plane amplitudes of the  $2p_z\sigma$  and  $2p_z\sigma^*$  molecular orbitals. (b) Make surface and contour plots of the  $xz$ -plane amplitudes of the  $2p_x\pi$  and  $2p_x\pi^*$  molecular orbitals. Include plots for both internuclear distances,  $R$ , of  $10a_0$  and  $3a_0$ , where  $a_0 = 52.9 \text{ pm}$ . Interpret the graphs, and describe why this graphical information is useful.

**10.6** Imagine a small electron-sensitive probe of volume  $1.00 \text{ pm}^3$  inserted into an  $\text{H}_2^+$  molecule-ion in its ground state. Calculate the probability that it

\* Problems denoted with the symbol † were supplied by Charles Trapp, Carmen Giunta, and Marshall Cady.

will register the presence of an electron at the following positions: (a) at nucleus A, (b) at nucleus B, (c) halfway between A and B, (c) at a point 20 pm along the bond from A and 10 pm perpendicularly. Do the same for the molecule-ion the instant after the electron has been excited into the antibonding LCAO-MO.

**10.7‡** J.G. Dojahn *et al.* (*J. Phys. Chem.* **100**, 9649 (1996)) characterized the potential energy curves of homonuclear diatomic halogen molecules and molecular anions. Among the properties they report are the equilibrium internuclear distance  $R_e$ , the vibrational wavenumber,  $\tilde{\nu}$ , and the dissociation energy,  $D_e$ :

| Species        | $R_e$ | $\tilde{\nu}/\text{cm}^{-1}$ | $D_e/\text{eV}$ |
|----------------|-------|------------------------------|-----------------|
| $\text{F}_2$   | 1.411 | 916.6                        | 1.60            |
| $\text{F}_2^-$ | 1.900 | 450.0                        | 1.31            |

Rationalize these data in terms of molecular orbital configurations.

**10.8** In a particular photoelectron spectrum using 21.21 eV photons, electrons were ejected with kinetic energies of 10.01 eV, 8.23 eV, and 5.22 eV. Sketch the molecular orbital energy level diagram for the species, showing the ionization energies of the three identifiable orbitals.

**10.9‡** Set up and solve the Hückel secular equations for the  $\pi$  electrons of  $\text{NO}_3^-$ . Express the energies in terms of the Coulomb integrals  $\alpha_O$  and  $\alpha_N$  and the resonance integral  $\beta$ . Determine the delocalization energy of the ion.

**10.10** In the ‘free electron molecular orbital’ (FEMO) theory, the electrons in a conjugated molecule are treated as independent particles in a box of length  $L$ . Sketch the form of the two occupied orbitals in butadiene predicted by this model and predict the minimum excitation energy of the molecule. The tetraene  $\text{CH}_2=\text{CHCH}=\text{CHCH}=\text{CH}_2$  can be treated as a box of length  $8R$ , where  $R \approx 140$  pm (as in this case, an extra half bond-length is often added at each end of the box). Calculate the minimum excitation energy of the molecule and sketch the HOMO and LUMO. Estimate the colour a sample of the compound is likely to appear in white light.

**10.11** The FEMO theory (Problem 10.10) of conjugated molecules is rather crude and better results are obtained with simple Hückel theory. (a) For a linear conjugated polyene with each of  $N_C$  carbon atoms contributing an electron in a 2p orbital, the energies  $E_k$  of the resulting  $\pi$  molecular orbitals are given by

$$E_k = \alpha + 2\beta \cos \frac{k\pi}{N_C + 1} \quad k = 1, 2, 3, \dots, N_C$$

Use this expression to determine a reasonable empirical estimate of the resonance integral  $\beta$  for the homologous series consisting of ethene, butadiene, hexatriene, and octatetraene given that  $\pi^* \leftarrow \pi$  ultraviolet absorptions from the HOMO to the LUMO occur at 61 500, 46 080, 39 750, and 32 900  $\text{cm}^{-1}$ , respectively. (b) Calculate the  $\pi$ -electron delocalization energy,  $E_{\text{deloc}} = E_\pi - N_\pi(\alpha + \beta)$ , of octatetraene, where  $E_\pi$  is the total  $\pi$ -electron binding energy and  $N_\pi$  is the total number of  $\pi$  electrons. (c) In the context of this Hückel model, the  $\pi$  molecular orbitals are written as linear combinations of the carbon 2p orbitals. The coefficient of the  $j$ th atomic orbital in the  $k$ th molecular orbital is given by

$$c_{kj} = \left( \frac{2}{N_C + 1} \right)^{1/2} \sin \frac{jk\pi}{N_C + 1} \quad j = 1, 2, 3, \dots, N_C$$

Determine the values of the coefficients of each of the six 2p orbitals in each of the six  $\pi$  molecular orbitals of hexatriene. Match each set of coefficients (that is, each molecular orbital) with a value of the energy calculated with the expression given in part (a) of the molecular orbital. Comment on trends that relate the energy of a molecular orbital with its ‘shape’, which can be inferred from the magnitudes and signs of the coefficients in the linear combination that describes the molecular orbital.

**10.12** For monocyclic conjugated polyenes (such as cyclobutadiene and benzene) with each of  $N$  carbon atoms contributing an electron in a 2p orbital, simple Hückel theory gives the following expression for the energies  $E_k$  of the resulting  $\pi$  molecular orbitals:

$$E_k = \alpha + 2\beta \cos \frac{2k\pi}{N_C} \quad \begin{aligned} k &= 0, \pm 1, \pm 2, \dots, \pm N_C/2 \text{ (even } N) \\ k &= 0, \pm 1, \pm 2, \dots, \pm (N_C - 1)/2 \text{ (odd } N) \end{aligned}$$

(a) Calculate the energies of the  $\pi$  molecular orbitals of benzene and cyclooctatetraene. Comment on the presence or absence of degenerate energy levels. (b) Calculate and compare the delocalization energies of benzene (using the expression above) and hexatriene (see Problem 10.11a). What do you conclude from your results? (c) Calculate and compare the delocalization energies of cyclooctaene and octatetraene. Are your conclusions for this pair of molecules the same as for the pair of molecules investigated in part (b)?

**10.13** Molecular orbital calculations based on semi-empirical, *ab initio*, and DFT methods describe the spectroscopic properties of conjugated molecules better than simple Hückel theory. (a) Using molecular modelling software and the computational method of your choice (semi-empirical, *ab initio*, or density functional methods), calculate the energy separation between the HOMO and LUMO of ethene, butadiene, hexatriene, and octatetraene. (b) Plot the HOMO–LUMO energy separations against the experimental frequencies for  $\pi^* \leftarrow \pi$  ultraviolet absorptions for these molecules (Problem 10.11). Use mathematical software to find the polynomial equation that best fits the data. (c) Use your polynomial fit from part (b) to estimate the frequency of the  $\pi^* \leftarrow \pi$  ultraviolet absorption of decapentaene from the calculated HOMO–LUMO energy separation. (d) Discuss why the calibration procedure of part (b) is necessary.

**10.14** Electronic excitation of a molecule may weaken or strengthen some bonds because bonding and antibonding characteristics differ between the HOMO and the LUMO. For example, a carbon–carbon bond in a linear polyene may have bonding character in the HOMO and antibonding character in the LUMO. Therefore, promotion of an electron from the HOMO to the LUMO weakens this carbon–carbon bond in the excited electronic state, relative to the ground electronic state. Display the HOMO and LUMO of each molecule in Problem 10.13 and discuss in detail any changes in bond order that accompany the  $\pi^* \leftarrow \pi$  ultraviolet absorptions in these molecules.

**10.15** As mentioned in Section 2.8b, computational chemistry may be used to estimate the standard enthalpy of formation of molecules in the gas phase. (a) Using molecular modelling software and a semi-empirical method of your choice, calculate the standard enthalpy of formation of ethene, butadiene, hexatriene, and octatetraene in the gas phase. (b) Consult a database of thermochemical data, such as the online sources listed in this textbook’s web site, and, for each molecule in part (a), calculate the relative error between the calculated and experimental values of the standard enthalpy of formation. (c) A good thermochemical database will also report the uncertainty in the experimental value of the standard enthalpy of formation. Compare experimental uncertainties with the relative errors calculated in part (b) and discuss the reliability of your chosen semi-empirical method for the estimation of thermochemical properties of linear polyenes.

### Theoretical problems

**10.16** Use hydrogenic atomic orbitals to write the explicit form of the  $\text{sp}^2$  hybrid orbital  $h_2$  in eqn 10.5. Determine the angle to the  $x$ -axis at which it has maximum amplitude.

**10.17** Show that the  $\text{sp}^2$  hybrids in eqn 10.5 make  $120^\circ$  to each other.

**10.18** Derive eqns 10.12 and 10.15 by working with the normalized LCAO-MOs for the  $\text{H}_2^+$  molecule-ion (Section 10.3a). Proceed by evaluating the expectation value of the hamiltonian for the ion. Make use of the fact that A and B each individually satisfy the Schrödinger equation for an isolated H atom.

**10.19** Show that eqns 10.12 and 10.15 produce the result that

$$\Delta E = E_{2\sigma} - E_{1\sigma} = \frac{2k - 2Sj}{1 - S^2}$$

and go on to use the explicit expressions in eqn 10.13 to explore the range of internuclear separations over which  $\Delta E > 0$ .

**10.20** Confirm the expressions for  $\partial E / \partial c_A$  and  $\partial E / \partial c_B$  derived in *Justification 10.3* (following eqn 10.30).

**10.21** Show that if a matrix  $M$  can be written as  $M = aI + O$ , where  $I$  is the unit matrix and  $O$  has off-diagonal elements, then to diagonalize  $M$  it is sufficient to diagonalize  $O$ . This result was used in Section 10.6b.

**10.22** Show that the solutions of the secular determinant expression

$$\begin{vmatrix} \alpha_A - E & \beta \\ \beta & \alpha_B - E \end{vmatrix} = 0$$

for the orbital basis  $A, B$  can be written in terms of an angle  $\theta$ , with

$$\begin{aligned} E_- &= \alpha_B - \beta \tan \theta & \psi_- &= -A \sin \theta + B \cos \theta \\ E_+ &= \alpha_A + \beta \tan \theta & \psi_+ &= A \cos \theta + B \sin \theta \end{aligned}$$

and  $\theta = \frac{1}{2} \arctan\{2\beta/(\alpha_B - \alpha_A)\}$ .

**10.23** We saw in the *brief illustration* in Section 10.7b that the product of two equivalent one-dimensional Gaussian functions is proportional to a Gaussian function. Repeat the calculation for a one-dimensional heteronuclear system.

**10.24** Derive the three other equations for the HF molecule, the first of which is derived in the first *brief illustration* in *Further information 10.1*.

**10.25** Derive the remaining terms for  $F_{AB}$ , the first of which is derived in the second *brief illustration* in *Further information 10.1*. Go on to identify equalities between the various integrals ( $AB|CD$ ) that you derive.

### Applications: to astrophysics and biology

**10.26†** In Exercise 10.17a you were invited to set up the Hückel secular determinant for linear and cyclic  $H_3$ . The same secular determinant applies to the molecular ions  $H_3^+$  and  $D_3^+$ . The molecular ion  $H_3^+$  was discovered as long ago as 1912 by J.J. Thomson, but only more recently has the equivalent equilateral triangular structure been confirmed by M.J. Gaillard *et al.* (*Phys. Rev. A* 17, 1797 (1978)). The molecular ion  $H_3^+$  is the simplest polyatomic species with a confirmed existence and plays an important role in chemical reactions occurring in interstellar clouds that may lead to the formation of water, carbon monoxide, and ethyl alcohol. The  $H_3^+$  ion has also been found in the atmospheres of Jupiter, Saturn, and Uranus. (a) Solve the Hückel secular equations for the energies of the  $H_3$  system in terms of the parameters  $\alpha$  and  $\beta$ , draw an energy level diagram for the orbitals, and determine the binding energies of  $H_3^+$ ,  $H_3$ , and  $H_3^-$ . (b) Accurate quantum mechanical calculations by G.D. Carney and R.N. Porter (*J. Chem. Phys.* 65, 3547 (1976)) give the dissociation energy for the process  $H_3^+ \rightarrow H + H + H^+$  as  $849 \text{ kJ mol}^{-1}$ . From this information and data in Table 10.3, calculate the enthalpy of the reaction  $H^+(g) + H_2(g) \rightarrow H_3^+(g)$ . (c) From your equations and the information given, calculate a value for the resonance integral  $\beta$  in  $H_3^+$ . Then go on to calculate the binding energies of the other  $H_3$  species in (a).

**10.27†** There is some indication that other hydrogen ring compounds and ions in addition to  $H_3$  and  $D_3$  species may play a role in interstellar chemistry. According to J.S. Wright and G.A. DiLabio (*J. Phys. Chem.* 96, 10793 (1992)),  $H_5^+$ ,  $H_6$ , and  $H_7^+$  are particularly stable whereas  $H_4$  and  $H_5^+$  are not. Confirm these statements by Hückel calculations.

**10.28** Here we develop a molecular orbital theory treatment of the peptide group  $-\text{CONH}-$ , which links amino acids in proteins. Specifically, we shall describe the factors that stabilize the planar conformation of the peptide

group. (a) It will be familiar from introductory chemistry the planar conformation of the peptide group is explained by invoking delocalization of the  $\pi$  bond between the oxygen, carbon, and nitrogen atoms. It follows that we can model the peptide group with molecular orbital theory by making LCAO-MOs from 2p orbitals perpendicular to the plane defined by the O, C, and N atoms. The three combinations have the form:

$$\psi_1 = a\chi_O + b\chi_C + c\chi_N \quad \psi_2 = d\chi_O - e\chi_N \quad \psi_3 = f\chi_O - g\chi_C + h\chi_N$$

where the coefficients  $a$  through  $h$  are all positive. Sketch the orbitals  $\psi_1$ ,  $\psi_2$ , and  $\psi_3$  and characterize them as bonding, non-bonding, or antibonding molecular orbitals. In a non-bonding molecular orbital, a pair of electrons resides in an orbital confined largely to one atom and not appreciably involved in bond formation. (b) Show that this treatment is consistent only with a planar conformation of the peptide link. (c) Draw a diagram showing the relative energies of these molecular orbitals and determine the occupancy of the orbitals. *Hint.* Convince yourself that there are four electrons to be distributed among the molecular orbitals. (d) Now consider a non-planar conformation of the peptide link, in which the O2p and C2p orbitals are perpendicular to the plane defined by the O, C, and N atoms, but the N2p orbital lies on that plane. The LCAO-MOs are given by

$$\psi_4 = a\chi_O + b\chi_C \quad \psi_5 = e\chi_N \quad \psi_6 = f\chi_O - g\chi_C$$

Just as before, sketch these molecular orbitals and characterize them as bonding, non-bonding, or antibonding. Also, draw an energy level diagram and determine the occupancy of the orbitals. (e) Why is this arrangement of atomic orbitals consistent with a non-planar conformation for the peptide link? (f) Does the bonding MO associated with the planar conformation have the same energy as the bonding MO associated with the non-planar conformation? If not, which bonding MO is lower in energy? Repeat the analysis for the non-bonding and anti-bonding molecular orbitals. (g) Use your results from parts (a)–(f) to construct arguments that support the planar model for the peptide link.

**10.29** Molecular orbital calculations may be used to predict trends in the standard potentials of conjugated molecules, such as the quinones and flavins, that are involved in biological electron transfer reactions. It is commonly assumed that decreasing the energy of the LUMO enhances the ability of a molecule to accept an electron into the LUMO, with an attendant increase in the value of the molecule's standard potential. Furthermore, a number of studies indicate that there is a linear correlation between the LUMO energy and the reduction potential of aromatic hydrocarbons. (a) The standard potentials at pH = 7 for the one-electron reduction of methyl-substituted 1,4-benzoquinones (11) to their respective semiquinone radical anions are:

| $R_2$           | $R_3$           | $R_5$           | $R_6$           | $E^\circ/V$ |
|-----------------|-----------------|-----------------|-----------------|-------------|
| H               | H               | H               | H               | 0.078       |
| CH <sub>3</sub> | H               | H               | H               | 0.023       |
| CH <sub>3</sub> | H               | CH <sub>3</sub> | H               | −0.067      |
| CH <sub>3</sub> | CH <sub>3</sub> | CH <sub>3</sub> | H               | −0.165      |
| CH <sub>3</sub> | CH <sub>3</sub> | CH <sub>3</sub> | CH <sub>3</sub> | −0.260      |

Using molecular modelling software and the computational method of your choice (semi-empirical, *ab initio*, or density functional theory methods), calculate  $E_{\text{LUMO}}$ , the energy of the LUMO of each substituted 1,4-benzoquinone, and plot  $E_{\text{LUMO}}$  against  $E^\circ$ . Do your calculations support a linear relation between  $E_{\text{LUMO}}$  and  $E^\circ$ ? (b) The 1,4-benzoquinone for which  $R_2 = R_3 = \text{CH}_3$  and  $R_5 = R_6 = \text{OCH}_3$  is a suitable model of ubiquinone, a component of the respiratory electron transport chain. Determine  $E_{\text{LUMO}}$  of this quinone and then use your results from part (a) to estimate its standard

potential. (c) The 1,4-benzoquinone for which  $R_2 = R_3 = R_5 = \text{CH}_3$  and  $R_6 = \text{H}$  is a suitable model of plastoquinone, a component of the photosynthetic electron transport chain. Determine  $E_{\text{LUMO}}$  of this quinone and then use your results from part (a) to estimate its standard potential. Is plastoquinone expected to be a better or worse oxidizing agent than ubiquinone? (d) Based on your predictions and on basic concepts of biological electron transport, suggest a reason why ubiquinone is used in respiration and plastoquinone is used in photosynthesis.

## MATHEMATICAL BACKGROUND 6

## Matrices

A **matrix** is an array of numbers that are generalizations of ordinary numbers. We shall consider only square matrices, which have the numbers arranged in the same number of rows and columns. By using matrices, we can manipulate large numbers of ordinary numbers simultaneously. A **determinant** is a particular combination of the numbers that appear in a matrix and is used to manipulate the matrix.

Matrices may be combined together by addition or multiplication according to generalizations of the rules for ordinary numbers. Although we describe below the key algebraic procedures involving matrices, it is important to note that most numerical matrix manipulations are now carried out with mathematical software. You are encouraged to use such software, if it is available to you.

## MB6.1 Definitions

Consider a square matrix  $M$  of  $n^2$  numbers arranged in  $n$  columns and  $n$  rows. These  $n^2$  numbers are the **elements** of the matrix, and may be specified by stating the row,  $r$ , and column,  $c$ , at which they occur. Each element is therefore denoted  $M_{rc}$ . A **diagonal matrix** is a matrix in which the only nonzero elements lie on the major diagonal (the diagonal from  $M_{11}$  to  $M_{nn}$ ). Thus, the matrix

$$M = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

is a  $3 \times 3$  diagonal square matrix. The condition may be written

$$M_{rc} = m_r \delta_{rc} \quad (\text{MB6.1})$$

where  $\delta_{rc}$  is the **Kronecker delta**, which is equal to 1 for  $r = c$  and to 0 for  $r \neq c$ . In the above example,  $m_1 = 1$ ,  $m_2 = 2$ , and  $m_3 = 1$ . The **unit matrix**,  $I$  (and occasionally  $I$ ), is a special case of a diagonal matrix in which all nonzero elements are 1.

The **transpose** of a matrix  $M$  is denoted  $M^T$  and is defined by

$$M_{mn}^T = M_{nm} \quad (\text{Transpose}) \quad (\text{MB6.2})$$

That is, the element in row  $n$ , column  $m$  of the original matrix becomes the element in row  $m$ , column  $n$  of the transpose (in effect, the elements are reflected across the diagonal). The **determinant**,  $|M|$ , of the matrix  $M$  is a real number arising from a specific procedure for taking sums and differences of products

of matrix elements. For example, a  $2 \times 2$  determinant is evaluated as

$$\begin{vmatrix} a & b \\ c & d \end{vmatrix} = ad - bc \quad (\text{Determinant}) \quad (\text{MB6.3a})$$

and a  $3 \times 3$  determinant is evaluated by expanding it as a sum of  $2 \times 2$  determinants:

$$\begin{vmatrix} a & b & c \\ d & e & f \\ g & h & i \end{vmatrix} = a \begin{vmatrix} e & f \\ h & i \end{vmatrix} - b \begin{vmatrix} d & f \\ g & i \end{vmatrix} + c \begin{vmatrix} d & e \\ g & h \end{vmatrix} \quad (\text{MB6.3b})$$

$$= a(ei - fh) - b(di - fg) + c(dh - eg)$$

Note the sign change in alternate columns ( $b$  occurs with a negative sign in the expansion). An important property of a determinant is that, if any two rows or any two columns are interchanged, then the determinant changes sign.

## • A brief illustration

The matrix

$$M = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}$$

is a  $2 \times 2$  matrix with the elements  $M_{11} = 1$ ,  $M_{12} = 2$ ,  $M_{21} = 3$ , and  $M_{22} = 4$ . Its transpose is

$$M^T = \begin{pmatrix} 1 & 3 \\ 2 & 4 \end{pmatrix}$$

and its determinant is

$$|M| = \begin{vmatrix} 1 & 2 \\ 3 & 4 \end{vmatrix} = 1 \times 4 - 2 \times 3 = -2 \quad \bullet$$

## MB6.2 Matrix addition and multiplication

Two matrices  $M$  and  $N$  may be added to give the sum  $S = M + N$ , according to the rule

$$S_{rc} = M_{rc} + N_{rc} \quad (\text{Matrix addition}) \quad (\text{MB6.4})$$

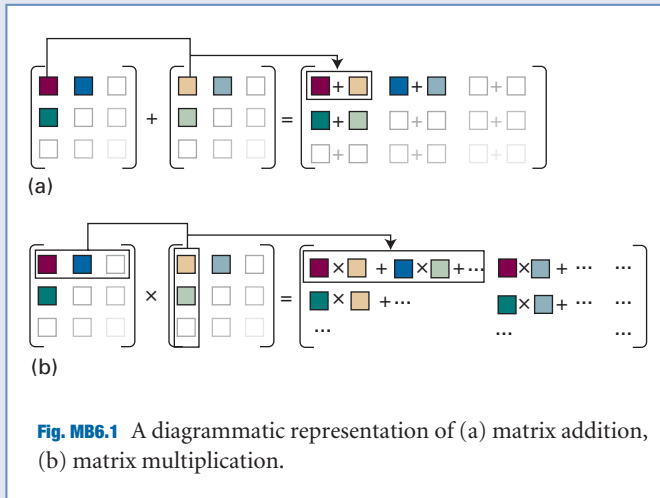

That is, corresponding elements are added.

Two matrices may also be multiplied to give the product  $P = MN$  according to the rule

$$P_{rc} = \sum_n M_{rn} N_{nc} \quad (\text{Matrix multiplication}) \quad (\text{MB6.5})$$

These procedures are illustrated in Fig. MB6.1. It should be noticed that in general  $MN \neq NM$ , and matrix multiplication is in general non-commutative (that is, depends on the order of multiplication).

### • A brief illustration

Consider the matrices

$$M = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} \quad \text{and} \quad N = \begin{pmatrix} 5 & 6 \\ 7 & 8 \end{pmatrix}$$

Their sum is

$$S = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} + \begin{pmatrix} 5 & 6 \\ 7 & 8 \end{pmatrix} = \begin{pmatrix} 6 & 8 \\ 10 & 12 \end{pmatrix}$$

and their product is

$$P = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} \begin{pmatrix} 5 & 6 \\ 7 & 8 \end{pmatrix} = \begin{pmatrix} 1 \times 5 + 2 \times 7 & 1 \times 6 + 2 \times 8 \\ 3 \times 5 + 4 \times 7 & 3 \times 6 + 4 \times 8 \end{pmatrix} = \begin{pmatrix} 19 & 22 \\ 43 & 50 \end{pmatrix} \bullet$$

The inverse of a matrix  $M$  is denoted  $M^{-1}$ , and is defined so that

$$MM^{-1} = M^{-1}M = 1 \quad \text{Inverse} \quad (\text{MB6.6})$$

The inverse of a matrix is best constructed by using mathematical software and the tedious analytical approach is rarely necessary.

### • A brief illustration

Consider the matrix  $M$  from the first *brief illustration* in this section. Mathematical software gives the following result:

$$M^{-1} = \begin{pmatrix} -2 & 1 \\ 3 & -1/2 \end{pmatrix} \bullet$$

## MB6.3 Eigenvalue equations

An eigenvalue equation is an equation of the form

$$Mx = \lambda x \quad \text{Eigenvalue equation} \quad (\text{MB6.7a})$$

where  $M$  is a square matrix with  $n$  rows and  $n$  columns,  $\lambda$  is a constant, the **eigenvalue**, and  $x$  is the **eigenvector**, an  $n \times 1$  (column) matrix that satisfies the conditions of the eigenvalue equation and has the form:

$$x = \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{pmatrix}$$

In general, there are  $n$  eigenvalues  $\lambda^{(i)}$ ,  $i = 1, 2, \dots, n$ , and  $n$  corresponding eigenvectors  $x^{(i)}$ . We write eqn MB6.7a as (noting that  $1x = x$ )

$$(M - \lambda 1)x = 0 \quad (\text{MB6.7b})$$

Equation MB6.7b has a solution only if the determinant  $|M - \lambda 1|$  of the coefficients of the matrix  $M - \lambda 1$  is zero. It follows that the  $n$  eigenvalues may be found from the solution of the **secular equation**:

$$|M - \lambda 1| = 0 \quad (\text{MB6.8})$$

### A brief comment

If the inverse of the matrix  $M - \lambda 1$  exists, then, from eqn MB6.7b,  $(M - \lambda 1)^{-1}(M - \lambda 1)x = x = 0$ , a trivial solution. For a nontrivial solution,  $(M - \lambda 1)^{-1}$  must not exist, which is the case if eqn MB6.8 holds.

### • A brief illustration

Once again we use the matrix  $M$  in the first *brief illustration*, and write eqn MB6.7 as

$$\begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \lambda \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \quad \text{rearranged into} \\ \begin{pmatrix} 1 - \lambda & 2 \\ 3 & 4 - \lambda \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = 0$$

From the rules of matrix multiplication, the latter form expands into

$$\begin{pmatrix} (1 - \lambda)x_1 + 2x_2 \\ 3x_1 + (4 - \lambda)x_2 \end{pmatrix} = 0$$

which is simply a statement of the two simultaneous equations

$$(1 - \lambda)x_1 + 2x_2 = 0 \quad \text{and} \quad 3x_1 + (4 - \lambda)x_2 = 0$$

The condition for these two equations to have solutions is

$$|M - \lambda 1| = \begin{vmatrix} 1 - \lambda & 2 \\ 3 & 4 - \lambda \end{vmatrix} = (1 - \lambda)(4 - \lambda) - 6 = 0$$

This condition corresponds to the quadratic equation

$$\lambda^2 - 5\lambda - 2 = 0$$

with solutions  $\lambda = +5.372$  and  $\lambda = -0.372$ , the two eigenvalues of the original equation. •

The  $n$  eigenvalues found by solving the secular equations are used to find the corresponding eigenvectors. To do so, we begin by considering an  $n \times n$  matrix  $X$  which will be formed from the eigenvectors corresponding to all the eigenvalues. Thus, if the eigenvalues are  $\lambda_1, \lambda_2, \dots$ , and the corresponding eigenvectors are

$$\mathbf{x}^{(1)} = \begin{pmatrix} x_1^{(1)} \\ x_2^{(1)} \\ \vdots \\ x_n^{(1)} \end{pmatrix} \quad \mathbf{x}^{(2)} = \begin{pmatrix} x_1^{(2)} \\ x_2^{(2)} \\ \vdots \\ x_n^{(2)} \end{pmatrix}, \text{ etc.} \quad (\text{MB6.9a})$$

the matrix  $X$  is

$$X = (\mathbf{x}^{(1)}, \mathbf{x}^{(2)}, \dots, \mathbf{x}^{(n)}) = \begin{pmatrix} x_1^{(1)} & x_1^{(2)} & \dots & x_1^{(n)} \\ x_2^{(1)} & x_2^{(2)} & \dots & x_2^{(n)} \\ \vdots & \vdots & \dots & \vdots \\ x_n^{(1)} & x_n^{(2)} & \dots & x_n^{(n)} \end{pmatrix} \quad (\text{MB6.9b})$$

Similarly, we form an  $n \times n$  matrix  $\Lambda$  with the eigenvalues  $\lambda$  along the diagonal and zeroes elsewhere:

$$\Lambda = \begin{pmatrix} \lambda_1 & 0 & \dots & 0 \\ 0 & \lambda_2 & \dots & 0 \\ \vdots & \vdots & \dots & \vdots \\ 0 & 0 & \dots & \lambda_n \end{pmatrix} \quad (\text{MB6.10})$$

Now all the eigenvalue equations  $M\mathbf{x}^{(i)} = \lambda_i \mathbf{x}^{(i)}$  may be confined into the single matrix equation

$$MX = X\Lambda \quad (\text{MB6.11})$$

#### • A brief illustration

In the preceding *brief illustration* we established that if

$$M = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} \text{ then } \lambda_1 = +5.372 \text{ and } \lambda_2 = -0.372, \text{ with eigenvectors}$$

$$\mathbf{x}^{(1)} = \begin{pmatrix} x_1^{(1)} \\ x_2^{(1)} \end{pmatrix} \quad \text{and} \quad \mathbf{x}^{(2)} = \begin{pmatrix} x_1^{(2)} \\ x_2^{(2)} \end{pmatrix}, \quad \text{respectively.}$$

We form

$$X = \begin{pmatrix} x_1^{(1)} & x_1^{(2)} \\ x_2^{(1)} & x_2^{(2)} \end{pmatrix} \quad \Lambda = \begin{pmatrix} 5.372 & 0 \\ 0 & -0.372 \end{pmatrix}$$

The expression  $MX = X\Lambda$  becomes

$$\begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} \begin{pmatrix} x_1^{(1)} & x_1^{(2)} \\ x_2^{(1)} & x_2^{(2)} \end{pmatrix} = \begin{pmatrix} x_1^{(1)} & x_1^{(2)} \\ x_2^{(1)} & x_2^{(2)} \end{pmatrix} \begin{pmatrix} 5.372 & 0 \\ 0 & -0.372 \end{pmatrix}$$

which expands to

$$\begin{pmatrix} x_1^{(1)} + 2x_2^{(1)} & x_1^{(2)} + 2x_2^{(2)} \\ 3x_1^{(1)} + 4x_2^{(1)} & 3x_1^{(2)} + 4x_2^{(2)} \end{pmatrix} = \begin{pmatrix} 5.372x_1^{(1)} & -0.372x_1^{(2)} \\ 5.372x_2^{(1)} & -0.372x_2^{(2)} \end{pmatrix}$$

This is a compact way of writing the four equations

$$\begin{aligned} x_1^{(1)} + 2x_2^{(1)} &= 5.372x_1^{(1)} & x_1^{(2)} + 2x_2^{(2)} &= -0.372x_1^{(2)} \\ 3x_1^{(1)} + 4x_2^{(1)} &= 5.372x_2^{(1)} & 3x_1^{(2)} + 4x_2^{(2)} &= -0.372x_2^{(2)} \end{aligned}$$

corresponding to the two original simultaneous equations and their two roots. •

Finally, we form  $X^{-1}$  from  $X$  and multiply eqn MB6.11 by it from the left:

$$X^{-1}MX = X^{-1}X\Lambda = \Lambda \quad (\text{MB6.12})$$

A structure of the form  $X^{-1}MX$  is called a **similarity transformation**. In this case the similarity transformation  $X^{-1}MX$  makes  $M$  diagonal (because  $\Lambda$  is diagonal). It follows that, if the matrix  $X$  that causes  $X^{-1}MX$  to be diagonal is known, then the problem is solved: the diagonal matrix so produced has the eigenvalues as its only nonzero elements, and the matrix  $X$  used to bring about the transformation has the corresponding eigenvectors as its columns. As will be appreciated once again, the solutions of eigenvalue equations are best found by using mathematical software.

#### • A brief illustration

To apply the similarity transformation, eqn MB6.12, to the matrix

$$\begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} \text{ from the preceding } \textit{brief illustration} \text{ it is best to use}$$

mathematical software to find the form of  $X$ . The result is

$$X = \begin{pmatrix} 0.416 & 0.825 \\ 0.909 & -0.566 \end{pmatrix}$$

This result can be verified by carrying out the multiplication

$$\begin{aligned} X^{-1}MX &= \begin{pmatrix} 0.574 & 0.837 \\ 0.922 & -0.422 \end{pmatrix} \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} \begin{pmatrix} 0.416 & 0.825 \\ 0.909 & -0.566 \end{pmatrix} \\ &= \begin{pmatrix} 5.372 & 0 \\ 0 & -0.372 \end{pmatrix} \end{aligned}$$

The result is indeed the diagonal matrix  $\Lambda$  calculated in the preceding *brief illustration*. It follows that the eigenvectors  $\mathbf{x}^{(1)}$  and  $\mathbf{x}^{(2)}$  are

$$\mathbf{x}^{(1)} = \begin{pmatrix} 0.416 \\ 0.909 \end{pmatrix} \quad \text{and} \quad \mathbf{x}^{(2)} = \begin{pmatrix} 0.825 \\ -0.566 \end{pmatrix} \quad \bullet$$

# Molecular symmetry

In this chapter we sharpen the concept of ‘shape’ into a precise definition of ‘symmetry’, and show that symmetry may be discussed systematically. We see how to classify any molecule according to its symmetry and how to use this classification to discuss molecular properties. After describing the symmetry properties of molecules themselves, we turn to a consideration of the effect of symmetry transformations on orbitals and see that their transformation properties can be used to set up a labelling scheme. These symmetry labels are used to identify integrals that necessarily vanish. One important integral is the overlap integral between two orbitals. By knowing which atomic orbitals may have nonzero overlap, we can decide which ones can contribute to molecular orbitals. We also see how to select linear combinations of atomic orbitals that match the symmetry of the nuclear framework. Finally, by considering the symmetry properties of integrals, we see that it is possible to derive the selection rules that govern spectroscopic transitions.

The systematic discussion of symmetry is called **group theory**. Much of group theory is a summary of common sense about the symmetries of objects. However, because group theory is systematic, its rules can be applied in a straightforward, mechanical way. In most cases the theory gives a simple, direct method for arriving at useful conclusions with the minimum of calculation, and this is the aspect we stress here. In some cases, though, it leads to unexpected results.

## The symmetry elements of objects

Some objects are ‘more symmetrical’ than others. A sphere is more symmetrical than a cube because it looks the same after it has been rotated through any angle about any diameter. A cube looks the same only if it is rotated through certain angles about specific axes, such as  $90^\circ$ ,  $180^\circ$ , or  $270^\circ$  about an axis passing through the centres of any of its opposite faces (Fig. 11.1), or by  $120^\circ$  or  $240^\circ$  about an axis passing through any of its opposite corners. Similarly, an  $\text{NH}_3$  molecule is ‘more symmetrical’ than an  $\text{H}_2\text{O}$  molecule because  $\text{NH}_3$  looks the same after rotations of  $120^\circ$  or  $240^\circ$  about the axis shown in Fig. 11.2, whereas  $\text{H}_2\text{O}$  looks the same only after a rotation of  $180^\circ$ .

An action that leaves an object looking the same after it has been carried out is called a **symmetry operation**. Typical symmetry operations include rotations, reflections, and inversions. There is a corresponding **symmetry element** for each symmetry operation, which is the point, line, or plane with respect to which the symmetry operation is performed. For instance, a rotation (a symmetry operation) is carried out around an axis (the corresponding symmetry element). We shall see that we can classify molecules by identifying all their symmetry elements, and grouping together

Problems

**Fig. 11.1** Some of the symmetry elements of a cube. The twofold, threefold, and fourfold axes are labelled with the conventional symbols.

**Fig. 11.2** (a) An  $\text{NH}_3$  molecule has a threefold ( $C_3$ ) axis and (b) an  $\text{H}_2\text{O}$  molecule has a twofold ( $C_2$ ) axis. Both have other symmetry elements too.

molecules that possess the same set of symmetry elements. This procedure, for example, puts the trigonal pyramidal species  $\text{NH}_3$  and  $\text{SO}_3^{2-}$  into one group and the angular species  $\text{H}_2\text{O}$  and  $\text{SO}_2$  into another group.

## 11.1 Operations and symmetry elements

**Key points** (a) Group theory is concerned with symmetry operations and the symmetry elements with which they are associated; point groups are composed of symmetry operations that preserve a single point. (b) A set of operations form a group if they satisfy certain criteria.

The classification of objects according to symmetry elements corresponding to operations that leave at least one common point unchanged gives rise to the **point groups**. There are five kinds of symmetry operation (and five kinds of symmetry element) of this kind. When we consider crystals (Chapter 19), we shall meet symmetries arising from translation through space. These more extensive groups are called **space groups**.

### (a) Notation

The **identity**,  $E$ , consists of doing nothing; the corresponding symmetry element is the entire object. Because every molecule is indistinguishable from itself if nothing is done to it, every object possesses at least the identity element. One reason for including the identity is that some molecules have only this symmetry element (1); another reason is technical and connected with the detailed formulation of group theory.

An  $n$ -fold rotation (the operation) about an  $n$ -fold axis of symmetry,  $C_n$  (the corresponding element) is a rotation through  $360^\circ/n$ . The operation  $C_1$  is a rotation through  $360^\circ$ , and is equivalent to the identity operation  $E$ . An  $\text{H}_2\text{O}$  molecule has one twofold axis,  $C_2$ . There is only one twofold rotation associated with a  $C_2$  axis because clockwise and counterclockwise  $180^\circ$  rotations have an identical outcome. An  $\text{NH}_3$  molecule has one threefold axis,  $C_3$ , with which is associated two symmetry operations, one being  $120^\circ$  rotation in a clockwise sense and the other  $120^\circ$  rotation in a counterclockwise sense. A pentagon has a  $C_5$  axis, with two (clockwise and counterclockwise) rotations through  $72^\circ$  associated with it. It also has an axis denoted  $C_5^2$ , corresponding to two successive  $C_5$  rotations; there are two such operations, one through  $144^\circ$  in a clockwise sense and the other through  $144^\circ$  in a counterclockwise sense. A cube has three  $C_4$  axes, four  $C_3$  axes, and six  $C_2$  axes. However, even this high symmetry is exceeded by a sphere, which possesses an infinite number of symmetry axes (along any diameter) of all possible integral values of  $n$ . If a molecule possesses several rotation axes, then the one (or more) with the greatest value of  $n$  is called the **principal axis**. The principal axis of a benzene molecule is the sixfold axis perpendicular to the hexagonal ring (2).

A **reflection** (the operation) in a **mirror plane**,  $\sigma$  (the element), may contain the principal axis of a molecule or be perpendicular to it. If the plane is parallel to the principal axis, it is called 'vertical' and denoted  $\sigma_v$ . An  $\text{H}_2\text{O}$  molecule has two vertical

**Fig. 11.3** An  $\text{H}_2\text{O}$  molecule has two mirror planes. They are both vertical (i.e. contain the principal axis), so are denoted  $\sigma_v$  and  $\sigma'_v$ .

**Fig. 11.4** Dihedral mirror planes ( $\sigma_d$ ) bisect the  $C_2$  axes perpendicular to the principal axis.

**Fig. 11.5** A regular octahedron has a centre of inversion ( $i$ ).

planes of symmetry (Fig. 11.3) and an  $\text{NH}_3$  molecule has three. A vertical mirror plane that bisects the angle between two  $C_2$  axes is called a ‘dihedral plane’ and is denoted  $\sigma_d$  (Fig. 11.4). When the plane of symmetry is perpendicular to the principal axis it is called ‘horizontal’ and denoted  $\sigma_h$ . A  $\text{C}_6\text{H}_6$  molecule has a  $C_6$  principal axis and a horizontal mirror plane (as well as several other symmetry elements).

In an **inversion** (the operation) through a **centre of symmetry**,  $i$  (the element), we imagine taking each point in a molecule, moving it to the centre of the molecule, and then moving it out the same distance on the other side; that is, the point  $(x, y, z)$  is taken into the point  $(-x, -y, -z)$ . Neither an  $\text{H}_2\text{O}$  molecule nor an  $\text{NH}_3$  molecule has a centre of inversion, but a sphere and a cube do have one. A  $\text{C}_6\text{H}_6$  molecule does have a centre of inversion, as does a regular octahedron (Fig. 11.5); a regular tetrahedron and a  $\text{CH}_4$  molecule do not.

An  **$n$ -fold improper rotation** (the operation) about an  **$n$ -fold axis of improper rotation** or an  **$n$ -fold improper rotation axis**,  $S_n$  (the symmetry element), is composed of two successive transformations, neither of which alone is necessarily a symmetry operation. The first component is a rotation through  $360^\circ/n$ , and the second is a reflection through a plane perpendicular to the axis of that rotation; neither operation alone needs to be a symmetry operation. A  $\text{CH}_4$  molecule has three  $S_4$  axes (Fig. 11.6).

### (b) The criteria for being a group

In mathematics, a ‘group’ has a special meaning and is the basis of the name ‘group theory’ for the quantitative description of symmetry. A set of operations constitute a **group** if they satisfy the following criteria:

- The identity operation is a member of the set.
- The inverse of each operation is a member of the set.
- If  $R$  and  $S$  are members of the set, then the operation  $RS$  is also a member.

These criteria are satisfied by a large number of objects, but our concern is with symmetry operations, and we confine our remarks to them.

It is quite easy to see that the symmetry operations of a molecule fulfil the criteria that let them qualify as a group. First, we have seen that every molecule possesses the identity operation  $E$ . To judge whether the inverse of a symmetry operation is always present we need to note whether for each operation we can find another operation (or the same operation) that brings the molecule back to its original state. A reflection applied twice in succession (which we denote  $\sigma\sigma$ ) is one example. A clockwise  $n$ -fold rotation followed by a counterclockwise  $n$ -fold rotation (denoted  $C_n^-C_n^+$ ) is another

**Fig. 11.6** (a) A  $\text{CH}_4$  molecule has a fourfold improper rotation axis ( $S_4$ ): the molecule is indistinguishable after a  $90^\circ$  rotation followed by a reflection across the horizontal plane, but neither operation alone is a symmetry operation. (b) The staggered form of ethane has an  $S_6$  axis composed of a  $60^\circ$  rotation followed by a reflection.

example. To every symmetry operation of a molecule there corresponds an inverse and, provided we include both, criterion 2 is satisfied.

The third criterion is very special, and is called the **group property**. It states that, if two symmetry operations are carried out in succession, then the outcome is equivalent to a *single* symmetry operation. For example, two clockwise threefold rotations applied in succession, giving an overall rotation of  $240^\circ$ , is equivalent to a single counterclockwise rotation, so we can write  $C_3^+C_3^+ = C_3^-$  and in this case two operations applied in succession are equivalent to a single operation. A twofold rotation through  $180^\circ$  followed by a reflection in a horizontal plane is equivalent to an inversion, so we can write  $\sigma_h C_2 = i$ . Once again, we see that successive operations are equivalent to a single operation, as criterion 3 requires.

All the symmetry operations of molecules satisfy the three criteria for them constituting a group, so we are justified in calling the theory of symmetry ‘group theory’ and using the powerful apparatus that mathematicians have assembled.

## 11.2 The symmetry classification of molecules

**Key point** Molecules are classified according to the symmetry elements they possess.

To classify molecules according to their symmetries, we list their symmetry elements and collect together molecules with the same list of elements. This procedure puts  $\text{CH}_4$  and  $\text{CCl}_4$ , which both possess the same symmetry elements as a regular tetrahedron, into the same group, and  $\text{H}_2\text{O}$  into another group.

The name of the group to which a molecule belongs is determined by the symmetry elements it possesses. There are two systems of notation (Table 11.1). The **Schoenflies system** (in which a name looks like  $C_{4v}$ ) is more common for the discussion of individual molecules, and the **Hermann–Mauguin system**, or **International system** (in which a name looks like  $4mm$ ), is used almost exclusively in the discussion of crystal symmetry. The identification of a molecule’s point group according to the Schoenflies system, which we outline below, is simplified by referring to the flow diagram in Fig. 11.7 and the shapes shown in Fig. 11.8.

**Table 11.1** The notation for point groups\*

|       |           |          |             |          |             |          |             |          |           |
|-------|-----------|----------|-------------|----------|-------------|----------|-------------|----------|-----------|
| $C_i$ | $\bar{1}$ |          |             |          |             |          |             |          |           |
| $C_s$ | $m$       |          |             |          |             |          |             |          |           |
| $C_1$ | 1         | $C_2$    | 2           | $C_3$    | 3           | $C_4$    | 4           | $C_6$    | 6         |
|       |           | $C_{2v}$ | $2mm$       | $C_{3v}$ | $3m$        | $C_{4v}$ | $4mm$       | $C_{6v}$ | $6mm$     |
|       |           | $C_{2h}$ | $2m$        | $C_{3h}$ | $\bar{6}$   | $C_{4h}$ | $4/m$       | $C_{6h}$ | $6/m$     |
|       |           | $D_2$    | 222         | $D_3$    | 32          | $D_4$    | 422         | $D_6$    | 622       |
|       |           | $D_{2h}$ | $mmm$       | $D_{3h}$ | $\bar{6}2m$ | $D_{4h}$ | $4/mmm$     | $D_{6h}$ | $6/mmm$   |
|       |           | $D_{2d}$ | $\bar{4}2m$ | $D_{3d}$ | $\bar{3}m$  | $S_4$    | $\bar{4}/m$ | $S_6$    | $\bar{3}$ |
| $T$   | 23        | $T_d$    | $\bar{4}3m$ | $T_h$    | $m\bar{3}$  |          |             |          |           |
| $O$   | 432       | $O_h$    | $m\bar{3}m$ |          |             |          |             |          |           |

\* In the International system (or Hermann–Mauguin system) for point groups, a number  $n$  denotes the presence of an  $n$ -fold axis and  $m$  denotes a mirror plane. A slash (/) indicates that the mirror plane is perpendicular to the symmetry axis. It is important to distinguish symmetry elements of the same type but of different classes, as in  $4/mmm$ , in which there are three classes of mirror plane. A bar over a number indicates that the element is combined with an inversion. The only groups listed here are the so-called ‘crystallographic point groups’ (Section 19.1).

**Fig. 11.7** A flow diagram for determining the point group of a molecule. Start at the top and answer the question posed in each diamond (Y = yes, N = no).

| $n =$    | 2                      | 3 | 4 | 5 | 6 | $\infty$ |
|----------|------------------------|---|---|---|---|----------|
| $C_n$    |                        |   |   |   |   |          |
| $D_n$    |                        |   |   |   |   |          |
| $C_{nv}$ | <br>Pyramid            |   |   |   |   |          |
| $C_{nh}$ |                        |   |   |   |   |          |
| $D_{nh}$ | <br>Plane or bipyramid |   |   |   |   |          |
| $D_{nd}$ |                        |   |   |   |   |          |
| $S_{2n}$ |                        |   |   |   |   |          |

**Fig. 11.8** A summary of the shapes corresponding to different point groups. The group to which a molecule belongs can often be identified from this diagram without going through the formal procedure in Fig. 11.7.

**Fig. 11.9** The presence of a twofold axis and a horizontal mirror plane jointly imply the presence of a centre of inversion in the molecule.

### (a) The groups *C*<sub>1</sub>, *C*<sub>i</sub>, and *C*<sub>s</sub>

A molecule belongs to the group *C*<sub>1</sub> if it has no element other than the identity, as in (1). It belongs to *C*<sub>i</sub> if it has the identity and the inversion alone (3), and to *C*<sub>s</sub> if it has the identity and a mirror plane alone (4).

### (b) The groups *C*<sub>*n*</sub>, *C*<sub>*n**v*</sub>, and *C*<sub>*n**h*</sub>

A molecule belongs to the group *C*<sub>*n*</sub> if it possesses an *n*-fold axis. Note that the symbol *C*<sub>*n*</sub> is now playing a triple role: as the label of a symmetry element, a symmetry operation, and the name of a group. For example, an H<sub>2</sub>O<sub>2</sub> molecule has the elements *E* and *C*<sub>2</sub> (5), so it belongs to the group *C*<sub>2</sub>.

If in addition to the identity and a *C*<sub>*n*</sub> axis a molecule has *n* vertical mirror planes *σ*<sub>*v*</sub>, then it belongs to the group *C*<sub>*n**v*</sub>. An H<sub>2</sub>O molecule, for example, has the symmetry elements *E*, *C*<sub>2</sub>, and 2*σ*<sub>*v*</sub>, so it belongs to the group *C*<sub>2*v*</sub>. An NH<sub>3</sub> molecule has the elements *E*, *C*<sub>3</sub>, and 3*σ*<sub>*v*</sub>, so it belongs to the group *C*<sub>3*v*</sub>. A heteronuclear diatomic molecule such as HCl belongs to the group *C*<sub>∞*v*</sub> because all rotations around the axis and reflections across the axis are symmetry operations. Other members of the group *C*<sub>∞*v*</sub> include the linear OCS molecule and a cone.

Objects that in addition to the identity and an *n*-fold principal axis also have a horizontal mirror plane *σ*<sub>*h*</sub> belong to the groups *C*<sub>*n**h*</sub>. An example is *trans*-CHCl=CHCl (6), which has the elements *E*, *C*<sub>2</sub>, and *σ*<sub>*h*</sub>, so belongs to the group *C*<sub>2*h*</sub>; the molecule B(OH)<sub>3</sub> in the conformation shown in (7) belongs to the group *C*<sub>3*h*</sub>. The presence of certain symmetry elements may be implied by the presence of others: thus, in *C*<sub>2*h*</sub> the operations *C*<sub>2</sub> and *σ*<sub>*h*</sub> jointly imply the presence of a centre of inversion (Fig. 11.9).

6 *trans*-CHCl=CHCl

7 B(OH)<sub>3</sub>

### (c) The groups *D*<sub>*n*</sub>, *D*<sub>*n**h*</sub>, and *D*<sub>*n**d*</sub>

We see from Fig. 11.7 that a molecule that has an *n*-fold principal axis and *n* twofold axes perpendicular to *C*<sub>*n*</sub> belongs to the group *D*<sub>*n*</sub>. A molecule belongs to *D*<sub>*n**h*</sub> if it also possesses a horizontal mirror plane. The planar trigonal BF<sub>3</sub> molecule has the elements *E*, *C*<sub>3</sub>, 3*C*<sub>2</sub>, and *σ*<sub>*h*</sub> (with one *C*<sub>2</sub> axis along each B–F bond), so belongs to *D*<sub>3*h*</sub> (8). The C<sub>6</sub>H<sub>6</sub> molecule has the elements *E*, *C*<sub>6</sub>, 3*C*<sub>2</sub>, 3*C*<sub>2</sub><sup>′</sup>, and *σ*<sub>*h*</sub> together with some others that these elements imply, so it belongs to *D*<sub>6*h*</sub>. The prime on 3*C*<sub>2</sub><sup>′</sup> indicates that these three twofold axes are different from the other three twofold axes. In benzene, three of the *C*<sub>2</sub> axes bisect C–C bonds and the other three pass through vertices of the hexagon formed by the carbon framework of the molecule. All homonuclear diatomic molecules, such as N<sub>2</sub>, belong to the group *D*<sub>∞*h*</sub> because all rotations around the axis are symmetry operations, as are end-to-end rotation and end-to-end reflection; *D*<sub>∞*h*</sub> is also the group of the linear OCO and HCCH molecules and of a uniform cylinder. Other examples of *D*<sub>*n**h*</sub> molecules are shown in (9), (10), and (11).

A molecule belongs to the group *D*<sub>*n**d*</sub> if in addition to the elements of *D*<sub>*n*</sub> it possesses *n* dihedral mirror planes *σ*<sub>*d*</sub>. The twisted, 90° allene (12) belongs to *D*<sub>2*d*</sub>, and the staggered conformation of ethane (13) belongs to *D*<sub>3*d*</sub>.

#### • A brief illustration

'Host' molecules, such as the bowl-shaped cryptophans, that encapsulate smaller 'guest' molecules have become a focus of interest for a wide variety of applications. Host-guest complexes are an important means of constructing nanoscale devices, selectively separating mixtures of small molecules on the basis of chemical and physical properties, delivering biologically active molecules to target cells, and providing unique environments to catalyse reactions. The shape of the host can influence both the encapsulation of guest molecules and the potential application of the complex. The anti and syn cryptophan isomers (14) and (15), for instance, belong to the groups  $D_3$  and  $C_{3h}$ , respectively. •

14

15

#### • Another brief illustration

Cucurbiturils are pumpkin-shaped water-soluble compounds composed of six, seven, or eight glycouril (16) units with a hydrophilic exterior and a hydrophobic interior cavity. With six glycouril units, for example, the host (17) belongs to the group  $D_{6h}$ . •

16 Glycouril

18 Tetraphenylmethane,  $C(C_6H_5)_4$  ( $S_4$ )19 Buckminsterfullerene,  $C_{60}$  ( $I$ )**(d) The groups  $S_n$** 

Molecules that have not been classified into one of the groups mentioned so far, but that possess one  $S_n$  axis, belong to the group  $S_n$ . An example is tetraphenylmethane, which belongs to the point group  $S_4$  (18). Molecules belonging to  $S_n$  with  $n > 4$  are rare. Note that the group  $S_2$  is the same as  $C_i$ , so such a molecule will already have been classified as  $C_i$ .

**(e) The cubic groups**

A number of very important molecules (e.g.  $CH_4$  and  $SF_6$ ) possess more than one principal axis. Most belong to the **cubic groups**, and in particular to the **tetrahedral groups**  $T$ ,  $T_d$ , and  $T_h$  (Fig. 11.10a) or to the **octahedral groups**  $O$  and  $O_h$  (Fig. 11.10b). A few icosahedral (20-faced) molecules belonging to the **icosahedral group**,  $I$  (Fig. 11.10c), are also known: they include some of the boranes and buckminsterfullerene,  $C_{60}$  (19). The groups  $T_d$  and  $O_h$  are the groups of the regular tetrahedron (for instance,  $CH_4$ ) and the regular octahedron (for instance,  $SF_6$ ), respectively. If the object possesses the rotational symmetry of the tetrahedron or the octahedron, but none of their planes of reflection, then it belongs to the simpler groups  $T$  or  $O$  (Fig. 11.11). The group  $T_h$  is based on  $T$  but also contains a centre of inversion (Fig. 11.12).

(a)

(b)

(c)

**Fig. 11.10** (a) Tetrahedral, (b) octahedral, and (c) icosahedral molecules are drawn in a way that shows their relation to a cube: they belong to the cubic groups  $T_d$ ,  $O_h$ , and  $I_h$ , respectively.

(a)

(b)

**Fig. 11.11** Shapes corresponding to the point groups (a)  $T$  and (b)  $O$ . The presence of the decorated slabs reduces the symmetry of the object from  $T_d$  and  $O_h$ , respectively.

#### • A brief illustration

The ion  $[\text{Ag}_8\text{Ni}_6\{\text{SC}(\text{Me})_2\text{CH}(\text{NH}_2)\text{CO}_2\}_{12}\text{Cl}]^{5-}$  (20) is a tetrahedral host belonging to the group  $T_h$ . •

#### (f) The full rotation group

The **full rotation group**,  $R_3$  (the 3 refers to rotation in three dimensions), consists of an infinite number of rotation axes with all possible values of  $n$ . A sphere and an atom belong to  $R_3$ , but no molecule does. Exploring the consequences of  $R_3$  is a very important way of applying symmetry arguments to atoms, and is an alternative approach to the theory of orbital angular momentum.

#### Example 11.1 Identifying a point group of a molecule

Identify the point group to which a ruthenocene molecule (21) belongs.

**Method** Use the flow diagram in Fig. 11.7.

**Answer** The path to trace through the flow diagram in Fig. 11.7 is shown by a green line; it ends at  $D_{nh}$ . Because the molecule has a fivefold axis, it belongs to the group  $D_{5h}$ . If the rings were staggered, as they are in an excited state of ferrocene that lies  $4 \text{ kJ mol}^{-1}$  above the ground state (22), the horizontal reflection plane would be absent, but dihedral planes would be present.

**Self-test 11.1** Classify the pentagonal antiprismatic excited state of ferrocene (22).

### 11.3 Some immediate consequences of symmetry

**Key points** (a) Only molecules belonging to the groups  $C_n$ ,  $C_{nv}$ , and  $C_s$  may have a permanent electric dipole moment. (b) A molecule may be chiral, and therefore optically active, only if it does not possess an axis of improper rotation,  $S_n$ .

Some statements about the properties of a molecule can be made as soon as its point group has been identified.

**Fig. 11.13** (a) A molecule with a  $C_n$  axis cannot have a dipole perpendicular to the axis, but (b) it may have one parallel to the axis. The arrows represent local contributions to the overall electric dipole, such as may arise from bonds between pairs of neighbouring atoms with different electronegativities.

**Fig. 11.14** Some symmetry elements are implied by the other symmetry elements in a group. Any molecule containing an inversion also possesses at least an  $S_2$  element because  $i$  and  $S_2$  are equivalent.

**23** L-Alanine,  $\text{NH}_2\text{CH}(\text{CH}_3)\text{COOH}$

**24** Glycine,  $\text{NH}_2\text{CH}_2\text{COOH}$

### (a) Polarity

A **polar molecule** is one with a permanent electric dipole moment ( $\text{HCl}$ ,  $\text{O}_3$ , and  $\text{NH}_3$  are examples). If the molecule belongs to the group  $C_n$  with  $n > 1$ , it cannot possess a charge distribution with a dipole moment perpendicular to the symmetry axis because the symmetry of the molecule implies that any dipole that exists in one direction perpendicular to the axis is cancelled by an opposing dipole (Fig. 11.13a). For example, the perpendicular component of the dipole associated with one O–H bond in  $\text{H}_2\text{O}$  is cancelled by an equal but opposite component of the dipole of the second O–H bond, so any dipole that the molecule has must be parallel to the twofold symmetry axis. However, as the group makes no reference to operations relating the two ends of the molecule, a charge distribution may exist that results in a dipole along the axis (Fig. 11.13b), and  $\text{H}_2\text{O}$  has a dipole moment parallel to its twofold symmetry axis. The same remarks apply generally to the group  $C_{nv}$ , so molecules belonging to any of the  $C_{nv}$  groups may be polar. In all the other groups, such as  $C_{3h}$ ,  $D$ , etc., there are symmetry operations that take one end of the molecule into the other. Therefore, as well as having no dipole perpendicular to the axis, such molecules can have none along the axis, for otherwise these additional operations would not be symmetry operations. We can conclude that

Only molecules belonging to the groups  $C_n$ ,  $C_{nv}$ , and  $C_s$  may have a permanent electric dipole moment.

Criterion for being polar

For  $C_n$  and  $C_{nv}$ , that dipole moment must lie along the symmetry axis. Thus ozone,  $\text{O}_3$ , which is angular and belongs to the group  $C_{2v}$ , may be polar (and is), but carbon dioxide,  $\text{CO}_2$ , which is linear and belongs to the group  $D_{\infty h}$ , is not.

### (b) Chirality

A **chiral molecule** (from the Greek word for ‘hand’) is a molecule that cannot be superimposed on its mirror image. An **achiral molecule** is a molecule that can be superimposed on its mirror image. Chiral molecules are **optically active** in the sense that they rotate the plane of polarized light. A chiral molecule and its mirror-image partner constitute an **enantiomeric pair** of optical isomers and rotate the plane of polarization in equal but opposite directions.

A molecule may be chiral, and therefore optically active, only if it does not possess an axis of improper rotation,  $S_n$ .

Criterion for being chiral

However, we need to be aware that such an axis may be present under a different name, and be implied by other symmetry elements that are present. For example, molecules belonging to the groups  $C_{nh}$  possess an  $S_n$  axis implicitly because they possess both  $C_n$  and  $\sigma_h$ , which are the two components of an improper rotation axis. Any molecule containing a centre of inversion,  $i$ , also possesses an  $S_2$  axis, because  $i$  is equivalent to  $C_2$  in conjunction with  $\sigma_h$ , and that combination of elements is  $S_2$  (Fig. 11.14). It follows that all molecules with centres of inversion are achiral and hence optically inactive. Similarly, because  $S_1 = \sigma$ , it follows that any molecule with a mirror plane is achiral.

A molecule may be chiral if it does not have a centre of inversion or a mirror plane, which is the case with the amino acid alanine (23), but not with glycine (24). However, a molecule may be achiral even though it does not have a centre of inversion. For example, the  $S_4$  species (25) is achiral and optically inactive: though it lacks  $i$  (that is,  $S_2$ ) it does have an  $S_4$  axis.

## Applications to molecular orbital theory and spectroscopy

We shall now turn our attention away from the symmetries of molecules themselves and direct it towards the symmetry characteristics of orbitals that belong to the various atoms in a molecule. This material will enable us to discuss the formulation and labelling of molecular orbitals and selection rules in spectroscopy.

### 11.4 Character tables and symmetry labels

**Key points** (a) The character of an operation summarizes the effect of a symmetry operation on a function; it is the sum of the diagonal elements of a matrix that represents the effect of the operation. (b) The rows under the labels for the operations in a character table express the symmetry properties of the basis and are labelled with the symmetry species. (c) The character of the identity operation  $E$  is the degeneracy of the orbitals that form a basis. (d) The entries in a character table indicate how the basis functions transform under the symmetry operations. (e) Linear combinations of orbitals are also classified according to their symmetry.

We saw in Chapter 10 that molecular orbitals of diatomic and linear polyatomic molecules are labelled  $\sigma$ ,  $\pi$ , etc. These labels refer to the symmetries of the orbitals with respect to rotations around the principal symmetry axis of the molecule. Thus, a  $\sigma$  orbital does not change sign under a rotation through any angle, a  $\pi$  orbital changes sign when rotated by  $180^\circ$ , and so on (Fig. 11.15). The symmetry classifications  $\sigma$  and  $\pi$  can also be assigned to individual atomic orbitals in a linear molecule. For example, we can speak of an individual  $p_z$  orbital as having  $\sigma$  symmetry if the  $z$ -axis lies along the bond, because  $p_z$  is cylindrically symmetrical about the bond. This labelling of orbitals according to their behaviour under rotations can be generalized and extended to nonlinear polyatomic molecules, where there may be reflections and inversions to take into account as well as rotations.

#### (a) Representations and characters

Labels analogous to  $\sigma$  and  $\pi$  are used to denote the symmetries of orbitals in polyatomic molecules. These labels look like  $a$ ,  $a_1$ ,  $e$ ,  $e_g$ , and we first encountered them in Fig. 10.45 in connection with the molecular orbitals of benzene. As we shall see, these labels indicate the behaviour of the orbitals under the symmetry operations of the relevant point group of the molecule.

A label is assigned to an orbital by referring to the **character table** of the group, a table that characterizes the different symmetry types possible in the point group. Thus, to assign the labels  $\sigma$  and  $\pi$ , we use the table shown in the margin. This table is a fragment of the full character table for a linear molecule. The entry +1 shows that the orbital remains the same and the entry  $-1$  shows that the orbital changes sign under the operation  $C_2$  at the head of the column (as illustrated in Fig. 11.15). So, to assign the label  $\sigma$  or  $\pi$  to a particular orbital, we compare the orbital's behaviour with the information in the character table.

The entries in a complete character table are derived by using the formal techniques of group theory and are called **characters**,  $\chi$  (chi). These numbers characterize the essential features of each symmetry type in a way that we can illustrate by considering the  $C_{2v}$  molecule  $\text{SO}_2$  and the valence  $p_x$  orbitals on each atom, which we shall denote  $p_S$ ,  $p_A$ , and  $p_B$  (Fig. 11.16).

25  $\text{N}(\text{CH}_2\text{CH}(\text{CH}_3)\text{CH}(\text{CH}_3)\text{CH}_2)_2^+$

**Fig. 11.15** A rotation through  $180^\circ$  about the internuclear axis (perpendicular to the page) (a) leaves the sign of a  $\sigma$  orbital unchanged but (b) the sign of a  $\pi$  orbital is changed. In the language introduced in this chapter, the characters of the  $C_2$  rotation are +1 and  $-1$  for the  $\sigma$  and  $\pi$  orbitals, respectively.

|          | $C_2$ | (i.e. rotation by $180^\circ$ ) |
|----------|-------|---------------------------------|
| $\sigma$ | +1    | (i.e. no change of sign)        |
| $\pi$    | -1    | (i.e. change of sign)           |

**Fig. 11.16** The three  $p_x$  orbitals that are used to illustrate the construction of a matrix representation in a  $C_{2v}$  molecule ( $\text{SO}_2$ ).

Under  $\sigma_v$ , the change  $(p_S, p_B, p_A) \leftarrow (p_S, p_A, p_B)$  takes place. We can express this transformation by using matrix multiplication (see *Mathematical background 6* following Chapter 10 for a summary of the rules of matrix algebra):

$$(p_S, p_B, p_A) = (p_S, p_A, p_B) \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix} = (p_S, p_A, p_B) D(\sigma_v) \quad (11.1)$$

The matrix  $D(\sigma_v)$  is called a **representative** of the operation  $\sigma_v$ . Representatives take different forms according to the **basis**, the set of orbitals that has been adopted.

We can use the same technique to find matrices that reproduce the other symmetry operations. For instance,  $C_2$  has the effect  $(-p_S, -p_B, -p_A) \leftarrow (p_S, p_A, p_B)$ , and its representative is

$$D(C_2) = \begin{pmatrix} -1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & -1 & 0 \end{pmatrix} \quad (11.2)$$

The effect of  $\sigma'_v$  is  $(-p_S, -p_A, -p_B) \leftarrow (p_S, p_A, p_B)$ , and its representative is

$$D(\sigma'_v) = \begin{pmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & -1 \end{pmatrix} \quad (11.3)$$

The identity operation leaves the basis unchanged, so its representative is the  $3 \times 3$  unit matrix:

$$D(E) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (11.4)$$

The set of matrices that represents *all* the operations of the group is called a **matrix representation**,  $\Gamma$  (uppercase gamma), of the group for the particular basis we have chosen. We denote this three-dimensional representation by  $\Gamma^{(3)}$ . The discovery of a matrix representation of the group means that we have found a link between symbolic manipulations of operations and algebraic manipulations of numbers. The following *Justification* explains why ‘representation’ is an accurate term.

**Fig. 11.17** Two reflections in mutually perpendicular mirror planes are equivalent to a twofold rotation.

#### Justification 11.1 The representation of symmetry operations

We saw in Section 11.1 that symmetry operations form a group if certain criteria are satisfied. Among them is the group property that, if  $R$  and  $S$  are symmetry operations, then  $RS$  is also a symmetry operation. The crucial point in this *Justification* is that the matrices used to reproduce the effect of symmetry operations on a given basis also satisfy the same group property. That is, if the operation  $S$  followed by the operation  $R$  is equivalent to the single operation  $RS$ , then the matrices also satisfy

$$D(R)D(S) = D(RS)$$

We can demonstrate this relation for the relation  $\sigma_v \sigma'_v = C_2$  for the group  $C_{2v}$ , that is, a reflection in one plane followed by a reflection in a perpendicular plane is equivalent to a  $180^\circ$  rotation (Fig. 11.17). We use the matrices developed in the text:

$$D(\sigma_v)D(\sigma'_v) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & -1 \end{pmatrix} = \begin{pmatrix} -1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & -1 & 0 \end{pmatrix} = D(C_2)$$

The same conclusion may be drawn for all combinations of the matrices listed above, so they do in fact ‘represent’ in a concrete way structure of the group of symmetry operations in this case.

The character of an operation in a particular matrix representation is the sum of the diagonal elements of the representative of that operation. Thus, in the basis we are illustrating, the characters of the representatives are

$$\begin{array}{cccc} D(E) & D(C_2) & D(\sigma_v) & D(\sigma'_v) \\ 3 & -1 & 1 & -3 \end{array}$$

The character of an operation depends on the basis.

Inspection of the representatives shows that they are all of **block-diagonal form**:

$$D = \begin{pmatrix} [\bullet] & 0 & 0 \\ 0 & [\bullet] & [\bullet] \\ 0 & [\bullet] & [\bullet] \end{pmatrix}$$

Block-diagonal matrix

The block-diagonal form of the representatives shows us that the symmetry operations of  $C_{2v}$  never mix  $p_s$  with the other two functions. Consequently, the basis can be cut into two parts, one consisting of  $p_s$  alone and the other of  $(p_A, p_B)$ . It is readily verified that the  $p_s$  orbital itself is a basis for the one-dimensional representation

$$D(E) = 1 \quad D(C_2) = -1 \quad D(\sigma_v) = 1 \quad D(\sigma'_v) = -1$$

which we shall call  $\Gamma^{(1)}$ . The functions  $(p_A, p_B)$  are jointly a basis for the two-dimensional representation  $\Gamma^{(2)}$ :

$$D(E) = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad D(C_2) = \begin{pmatrix} 0 & -1 \\ -1 & 0 \end{pmatrix} \quad D(\sigma_v) = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \quad D(\sigma'_v) = \begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix}$$

These matrices are the same as those of the original three-dimensional representation, except for the loss of the first row and column. We say that the original three-dimensional representation has been **reduced** to the ‘direct sum’ of a one-dimensional representation ‘spanned’ by  $p_s$ , and a two-dimensional representation spanned by  $(p_A, p_B)$ . This reduction is consistent with the common sense view that the central orbital plays a role different from the other two. We denote the reduction symbolically by writing

$$\Gamma^{(3)} = \Gamma^{(1)} + \Gamma^{(2)} \quad (11.5)$$

The one-dimensional representation  $\Gamma^{(1)}$  cannot be reduced any further, and is called an **irreducible representation** of the group (an ‘irrep’). We can demonstrate that the two-dimensional representation  $\Gamma^{(2)}$  is reducible (for this basis in this group) by switching attention to the linear combinations  $p_1 = p_A + p_B$  and  $p_2 = p_A - p_B$ . These combinations are sketched in Fig. 11.18. The representatives in the new basis can be constructed from the old by noting, for example, that because, under  $\sigma_v$ ,  $(p_B, p_A) \leftarrow (p_A, p_B)$  it follows that  $(p_1, -p_2) \leftarrow (p_1, p_2)$ . In this way we find the following representation in the new basis:

$$D(E) = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad D(C_2) = \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix} \quad D(\sigma_v) = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \quad D(\sigma'_v) = \begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix}$$

The new representatives are all in block-diagonal form (in this case, all the blocks are  $1 \times 1$ ), and the two combinations are not mixed with each other by any operation of the group. We have therefore achieved the reduction of  $\Gamma^{(2)}$  to the sum of two one-dimensional representations. Thus,  $p_1$  spans

$$D(E) = 1 \quad D(C_2) = -1 \quad D(\sigma_v) = 1 \quad D(\sigma'_v) = -1$$

which is the same one-dimensional representation as that spanned by  $p_s$ , and  $p_2$  spans

$$D(E) = 1 \quad D(C_2) = 1 \quad D(\sigma_v) = -1 \quad D(\sigma'_v) = -1$$

which is a different one-dimensional representation; we shall denote it  $\Gamma^{(1)'}.$

**Fig. 11.18** Two symmetry-adapted linear combinations of the basis orbitals shown in Fig. 11.16. The two combinations each span a one-dimensional irreducible representation, and their symmetry species are different.

**Table 11.2\*** The  $C_{2v}$  character table

| $C_{2v}, 2mm$ | $E$ | $C_2$ | $\sigma_v$ | $\sigma'_v$ | $h=4$ |                 |
|---------------|-----|-------|------------|-------------|-------|-----------------|
| $A_1$         | 1   | 1     | 1          | 1           | $z$   | $z^2, y^2, x^2$ |
| $A_2$         | 1   | 1     | -1         | -1          |       | $xy$            |
| $B_1$         | 1   | -1    | 1          | -1          | $x$   | $zx$            |
| $B_2$         | 1   | -1    | -1         | 1           | $y$   | $yz$            |

\* More character tables are given at the end of the *Resource section*.

At this point we have found two irreducible representations of the group  $C_{2v}$  (Table 11.2). The two irreducible representations are normally labelled  $B_1$  and  $A_2$ , respectively. An A or a B is used to denote a one-dimensional representation; A is used if the character under the principal rotation is +1, and B is used if the character is -1. Subscripts are used to distinguish the irreducible representations if there is more than one of the same type:  $A_1$  is reserved for the representation with character 1 for all operations. When higher dimensional irreducible representations are permitted, E denotes a two-dimensional irreducible representation and T a three-dimensional irreducible representation; all the irreducible representations of  $C_{2v}$  are one-dimensional.

There are in fact only two more species of irreducible representations of this group, for a surprising theorem of group theory states that

$$\text{Number of symmetry species} = \text{number of classes} \quad (11.6)$$

Symmetry operations fall into the same class if they are of the same type (for example, rotations) and can be transformed into one another by a symmetry operation of the group. In  $C_{2v}$ , for instance, there are four classes (four columns in the character table), so there are only four species of irreducible representation. The character table in Table 11.2 therefore shows the characters of all the irreducible representations of this group.

### (b) The structure of character tables

In general, the columns in a character table are labelled with the symmetry operations of the group. For instance, for the group  $C_{3v}$  the columns are headed  $E$ ,  $C_3$ , and  $\sigma_v$  (Table 11.3). The numbers multiplying each operation are the numbers of members of each class. In the  $C_{3v}$  character table we see that the two threefold rotations (clockwise and counterclockwise rotations by  $120^\circ$ ) belong to the same class: they are related by a reflection (Fig. 11.19). The three reflections (one through each of the three

**Fig. 11.19** Symmetry operations in the same class are related to one another by the symmetry operations of the group. Thus, the three mirror planes shown here are related by threefold rotations, and the two rotations shown here are related by reflection in  $\sigma_v$ .

**Table 11.3\*** The  $C_{3v}$  character table

| $C_{3v}, 3m$ | $E$ | $2C_3$ | $3\sigma_v$ | $h=6$    |                             |
|--------------|-----|--------|-------------|----------|-----------------------------|
| $A_1$        | 1   | 1      | 1           | $z$      | $z^2, x^2 + y^2$            |
| $A_2$        | 1   | 1      | -1          |          |                             |
| E            | 2   | -1     | 0           | $(x, y)$ | $(xy, x^2 - y^2), (yz, zx)$ |

\* More character tables are given at the end of the *Resource section*.

vertical mirror planes) also lie in the same class: they are related by the threefold rotations. The two reflections of the group  $C_{2v}$  fall into different classes: although they are both reflections, one cannot be transformed into the other by any symmetry operation of the group.

The total number of operations in a group is called the **order**,  $h$ , of the group. The order of the group  $C_{3v}$ , for instance, is 6.

The rows under the labels for the operations summarize the symmetry properties of the orbitals. They are labelled with the **symmetry species** (the analogues of the labels  $\sigma$  and  $\pi$ ). More formally, the symmetry species label the irreducible representations of the group, which are the basic types of behaviour that orbitals may show when subjected to the symmetry operations of the group, as we have illustrated for the group  $C_{2v}$ . By convention, irreducible representations are labelled with upper-case roman letters (such as  $A_1$  and  $E$ ) and the orbitals to which they apply are labelled with the lower-case equivalents (so an orbital of symmetry species  $A_1$  is called an  $a_1$  orbital). Examples of each type of orbital are shown in Fig. 11.20.

### (c) Character tables and orbital degeneracy

The character of the identity operation  $E$  tells us the degeneracy of the orbitals. Thus, in a  $C_{3v}$  molecule, any orbital with a symmetry label  $a_1$  or  $a_2$  is nondegenerate. Any doubly degenerate pair of orbitals in  $C_{3v}$  must be labelled  $e$  because, in this group, only  $E$  symmetry species have characters greater than 1.

Because there are no characters greater than 2 in the column headed  $E$  in  $C_{3v}$ , we know that there can be no triply degenerate orbitals in a  $C_{3v}$  molecule. This last point is a powerful result of group theory, for it means that, with a glance at the character table of a molecule, we can state the maximum possible degeneracy of its orbitals.

#### Example 11.2 Using a character table to judge degeneracy

Can a trigonal planar molecule such as  $BF_3$  have triply degenerate orbitals? What is the minimum number of atoms from which a molecule can be built that does display triple degeneracy?

**Method** First, identify the point group, and then refer to the corresponding character table in the *Resource section*. The maximum number in the column headed by the identity  $E$  is the maximum orbital degeneracy possible in a molecule of that point group. For the second part, consider the shapes that can be built from two, three, etc. atoms, and decide which number can be used to form a molecule that can have orbitals of symmetry species  $T$ .

**Answer** Trigonal planar molecules belong to the point group  $D_{3h}$ . Reference to the character table for this group shows that the maximum degeneracy is 2, as no character exceeds 2 in the column headed  $E$ . Therefore, the orbitals cannot be triply degenerate. A tetrahedral molecule (symmetry group  $T$ ) has an irreducible representation with a  $T$  symmetry species. The minimum number of atoms needed to build such a molecule is four (as in  $P_4$ , for instance).

**Self-test 11.2** A buckminsterfullerene molecule,  $C_{60}$  (19), belongs to the icosahedral point group. What is the maximum possible degree of degeneracy of its orbitals? [5]

#### A brief comment

Note that care must be taken to distinguish the identity element  $E$  (italic, a column heading) from the symmetry label  $E$  (roman, a row label).

Fig. 11.20 Typical symmetry-adapted linear combinations of orbitals in a  $C_{3v}$  molecule.

**Fig. 11.21** The two orbitals shown here have different properties under reflection through the mirror plane: one changes sign (character  $-1$ ), the other does not (character  $+1$ ).

**Fig. 11.22** A  $p_x$  orbital on the central atom of a  $C_{2v}$  molecule and the symmetry elements of the group.

**Fig. 11.23** The three  $1s$  orbitals used to construct symmetry-adapted linear combinations in a  $C_{3v}$  molecule such as  $\text{NH}_3$ .

#### A brief comment

In previous chapters we used the Greek letter  $\chi$  (chi) to denote atomic orbitals that comprise a basis set for molecular orbital calculations. To avoid confusion with our use of  $\chi$  for characters in this chapter, atomic orbitals will be denoted by the Greek letter  $\psi$  (psi).

#### (d) Characters and operations

The characters in the rows labelled A and B and in the columns headed by symmetry operations other than the identity  $E$  indicate the behaviour of an orbital under the corresponding operations: a  $+1$  indicates that an orbital is unchanged, and a  $-1$  indicates that it changes sign. It follows that we can identify the symmetry label of the orbital by comparing the changes that occur to an orbital under each operation, and then comparing the resulting  $+1$  or  $-1$  with the entries in a row of the character table for the point group concerned.

For the rows labelled E or T (which refer to the behaviour of sets of doubly and triply degenerate orbitals, respectively), the characters in a row of the table are the sums of the characters summarizing the behaviour of the individual orbitals in the basis. Thus, if one member of a doubly degenerate pair remains unchanged under a symmetry operation but the other changes sign (Fig. 11.21), then the entry is reported as  $\chi = 1 - 1 = 0$ . Care must be exercised with these characters because the transformations of orbitals can be quite complicated; nevertheless, the sums of the individual characters are integers.

As an example, consider the  $\text{O}2p_x$  orbital in  $\text{H}_2\text{O}$ . Because  $\text{H}_2\text{O}$  belongs to the point group  $C_{2v}$ , we know by referring to the  $C_{2v}$  character table (Table 11.2) that the labels available for the orbitals are  $a_1$ ,  $a_2$ ,  $b_1$ , and  $b_2$ . We can decide the appropriate label for  $\text{O}2p_x$  by noting that under a  $180^\circ$  rotation ( $C_2$ ) the orbital changes sign (Fig. 11.22), so it must be either  $B_1$  or  $B_2$ , as only these two symmetry types have character  $-1$  under  $C_2$ . The  $\text{O}2p_x$  orbital also changes sign under the reflection  $\sigma'_v$ , which identifies it as  $B_1$ . As we shall see, any molecular orbital built from this atomic orbital will also be a  $b_1$  orbital. Similarly,  $\text{O}2p_y$  changes sign under  $C_2$  but not under  $\sigma'_v$ ; therefore, it can contribute to  $b_2$  orbitals.

The behaviour of  $s$ ,  $p$ , and  $d$  orbitals on a central atom under the symmetry operations of the molecule is so important that the symmetry species of these orbitals are generally indicated in a character table. To make these allocations, we look at the symmetry species of  $x$ ,  $y$ , and  $z$ , which appear on the right-hand side of the character table. Thus, the position of  $z$  in Table 11.3 shows that  $p_z$  (which is proportional to  $zf(r)$ ), has symmetry species  $A_1$  in  $C_{3v}$ , whereas  $p_x$  and  $p_y$  (which are proportional to  $xf(r)$  and  $yf(r)$ , respectively) are jointly of E symmetry. In technical terms, we say that  $p_x$  and  $p_y$  jointly span an irreducible representation of symmetry species E. An  $s$  orbital on the central atom always spans the fully symmetrical irreducible representation (typically labelled  $A_1$  but sometimes  $A'_1$ ) of a group as it is unchanged under all symmetry operations.

The five  $d$  orbitals of a shell are represented by  $xy$  for  $d_{xy}$ , etc., and are also listed on the right of the character table. We can see at a glance that in  $C_{3v}$ ,  $d_{xy}$  and  $d_{x^2-y^2}$  on a central atom jointly belong to E and hence form a doubly degenerate pair.

#### (e) The classification of linear combinations of orbitals

So far, we have dealt with the symmetry classification of individual orbitals. The same technique may be applied to linear combinations of orbitals on atoms that are related by symmetry transformations of the molecule, such as the combination  $\psi_1 = \psi_A + \psi_B + \psi_C$  of the three  $1s$  orbitals in the  $C_{3v}$  molecule  $\text{NH}_3$  (Fig. 11.23). This combination remains unchanged under a  $C_3$  rotation and under any of the three vertical reflections of the group, so its characters are

$$\chi(E) = 1 \quad \chi(C_3) = 1 \quad \chi(\sigma_v) = 1$$

Comparison with the  $C_{3v}$  character table shows that  $\psi_1$  is of symmetry species  $A_1$ , and therefore that it contributes to  $a_1$  molecular orbitals in  $\text{NH}_3$ .

**Example 11.3** Identifying the symmetry species of orbitals

Identify the symmetry species of the orbital  $\psi = \psi_A - \psi_B$  in a  $C_{2v}$   $\text{NO}_2$  molecule, where  $\psi_A$  is an  $\text{O}2p_x$  orbital on one O atom and  $\psi_B$  that on the other O atom.

**Method** The negative sign in  $\psi$  indicates that the sign of  $\psi_B$  is opposite to that of  $\psi_A$ . We need to consider how the combination changes under each operation of the group, and then write the character as +1, -1, or 0 as specified above. Then we compare the resulting characters with each row in the character table for the point group, and hence identify the symmetry species.

**Answer** The combination is shown in Fig. 11.24. Under  $C_2$ ,  $\psi$  changes into itself, implying a character of +1. Under the reflection  $\sigma_v$ , both orbitals change sign, so  $\psi \rightarrow -\psi$ , implying a character of -1. Under  $\sigma'_v$ ,  $\psi \rightarrow -\psi$ , so the character for this operation is also -1. The characters are therefore

$$\chi(E) = 1 \quad \chi(C_2) = 1 \quad \chi(\sigma_v) = -1 \quad \chi(\sigma'_v) = -1$$

These values match the characters of the  $A_2$  symmetry species, so  $\psi$  can contribute to an  $a_2$  orbital.

**Self-test 11.3** Consider  $\text{PtCl}_4$ , in which the Cl ligands form a square planar array of point group  $D_{4h}$  (26). Identify the symmetry type of the combination  $\psi_A - \psi_B + \psi_C - \psi_D$  where each  $\psi$  is a  $\text{Cl}3s$  orbital.  $[B_{2g}]$

**Fig. 11.24** One symmetry-adapted linear combination of  $\text{O}2p_x$  orbitals in the  $C_{2v}$   $\text{NO}_2$  molecule.

## 11.5 Vanishing integrals and orbital overlap

**Key points** Character tables provide a basis for making various judgements based on symmetry. (a) They are used to decide whether an integral is necessarily zero: it must include a component that is a basis for the totally symmetric representation. (b) Only orbitals of the same symmetry species may have nonzero overlap. (c) Symmetry-adapted linear combinations are the building blocks of LCAO molecular orbitals.

Suppose we had to evaluate the integral

$$I = \int f_1 f_2 \, d\tau \quad (11.7)$$

where  $f_1$  and  $f_2$  are functions. For example,  $f_1$  might be an atomic orbital  $A$  on one atom and  $f_2$  an atomic orbital  $B$  on another atom, in which case  $I$  would be their overlap integral. If we knew that the integral is zero, we could say at once that a molecular orbital does not result from  $(A,B)$  overlap in that molecule. We shall now see that character tables provide a quick way of judging whether an integral is necessarily zero.

### (a) The criteria for vanishing integrals

The key point in dealing with the integral  $I$  is that the value of any integral, and of an overlap integral in particular, is independent of the orientation of the molecule (Fig. 11.25). In group theory we express this point by saying that  $I$  is *invariant under any symmetry operation of the molecule*, and that each operation brings about the trivial transformation  $I \rightarrow I$ . Because the volume element  $d\tau$  is invariant under any symmetry operation, it follows that the integral is nonzero only if the integrand itself, the product  $f_1 f_2$ , is unchanged by any symmetry operation of the molecular point group. If the integrand changed sign under a symmetry operation, the integral would

**Fig. 11.25** The value of an integral  $I$  (for example, an area) is independent of the coordinate system used to evaluate it. That is,  $I$  is a basis of a representation of symmetry species  $A_1$  (or its equivalent).

**Fig. 11.26** A symmetry-adapted linear combination that belongs to the symmetry species E in a  $C_{3v}$  molecule such as  $\text{NH}_3$ . This combination can form a molecular orbital by overlapping with the  $p_x$  orbital on the central atom (the orbital with its axis parallel to the width of the page; see Fig. 11.29c).

be the sum of equal and opposite contributions, and hence would be zero. It follows that the only contribution to a nonzero integral comes from functions for which under any symmetry operation of the molecular point group  $f_1 f_2 \rightarrow f_1 f_2$ , and hence for which the characters of the operations are all equal to +1. Therefore, for  $I$  not to be zero, the integrand  $f_1 f_2$  must have symmetry species  $A_1$  (or its equivalent in the specific molecular point group).

We use the following procedure to deduce the symmetry species spanned by the product  $f_1 f_2$  and hence to see whether it does indeed span  $A_1$ .

1. Decide on the symmetry species of the individual functions  $f_1$  and  $f_2$  by reference to the character table, and write their characters in two rows in the same order as in the table.
2. Multiply the numbers in each column, writing the results in the same order.
3. Inspect the row so produced, and see if it can be expressed as a sum of characters from each column of the group. The integral must be zero if this sum does not contain  $A_1$ .

For example, if  $f_1$  is the  $s_N$  orbital in  $\text{NH}_3$  and  $f_2$  is the linear combination  $s_3 = s_B - s_C$  (Fig. 11.26), then, because  $s_N$  spans  $A_1$  and  $s_3$  is a member of the basis spanning E, we write

|             |   |    |   |
|-------------|---|----|---|
| $f_1$ :     | 1 | 1  | 1 |
| $f_2$ :     | 2 | -1 | 0 |
| $f_1 f_2$ : | 2 | -1 | 0 |

The characters 2, -1, 0 are those of E alone, so the integrand does not span  $A_1$ . It follows that the integral must be zero. Inspection of the form of the functions (see Fig. 11.26) shows why this is so:  $s_3$  has a node running through  $s_N$ . Had we taken  $f_1 = s_N$  and  $f_2 = s_1$  instead, where  $s_1 = s_A + s_B + s_C$ , then because each spans  $A_1$  with characters 1, 1, 1:

|             |   |   |   |
|-------------|---|---|---|
| $f_1$ :     | 1 | 1 | 1 |
| $f_2$ :     | 1 | 1 | 1 |
| $f_1 f_2$ : | 1 | 1 | 1 |

The characters of the product are those of  $A_1$  itself. Therefore,  $s_1$  and  $s_N$  may have nonzero overlap. A short cut that works when  $f_1$  and  $f_2$  are bases for irreducible representations of a group is to note their symmetry species: if they are different, then the integral of their product must vanish; if they are the same, then the integral may be nonzero.

It is important to note that group theory is specific about when an integral must be zero, but integrals that it allows to be nonzero may be zero for reasons unrelated to symmetry. For example, the N-H distance in ammonia may be so great that the  $(s_1, s_N)$  overlap integral is zero simply because the orbitals are so far apart.

**Fig. 11.27** The integral of the function  $f = xy$  over the tinted region is zero. In this case, the result is obvious by inspection, but group theory can be used to establish similar results in less obvious cases. The insert shows the shape of the function in three dimensions.

#### Example 11.4 Deciding if an integral must be zero (1)

May the integral of the function  $f = xy$  be nonzero when evaluated over a region the shape of an equilateral triangle centred on the origin (Fig. 11.27)?

**Method** First, note that an integral over a single function  $f$  is included in the previous discussion if we take  $f_1 = f$  and  $f_2 = 1$  in eqn 11.7. Therefore, we need to judge whether  $f$  alone belongs to the symmetry species  $A_1$  (or its equivalent) in the point group of the system. To decide that, we identify the point group and then examine the character table to see whether  $f$  belongs to  $A_1$  (or its equivalent).

**Answer** An equilateral triangle has the point-group symmetry  $D_{3h}$ . If we refer to the character table of the group, we see that  $xy$  is a member of a basis that spans the irreducible representation  $E''$ . Therefore, its integral must be zero, because the integrand has no component that spans  $A'_1$ .

**Self-test 11.4** Can the function  $x^2 + y^2$  have a nonzero integral when integrated over a regular pentagon centred on the origin? [Yes, Fig. 11.28]

In many cases, the product of functions  $f_1$  and  $f_2$  spans a sum of irreducible representations. For instance, in  $C_{2v}$  we may find the characters 2, 0, 0,  $-2$  when we multiply the characters of  $f_1$  and  $f_2$  together. In this case, we note that these characters are the sum of the characters for  $A_2$  and  $B_1$ :

|             | $E$ | $C_{2v}$ | $\sigma_v$ | $\sigma'_v$ |
|-------------|-----|----------|------------|-------------|
| $A_2$       | 1   | 1        | $-1$       | $-1$        |
| $B_1$       | 1   | $-1$     | 1          | $-1$        |
| $A_2 + B_1$ | 2   | 0        | 0          | $-2$        |

To summarize this result we write the symbolic expression  $A_2 \times B_1 = A_2 + B_1$ , which is called the **decomposition of a direct product**. This expression is symbolic. The  $\times$  and  $+$  signs in this expression are not ordinary multiplication and addition signs: formally, they denote technical procedures with matrices called a 'direct product' and a 'direct sum'. Because the sum on the right does not include a component that is a basis for an irreducible representation of symmetry species  $A_1$ , we can conclude that the integral of  $f_1 f_2$  over all space is zero in a  $C_{2v}$  molecule.

Whereas the decomposition of the characters 2, 0, 0,  $-2$  can be done by inspection in this simple case, in other cases and more complex groups the decomposition is often far from obvious. For example, if we found the characters 8,  $-2$ ,  $-6$ , 4, it would not be obvious that the sum contains  $A_1$ . Group theory, however, provides a systematic way of using the characters of the representation spanned by a product to find the symmetry species of the irreducible representations. The formal statement of the approach is as follows. We write the reduction of the representation as

$$\Gamma = \sum_n N_n \Gamma^{(n)} \quad (11.8a)$$

where  $N_n$  is the number of times that the irreducible representation  $\Gamma^{(n)}$  occurs in the reducible representation  $\Gamma$ ; then

$$N_n = \frac{1}{h} \sum_R \chi^{(n)}(R)^* \chi(R) \quad \text{Reduction of a representation} \quad (11.8b)$$

where  $h$  is the order of the group,  $\chi(R)$  the characters we are analysing for each operation  $R$ , and  $\chi^{(n)}(R)$  the corresponding characters for the irreducible representation  $\Gamma^{(n)}$ . We have allowed for the possibility that the characters are complex, but in most cases they are real. The verbal interpretation of this recipe is as follows:

1. Write down a table with columns headed by the symmetry operations of the group.
2. In the first row write down the characters of the symmetry species we want to analyse.
3. In the second row, write down the characters of the irreducible representation  $\Gamma$  we are interested in.

**Fig. 11.28** The integration of a function over a pentagonal region. The insert shows the shape of the function in three dimensions.

4. Multiply the two rows together, add the products together, and divide by the order of the group.

The resulting number is the number of times  $\Gamma^{(n)}$  occurs in the decomposition.

#### • A brief illustration

To find whether  $A_1$  does indeed occur in the product with characters 8, -2, -6, 4 in  $C_{2v}$ , we draw up the following table:

|           | $E$ | $C_{2v}$ | $\sigma_v$ | $\sigma'_v$ | $h = 4$ (the order of the group)            |
|-----------|-----|----------|------------|-------------|---------------------------------------------|
| $f_1 f_2$ | 8   | -2       | -6         | 4           | (the characters of the product)             |
| $A_1$     | 1   | 1        | 1          | 1           | (the symmetry species we are interested in) |
|           | 8   | -2       | -6         | 4           | (the product of the two sets of characters) |

The sum of the numbers in the last line is 4; when that number is divided by the order of the group, we get 1, so  $A_1$  occurs once in the decomposition. When the procedure is repeated for all four symmetry species, we find that  $f_1 f_2$  spans  $A_1 + 2A_2 + 5B_2$ . •

**Self-test 11.5** Does  $A_2$  occur among the symmetry species of the irreducible representations spanned by a product with characters 7, -3, -1, 5 in the group  $C_{2v}$ ? [No]

**Fig. 11.29** Orbitals of the same symmetry species may have non-vanishing overlap. This diagram illustrates the three bonding orbitals that may be constructed from (N2s, H1s) and (N2p, H1s) overlap in a  $C_{3v}$  molecule. (a)  $a_1$ ; (b) and (c) the two components of the doubly degenerate e orbitals. (There are also three antibonding orbitals of the same species.)

#### (b) Orbitals with nonzero overlap

The rules just given let us decide which atomic orbitals may have nonzero overlap in a molecule. We have seen that  $s_N$  may have nonzero overlap with  $s_1$  (the combination  $s_A + s_B + s_C$ ), so bonding and antibonding molecular orbitals can form from ( $s_N$ ,  $s_1$ ) overlap (Fig. 11.29). The general rule is that *only orbitals of the same symmetry species may have nonzero overlap*, so only orbitals of the same symmetry species form bonding and antibonding combinations. It should be recalled from Chapter 10 that the selection of atomic orbitals that had mutual nonzero overlap is the central and initial step in the construction of molecular orbitals by the LCAO procedure. We are therefore at the point of contact between group theory and the material introduced in that chapter. The molecular orbitals formed from a particular set of atomic orbitals with nonzero overlap are labelled with the lower-case letter corresponding to the symmetry species. Thus, the ( $s_N$ ,  $s_1$ )-overlap orbitals are called  $a_1$  orbitals (or  $a_1^*$  if we wish to emphasize that they are antibonding).

The linear combinations  $s_2 = 2s_A - s_B - s_C$  and  $s_3 = s_B - s_C$  have symmetry species E. Does the N atom have orbitals that have nonzero overlap with them (and give rise to e molecular orbitals)? Intuition (as supported by Figs. 11.29b and c) suggests that  $N2p_x$  and  $N2p_y$  should be suitable. We can confirm this conclusion by noting that the character table shows that, in  $C_{3v}$ , the functions  $x$  and  $y$  jointly belong to the symmetry species E. Therefore,  $N2p_x$  and  $N2p_y$  also belong to E, so may have nonzero overlap with  $s_2$  and  $s_3$ . This conclusion can be verified by multiplying the characters and finding that the product of characters can be expressed as the decomposition  $E \times E = A_1 + A_2 + E$ . The two e orbitals that result are shown in Fig. 11.29 (there are also two antibonding e orbitals).

We can see the power of the method by exploring whether any d orbitals on the central atom can take part in bonding. As explained earlier, reference to the  $C_{3v}$  character table shows that  $d_{z^2}$  has  $A_1$  symmetry and that the pairs ( $d_{x^2-y^2}$ ,  $d_{xy}$ ) and ( $d_{yz}$ ,  $d_{zx}$ ) each transform as E. It follows that molecular orbitals may be formed by ( $s_1$ ,  $d_{z^2}$ ) overlap

and by overlap of the ( $s_2, s_3$ ) combinations with the E d orbitals. Whether or not the d orbitals are in fact important is a question group theory cannot answer because the extent of their involvement depends on energy considerations, not symmetry.

**Example 11.5** *Determining which orbitals can contribute to bonding*

The four H1s orbitals of methane span  $A_1 + T_2$ . With which of the C atom orbitals can they overlap? What bonding pattern would be possible if the C atom had d orbitals available?

**Method** Refer to the  $T_d$  character table (in the *Resource section*) and look for s, p, and d orbitals spanning  $A_1$  or  $T_2$ .

**Answer** An s orbital spans  $A_1$ , so it may have nonzero overlap with the  $A_1$  combination of H1s orbitals. The C2p orbitals span  $T_2$ , so they may have nonzero overlap with the  $T_2$  combination. The  $d_{xy}$ ,  $d_{yz}$ , and  $d_{zx}$  orbitals span  $T_2$ , so they may overlap the same combination. Neither of the other two d orbitals span  $A_1$  (they span E), so they remain nonbonding orbitals. It follows that in methane there are (C2s,H1s)-overlap  $a_1$  orbitals and (C2p,H1s)-overlap  $t_2$  orbitals. The C3d orbitals might contribute to the latter. The lowest energy configuration is probably  $a_1^2 t_2^6$ , with all bonding orbitals occupied.

**Self-test 11.6** Consider the octahedral  $SF_6$  molecule, with the bonding arising from overlap of S orbitals and a 2p orbital on each F directed towards the central S atom. The latter span  $A_{1g} + E_g + T_{1u}$ . What S orbitals have nonzero overlap? Suggest what the ground-state configuration is likely to be.

$$[3s(A_{1g}), 3p(T_{1u}), 3d(E_g); a_{1g}^2 t_{1u}^6 e_g^4]$$

### (c) Symmetry-adapted linear combinations

So far, we have only asserted the forms of the linear combinations (such as  $s_1$ , etc.) that have a particular symmetry. Group theory also provides machinery that takes an arbitrary basis, or set of atomic orbitals ( $s_A$ , etc.), as input and generates combinations of the specified symmetry. Because these combinations are adapted to the symmetry of the molecule, they are called **symmetry-adapted linear combinations** (SALC). Symmetry-adapted linear combinations are the building blocks of LCAO molecular orbitals, for they include combinations such as those used to construct molecular orbitals in benzene. The construction of SALCs is the first step in any molecular orbital treatment of molecules.

The technique for building SALCs is derived by using the full power of group theory. We shall not show the derivation, which is very lengthy, but present the main conclusions as a set of rules. The formal expression is

$$\psi^{(n)} = \frac{1}{h} \sum_R \chi^{(n)}(R)^* R \phi_i \quad \text{Generation of SALC} \quad (11.9)$$

where  $\psi^{(n)}$  is the symmetry-adapted linear combination we want to develop for the symmetry species  $\Gamma^{(n)}$ ,  $h$  is the order of the group,  $R$  is an operation of the group,  $\chi^{(n)}(R)$  is the character for that operation, and  $\phi_i$  is one of the basis functions. As before, we have allowed for the possibility that a character is complex, but most are real. The verbal interpretation of this expression is:

1. Construct a table showing the effect of each operation on each orbital of the original basis.
2. To generate the combination of a specified symmetry species, take each column in turn and:
  - (i) Multiply each member of the column by the character of the corresponding operation.
  - (ii) Add together all the orbitals in each column with the factors as determined in (i).
  - (iii) Divide the sum by the order of the group.

|              | $s_N$ | $s_A$ | $s_B$ | $s_C$ |
|--------------|-------|-------|-------|-------|
| $E$          | $s_N$ | $s_A$ | $s_B$ | $s_C$ |
| $C_3^+$      | $s_N$ | $s_B$ | $s_C$ | $s_A$ |
| $C_3^-$      | $s_N$ | $s_C$ | $s_A$ | $s_B$ |
| $\sigma_v$   | $s_N$ | $s_A$ | $s_C$ | $s_B$ |
| $\sigma'_v$  | $s_N$ | $s_B$ | $s_A$ | $s_C$ |
| $\sigma''_v$ | $s_N$ | $s_C$ | $s_B$ | $s_A$ |

#### • A brief illustration

From the  $(s_N, s_A, s_B, s_C)$  basis in  $\text{NH}_3$  we form the table shown in the margin. To generate the  $A_1$  combination, we take the characters for  $A_1$  (1,1,1,1,1,1); then rules (i) and (ii) lead to

$$\psi \propto s_N + s_N + \dots = 6s_N$$

The order of the group (the number of elements) is 6, so the combination of  $A_1$  symmetry that can be generated from  $s_N$  is  $s_N$  itself. Applying the same technique to the column under  $s_A$  gives

$$\psi = \frac{1}{6}(s_A + s_B + s_C + s_A + s_B + s_C) = \frac{1}{3}(s_A + s_B + s_C)$$

The same combination is built from the other two columns, so they give no further information. The combination we have just formed is the  $s_1$  combination we used before (apart from the numerical factor). •

We now form the overall molecular orbital by forming a linear combination of all the SALCs of the specified symmetry species. In this case, therefore, the  $a_1$  molecular orbital is

$$\psi = c_N s_N + c_1 s_1$$

This is as far as group theory can take us. The coefficients are found by solving the Schrödinger equation by using the techniques outlined in Chapter 10; they do not come directly from the symmetry of the system.

We run into a problem when we try to generate an SALC of symmetry species  $E$ , because, for representations of dimension 2 or more, the rules generate sums of SALCs. This problem can be illustrated as follows. In  $C_{3v}$ , the  $E$  characters are 2, -1, -1, 0, 0, 0, so the column under  $s_N$  gives

$$\psi = \frac{1}{6}(2s_N - s_N - s_N + 0 + 0 + 0) = 0$$

The other columns give

$$\frac{1}{6}(2s_A - s_B - s_C) \quad \frac{1}{6}(2s_B - s_A - s_C) \quad \frac{1}{6}(2s_C - s_B - s_A)$$

However, any one of these three expressions can be expressed as a sum of the other two (they are not 'linearly independent'). The difference of the second and third gives  $\frac{1}{2}(s_B - s_C)$ , and this combination and the first,  $\frac{1}{6}(2s_A - s_B - s_C)$ , are the two (now linearly independent) SALCs we have used in the discussion of e orbitals.

## 11.6 Vanishing integrals and selection rules

**Key points** A transition dipole moment is nonzero only if the direct product of its three components includes the totally symmetric representation.

Integrals of the form

$$I = \int f_1 f_2 f_3 d\tau \quad (11.10)$$

are also common in quantum mechanics for they include matrix elements of operators (Section 7.5e), and it is important to know when they are necessarily zero. For the integral to be nonzero:

The product  $f_1 f_2 f_3$  must span  $A_1$  (or its equivalent) or contain a component that spans  $A_1$ .

Criterion for not necessarily vanishing

To test whether this is so, the characters of all three functions are multiplied together in the same way as in the rules set out above.

### Example 11.6 Deciding if an integral must be zero (2)

Does the integral  $\int (3d_{z^2})x(3d_{xy}) d\tau$  vanish in a  $C_{2v}$  molecule?

**Method** We must refer to the  $C_{2v}$  character table (Table 11.2) and the characters of the irreducible representations spanned by  $3z^2 - r^2$  (the form of the  $d_{z^2}$  orbital),  $x$ , and  $xy$ ; then we can use the procedure set out above (with one more row of multiplication).

**Answer** We draw up the following table:

|                 | $E$ | $C_2$ | $\sigma_v$ | $\sigma'_v$ |       |
|-----------------|-----|-------|------------|-------------|-------|
| $f_3 = d_{xy}$  | 1   | 1     | -1         | -1          | $A_2$ |
| $f_2 = x$       | 1   | -1    | 1          | -1          | $B_1$ |
| $f_1 = d_{z^2}$ | 1   | 1     | 1          | 1           | $A_1$ |
| $f_1 f_2 f_3$   | 1   | -1    | -1         | 1           |       |

The characters are those of  $B_2$ . Therefore, the integral is necessarily zero.

**Self-test 11.7** Does the integral  $\int (2p_x)(2p_y)(2p_z) d\tau$  necessarily vanish in an octahedral  $O_h$  environment? [Yes]

We saw in Chapter 9 (*Justification 9.4*), and will see in more detail in Chapters 12 and 13, that the intensity of a spectral line arising from a molecular transition between some initial state with wavefunction  $\psi_i$  and a final state with wavefunction  $\psi_f$  depends on the (electric) transition dipole moment,  $\mu_{fi}$ . The  $z$ -component of this vector is defined through

$$\mu_{z,fi} = -e \int \psi_f^* z \psi_i d\tau \quad [11.11]$$

where  $-e$  is the charge of the electron. The transition moment has the form of the integral in eqn 11.10, so, once we know the symmetry species of the states, we can use group theory to formulate the selection rules for the transitions.

**Fig. 11.30** The polarizations of the allowed transitions in a  $C_{2v}$  molecule. The shading indicates the structure of the orbitals of the specified symmetry species. The perspective view of the molecule makes it look rather like a door stop; however, from the side, each 'door stop' is in fact an isosceles triangle.

As an example, we investigate whether an electron in an  $a_1$  orbital in  $H_2O$  (which belongs to the group  $C_{2v}$ ) can make an electric dipole transition to a  $b_1$  orbital (Fig. 11.30). We must examine all three components of the transition dipole moment, and take  $f_2$  in eqn 11.10 as  $x$ ,  $y$ , and  $z$  in turn. Reference to the  $C_{2v}$  character table shows that these components transform as  $B_1$ ,  $B_2$ , and  $A_1$ , respectively. The three calculations run as follows:

|               | z-component |       |            |             | y-component |       |            |             | x-component |       |            |             |       |
|---------------|-------------|-------|------------|-------------|-------------|-------|------------|-------------|-------------|-------|------------|-------------|-------|
|               | $E$         | $C_2$ | $\sigma_v$ | $\sigma'_v$ | $E$         | $C_2$ | $\sigma_v$ | $\sigma'_v$ | $E$         | $C_2$ | $\sigma_v$ | $\sigma'_v$ |       |
| $f_3$         | 1           | -1    | 1          | -1          | 1           | -1    | 1          | -1          | 1           | -1    | 1          | -1          | $B_1$ |
| $f_2$         | 1           | -1    | 1          | -1          | 1           | -1    | -1         | 1           | 1           | 1     | 1          | 1           |       |
| $f_1$         | 1           | 1     | 1          | 1           | 1           | 1     | 1          | 1           | 1           | 1     | 1          | 1           | $A_1$ |
| $f_1 f_2 f_3$ | 1           | 1     | 1          | 1           | 1           | 1     | -1         | -1          | 1           | -1    | 1          | -1          |       |

Only the first product (with  $f_2 = x$ ) spans  $A_1$ , so only the  $x$ -component of the transition dipole moment may be nonzero. Therefore, we conclude that the electric dipole transitions between  $a_1$  and  $b_1$  are allowed. We can go on to state that the radiation emitted (or absorbed) is  $x$ -polarized and has its electric field vector in the  $x$ -direction, because that form of radiation couples with the  $x$ -component of a transition dipole.

#### Example 11.7 Deducing a selection rule

Is  $p_x \rightarrow p_y$  an allowed transition in a tetrahedral environment?

**Method** We must decide whether the product  $p_y q p_x$ , with  $q = x, y$ , or  $z$ , spans  $A_1$  by using the  $T_d$  character table.

**Answer** The procedure works out as follows:

|               | $E$ | $8C_3$ | $3C_2$ | $6\sigma_d$ | $6S_4$ |       |
|---------------|-----|--------|--------|-------------|--------|-------|
| $f_3(p_y)$    | 3   | 0      | -1     | 1           | -1     | $T_2$ |
| $f_2(q)$      | 3   | 0      | -1     | 1           | -1     | $T_2$ |
| $f_1(p_x)$    | 3   | 0      | -1     | 1           | -1     | $T_2$ |
| $f_1 f_2 f_3$ | 27  | 0      | -1     | 1           | -1     |       |

We can use the decomposition procedure described in Section 11.5a to deduce that  $A_1$  occurs (once) in this set of characters, so  $p_x \rightarrow p_y$  is allowed.

A more detailed analysis (using the matrix representatives rather than the characters) shows that only  $q = z$  gives an integral that may be nonzero, so the transition is  $z$ -polarized. That is, the electromagnetic radiation involved in the transition has its electric vector aligned in the  $z$ -direction.

**Self-test 11.8** What are the allowed transitions, and their polarizations, of a  $b_1$  electron in a  $C_{4v}$  molecule?  $[b_1 \rightarrow b_1(z); b_1 \rightarrow e(x,y)]$

The following chapters will show many more examples of the systematic use of symmetry. We shall see that the techniques of group theory greatly simplify the analysis of molecular structure and spectra.

## Checklist of key equations

| Property                          | Equation                                                                       | Comment                                                                                      |
|-----------------------------------|--------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------|
| Group property                    | If $R$ and $S$ are members of a group, then $RS$ is also a member of the group | A criterion for being considered a group                                                     |
| Decomposition of a direct product | $\Gamma \times \Gamma' = \Gamma^{(1)} + \Gamma^{(2)} + \dots$                  |                                                                                              |
| Reduction of a representation     | $N_n = \frac{1}{h} \sum_R \chi^{(n)}(R)^* \chi(R)$                             |                                                                                              |
| Generation of a SALC              | $\psi^{(n)} = \frac{1}{h} \sum_R \chi^{(n)}(R)^* R \phi_i$                     |                                                                                              |
| Typical integral                  | $I = \int f_1 f_2 f_3 d\tau$                                                   | Necessarily zero if integrand does not form a basis for the totally symmetric representation |

## Discussion questions

- 11.1** Explain what is meant by a ‘group’.
- 11.2** Explain how a molecule is assigned to a point group.
- 11.3** List the symmetry operations and the corresponding symmetry elements of the point groups.
- 11.4** Explain the symmetry criteria that allow a molecule to be polar.
- 11.5** Explain the symmetry criteria that allow a molecule to be optically active.
- 11.6** Explain what is meant by (a) a representative and (b) a representation in the context of group theory.
- 11.7** Explain the construction and content of a character table.
- 11.8** Explain how spectroscopic selection rules arise and how they are formulated by using group theory.
- 11.9** Outline how a direct product is expressed as a direct sum and how to decide whether the totally symmetric irreducible representation is present in the direct product.
- 11.10** Identify and list four applications of character tables.

## Exercises

- 11.1(a)** The  $\text{CH}_3\text{Cl}$  molecule belongs to the point group  $C_{3v}$ . List the symmetry elements of the group and locate them in the molecule.
- 11.1(b)** The  $\text{CCl}_4$  molecule belongs to the point group  $T_d$ . List the symmetry elements of the group and locate them in the molecule.
- 11.2(a)** Identify the point groups to which the following objects belong: (a) a sphere, (b) an isosceles triangle, (c) an equilateral triangle, (d) an unsharpened cylindrical pencil.
- 11.2(b)** Identify the point groups to which the following objects belong: (a) a sharpened cylindrical pencil, (b) a three-bladed propellor, (c) a four-legged table, (d) yourself (approximately).
- 11.3(a)** List the symmetry elements of the following molecules and name the point groups to which they belong: (a)  $\text{NO}_2$ , (b)  $\text{N}_2\text{O}$ , (c)  $\text{CHCl}_3$ , (d)  $\text{CH}_2=\text{CH}_2$ .
- 11.3(b)** List the symmetry elements of the following molecules and name the point groups to which they belong: (a) naphthalene, (b) anthracene, (c) the three dichlorobenzenes.
- 11.4(a)** Assign (a) *cis*-dichloroethene and (b) *trans*-dichloroethene to point groups.
- 11.4(b)** Assign the following molecules to point groups: (a)  $\text{HF}$ , (b)  $\text{IF}_7$  (pentagonal bipyramid), (c)  $\text{XeO}_2\text{F}_2$  (see-saw), (d)  $\text{Fe}_2(\text{CO})_9$  (27), (e) cubane,  $\text{C}_8\text{H}_8$ , (f) tetrafluorocubane,  $\text{C}_8\text{H}_4\text{F}_4$  (28).

**11.5(a)** Which of the following molecules may be polar? (a) pyridine ( $C_{2v}$ ), (b) nitroethane ( $C_s$ ), (c) gas-phase  $\text{HgBr}_2$  ( $D_{\infty h}$ ), (d)  $\text{B}_3\text{N}_3\text{N}_6$  ( $D_{3h}$ ).

**11.5(b)** Which of the following molecules may be polar? (a)  $\text{CH}_3\text{Cl}$  ( $C_{3v}$ ), (b)  $\text{HW}_2(\text{CO})_{10}$  ( $D_{4h}$ ), (c)  $\text{SnCl}_4$  ( $T_d$ ).

**11.6(a)** Which of the molecules in Exercises 11.3a and 11.4a can be chiral?

**11.6(b)** Which of the molecules in Exercises 11.3b and 11.4b can be chiral?

**11.7(a)** Molecules belonging to the point groups  $D_{2h}$  or  $C_{3h}$  cannot be chiral. Which elements of these groups rule out chirality?

**11.7(b)** Molecules belonging to the point groups  $T_h$  or  $T_d$  cannot be chiral. Which elements of these groups rule out chirality?

**11.8(a)** The group  $D_2$  consists of the elements  $E$ ,  $C_2$ ,  $C_2'$ , and  $C_2''$ , where the three twofold rotations are around mutually perpendicular axes. Construct the group multiplication table.

**11.8(b)** The group  $C_{4v}$  consists of the elements  $E$ ,  $2C_4$ ,  $C_2$ , and  $2\sigma_v$ ,  $2\sigma_d$ . Construct the group multiplication table.

**11.9(a)** Use symmetry properties to determine whether or not the integral  $\int p_x z p_z d\tau$  is necessarily zero in a molecule with symmetry  $C_{4v}$ .

**11.9(b)** Use symmetry properties to determine whether or not the integral  $\int p_x z p_z d\tau$  is necessarily zero in a molecule with symmetry  $D_{6h}$ .

**11.10(a)** Show that the transition  $A_1 \rightarrow A_2$  is forbidden for electric dipole transitions in a  $C_{3v}$  molecule.

**11.10(b)** Is the transition  $A_{1g} \rightarrow E_{2u}$  forbidden for electric dipole transitions in a  $D_{6h}$  molecule?

**11.11(a)** Show that the function  $xy$  has symmetry species  $B_2$  in the group  $C_{4v}$ .

**11.11(b)** Show that the function  $xyz$  has symmetry species  $A_1$  in the group  $D_2$ .

**11.12(a)** Consider the  $C_{2v}$  molecule  $\text{NO}_2$ . The combination  $p_x(A) - p_x(B)$  of the two O atoms (with  $x$  perpendicular to the plane) spans  $A_2$ . Is there any orbital of the central N atom that can have a nonzero overlap with that combination of O orbitals? What would be the case in  $\text{SO}_2$ , where 3d orbitals might be available?

**11.12(b)** Consider the  $D_{3h}$  ion  $\text{NO}_3^-$ . Is there any orbital of the central N atom that can have a nonzero overlap with the combination  $2p_z(A) - p_z(B) - p_z(C)$  of the three O atoms (with  $z$  perpendicular to the plane). What would be the case in  $\text{SO}_3$ , where 3d orbitals might be available?

**11.13(a)** The ground state of  $\text{NO}_2$  is  $A_1$  in the group  $C_{2v}$ . To what excited states may it be excited by electric dipole transitions, and what polarization of light is it necessary to use?

**11.13(b)** The  $\text{ClO}_2$  molecule (which belongs to the group  $C_{2v}$ ) was trapped in a solid. Its ground state is known to be  $B_1$ . Light polarized parallel to the  $y$ -axis (parallel to the OO separation) excited the molecule to an upper state. What is the symmetry of that state?

**11.14(a)** A set of basis functions is found to span a reducible representation of the group  $C_{4v}$  with characters 5, 1, 1, 3, 1 (in the order of operations in the character table in the *Resource section*). What irreducible representations does it span?

**11.14(b)** A set of basis functions is found to span a reducible representation of the group  $D_2$  with characters 6, -2, 0, 0 (in the order of operations in the character table in the *Resource section*). What irreducible representations does it span?

**11.15(a)** What states of (a) benzene, (b) naphthalene may be reached by electric dipole transitions from their (totally symmetrical) ground states?

**11.15(b)** What states of (a) anthracene, (b) coronene (29) may be reached by electric dipole transitions from their (totally symmetrical) ground states?

29 Coronene

**11.16(a)** Write  $f_1 = \sin \theta$  and  $f_2 = \cos \theta$ , and show by symmetry arguments using the group  $C_s$  that the integral of their product over a symmetrical range around  $\theta = 0$  is zero.

**11.16(b)** Write  $f_1 = x$  and  $f_2 = 3x^2 - 1$ , and show by symmetry arguments using the group  $C_s$  that the integral of their product over a symmetrical range around  $x = 0$  is zero.

## Problems\*

**11.1** List the symmetry elements of the following molecules and name the point groups to which they belong: (a) staggered  $\text{CH}_3\text{CH}_3$ , (b) chair and boat cyclohexane, (c)  $\text{B}_2\text{H}_6$ , (d)  $[\text{Co}(\text{en})_3]^{3+}$ , where en is ethylenediamine (ignore its detailed structure), (e) crown-shaped  $\text{S}_8$ . Which of these molecules can be (i) polar, (ii) chiral?

**11.2** The group  $C_{2h}$  consists of the elements  $E$ ,  $C_2$ ,  $\sigma_h$ ,  $i$ . Construct the group multiplication table and find an example of a molecule that belongs to the group.

**11.3** The group  $D_{2h}$  has a  $C_2$  axis perpendicular to the principal axis and a horizontal mirror plane. Show that the group must therefore have a centre of inversion.

**11.4** Consider the  $\text{H}_2\text{O}$  molecule, which belongs to the group  $C_{2v}$ . Take as a basis the two  $1s$  orbitals and the four valence orbitals of the O atom and set up the  $6 \times 6$  matrices that represent the group in this basis. Confirm by explicit matrix multiplication that the group multiplications (a)  $C_2\sigma_v = \sigma_v'$  and (b)  $\sigma_v\sigma_v' = C_2$ . Confirm, by calculating the traces of the matrices, (a) that symmetry elements in the same class have the same character, (b) that the representation is reducible, and (c) that the basis spans  $3A_1 + B_1 + 2B_2$ .

**11.5** Confirm that the  $z$ -component of orbital angular momentum is a basis for an irreducible representation of  $A_2$  symmetry in  $C_{3v}$ .

**11.6** The (one-dimensional) matrices  $D(C_3) = 1$  and  $D(C_2) = 1$ , and  $D(C_3) = 1$  and  $D(C_2) = -1$  both represent the group multiplication  $C_3C_2 = C_6$  in the

\* Problems denoted with the symbol ‡ were supplied by Charles Trapp and Carmen Giunta.

group  $C_{6v}$  with  $D(C_6) = +1$  and  $-1$ , respectively. Use the character table to confirm these remarks. What are the representatives of  $\sigma_v$  and  $\sigma_d$  in each case?

**11.7** Construct the multiplication table of the Pauli spin matrices,  $\sigma$ , and the  $2 \times 2$  unit matrix:

$$\sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \quad \sigma_y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} \quad \sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \quad \sigma_0 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$$

Do the four matrices from a group under multiplication?

**11.8** What irreducible representations do the four H1s orbitals of  $CH_4$  span? Are there s and p orbitals of the central C atom that may form molecular orbitals with them? Could d orbitals, even if they were present on the C atom, play a role in orbital formation in  $CH_4$ ?

**11.9** Suppose that a methane molecule became distorted to (a)  $C_{3v}$  symmetry by the lengthening of one bond, (b)  $C_{2v}$  symmetry, by a kind of scissors action in which one bond angle opened and another closed slightly. Would more d orbitals become available for bonding?

**11.10†** B.A. Bovenzi and G.A. Pearce, Jr. (*J. Chem. Soc. Dalton Trans.*, 2763 (1997)) synthesized coordination compounds of the tridentate ligand pyridine-2,6-diamidoxime ( $C_7H_9N_5O_2$ , **30**). Reaction with  $NiSO_4$  produced a complex in which two of the essentially planar ligands are bonded at right angles to a single Ni atom. Name the point group and the symmetry operations of the resulting  $[Ni(C_7H_9N_5O_2)_2]^{2+}$  complex cation.

**11.11†** R. Eujen *et al.* (*Inorg. Chem.* **36**, 1464 (1997)) prepared and characterized several square-planar Ag(III) complex anions. In the complex anion  $[trans-Ag(CF_3)_2(CN)_2]^-$ , the Ag–CN groups are collinear. (a) Assuming free rotation of the  $CF_3$  groups (that is, disregarding the AgCF angles), name the point group of this complex anion. (b) Now suppose the  $CF_3$  groups cannot rotate freely (because the ion was in a solid, for example). Structure (31) shows a plane that bisects the NC–Ag–CN axis and is perpendicular to it. Name the point group of the complex if each  $CF_3$  group has a CF bond in that plane (so the  $CF_3$  groups do not point to either CN group preferentially) and the  $CF_3$  groups are (i) staggered (ii) eclipsed.

**11.12†** A computational study by C.J. Marsden (*Chem. Phys. Letts.* **245**, 475 (1995)) of  $AM_x$  compounds, where A is in Group 14 of the periodic table and M is an alkali metal, shows several deviations from the most symmetric

structures for each formula. For example, most of the  $AM_4$  structures were not tetrahedral but had two distinct values for MAM bond angles. They could be derived from a tetrahedron by a distortion shown in (32). (a) What is the point group of the distorted tetrahedron? (b) What is the symmetry species of the distortion considered as a vibration in the new, less symmetric group? Some  $AM_6$  structures are not octahedral, but could be derived from an octahedron by translating a C–M–C axis as in (33). (c) What is the point group of the distorted octahedron? (d) What is the symmetry species of the distortion considered as a vibration in the new, less symmetric group?

**32**

**33**

**11.13** The algebraic forms of the f orbitals are a radial function multiplied by one of the factors (a)  $z(5z^2 - 3r^2)$ , (b)  $y(5y^2 - 3r^2)$ , (c)  $x(5x^2 - 3r^2)$ , (d)  $z(x^2 - y^2)$ , (e)  $y(x^2 - z^2)$ , (f)  $x(z^2 - y^2)$ , (g)  $xyz$ . Identify the irreducible representations spanned by these orbitals in (a)  $C_{2v}$ , (b)  $C_{3v}$ , (c)  $T_d$ , (d)  $O_h$ . Consider a lanthanoid ion at the centre of (a) a tetrahedral complex, (b) an octahedral complex. What sets of orbitals do the seven f orbitals split into?

**11.14** Does the product  $xyz$  necessarily vanish when integrated over (a) a cube, (b) a tetrahedron, (c) a hexagonal prism, each centred on the origin?

**11.15** The  $NO_2$  molecule belongs to the group  $C_{2v}$ , with the  $C_2$  axis bisecting the  $ONO$  angle. Taking as a basis the  $N2s$ ,  $N2p$ , and  $O2p$  orbitals, identify the irreducible representations they span, and construct the symmetry-adapted linear combinations.

**11.16** Construct the symmetry-adapted linear combinations of  $C2p_z$  orbitals for benzene, and use them to calculate the Hückel secular determinant. This procedure leads to equations that are much easier to solve than using the original orbitals and show that the Hückel orbitals are those specified in Section 10.6d.

**11.17** The phenanthrene molecule (34) belongs to the group  $C_{2v}$  with the  $C_2$  axis perpendicular to the molecular plane. (a) Classify the irreducible representations spanned by the carbon  $2p_z$  orbitals and find their symmetry-adapted linear combinations. (b) Use your results from part (a) to calculate the Hückel secular determinant. (c) What states of phenanthrene may be reached by electric dipole transitions from its (totally symmetrical) ground state?

**34 Phenanthrene**

**11.18†** In a spectroscopic study of  $C_{60}$ , F. Negri *et al.* (*J. Phys. Chem.* **100**, 10849 (1996)) assigned peaks in the fluorescence spectrum. The molecule has icosahedral symmetry ( $I_h$ ). The ground electronic state is  $A_{1g}$ , and the lowest-lying excited states are  $T_{1g}$  and  $G_g$ . (a) Are photon-induced transitions allowed from the ground state to either of these excited states? Explain your answer. (b) What if the transition is accompanied by a vibration that breaks the parity?

**11.19** In the square-planar  $\text{XeF}_4$  molecule, consider the symmetry-adapted linear combination  $p_1 = p_A - p_B + p_C - p_D$  where  $p_A, p_B, p_C$ , and  $p_D$  are  $2p_z$  atomic orbitals on the fluorine atoms (clockwise labelling of the F atoms). Using the reduced point group  $D_4$  rather than the full symmetry point group of the molecule, determine which of the various s, p, and d atomic orbitals on the central Xe atom can form molecular orbitals with  $p_1$ .

### Applications: to astrophysics and biology

**11.20†** The  $\text{H}_3^+$  molecular ion, which plays an important role in chemical reactions occurring in interstellar clouds, is known to be equilateral triangular. (a) Identify the symmetry elements and determine the point group of this molecule. (b) Take as a basis for a representation of this molecule the three  $1s$  orbitals and set up the matrices that group in this basis. (c) Obtain the group multiplication table by explicit multiplication of the matrices. (d) Determine if the representation is reducible and, if so, give the irreducible representations obtained.

**11.21†** The  $\text{H}_3^+$  molecular ion has recently been found in the interstellar medium and in the atmospheres of Jupiter, Saturn, and Uranus. The  $\text{H}_4$  analogues have not yet been found, and the square-planar structure is thought to be unstable with respect to vibration. Take as a basis for a representation of the point group of this molecule the four  $1s$  orbitals and determine if this representation is reducible.

**11.22** Some linear polyenes, of which  $\beta$ -carotene is an example, are important biological co-factors that participate in processes as diverse as the absorption of solar energy in photosynthesis (*Impact I21.1*) and protection against

harmful biological oxidations. Use as a model of  $\beta$ -carotene a linear polyene containing 22 conjugated C atoms. (a) To what point group does this model of  $\beta$ -carotene belong? (b) Classify the irreducible representations spanned by the carbon  $2p_z$  orbitals and find their symmetry-adapted linear combinations. (c) Use your results from part (b) to calculate the Hückel secular determinant. (d) What states of this model of  $\beta$ -carotene may be reached by electric dipole transitions from its (totally symmetrical) ground state?

**11.23** The chlorophylls that participate in photosynthesis (*Impact I21.1*) and the haem groups of cytochromes (*Impact I6.1*) are derived from the porphine dianion group (35), which belongs to the  $D_{4h}$  point group. The ground electronic state is  $A_{1g}$  and the lowest-lying excited state is  $E_u$ . Is a photon-induced transition allowed from the ground state to the excited state? Explain your answer.

**35** Porphine dianion

# Molecular spectroscopy 1: rotational and vibrational spectra

The general strategy we adopt in the chapter is to set up expressions for the energy levels of molecules and then apply selection rules and considerations of populations to infer the form of spectra. Rotational energy levels are considered first: we see how to derive expressions for their values and how to interpret rotational spectra in terms of molecular dimensions. Not all molecules can occupy all rotational states: we see the experimental evidence for this restriction and its explanation in terms of nuclear spin and the Pauli principle. Next, we consider the vibrational energy levels of diatomic molecules and see that we can use the properties of harmonic oscillators developed in Chapter 8. Then we consider polyatomic molecules and find that their vibrations may be discussed as though they consisted of a set of independent harmonic oscillators, so the same approach as employed for diatomic molecules may be used. We also see that the symmetry properties of the vibrations of polyatomic molecules are helpful for deciding which modes of vibration can be studied spectroscopically.

The origin of spectral lines in molecular spectroscopy is the absorption, emission, or scattering of a photon when the energy of a molecule changes. The difference from atomic spectroscopy is that the energy of a molecule can change not only as a result of electronic transitions but also because it can undergo changes of rotational and vibrational state. Molecular spectra are therefore more complex than atomic spectra. However, they also contain information relating to more properties, and their analysis leads to values of bond strengths, lengths, and angles. They also provide a way of determining a variety of molecular properties, such as dipole moments. Molecular spectroscopy is also useful to astrophysicists and environmental scientists, for the chemical composition of interstellar space and of planetary atmospheres can be inferred from the rotational, vibrational, and electronic spectra of their constituents.

Pure rotational spectra, in which only the rotational state of a molecule changes, can be observed in the gas phase. Vibrational spectra of gaseous samples show features that arise from rotational transitions that accompany the excitation of vibration. Electronic spectra, which are described in Chapter 13, show features arising from simultaneous vibrational and rotational transitions. The simplest way of dealing with these complexities is to tackle each type of transition in turn, and then to see how simultaneous changes affect the appearance of spectra.

Discussion questions

Exercises

Problems

**Fig. 12.1** In Raman spectroscopy, an incident photon is scattered from a molecule with either an increase in frequency (if the radiation collects energy from the molecule) or with a lower frequency if it loses energy to the molecule to give the anti-Stokes and Stokes lines, respectively. Scattering without change of frequency results in the Rayleigh line. The process can be regarded as taking place by an excitation of the molecule to a wide range of states (represented by the shaded band), and the subsequent return of the molecule to a lower state; the net energy change is then carried away by the photon.

## General features of molecular spectroscopy

All types of spectra have some features in common, and we examine these first. In **emission spectroscopy**, a molecule undergoes a transition from a state of high energy  $E_1$  to a state of lower energy  $E_2$  and emits the excess energy as a photon. In **absorption spectroscopy**, the net absorption of incident radiation is monitored as its frequency is varied. We say *net* absorption, because it will become clear that, when a sample is irradiated, both absorption and emission at a given frequency are stimulated, and the detector measures the difference, the net absorption. In **Raman spectroscopy**, changes in molecular state are explored by examining the frequencies present in the radiation scattered by molecules. In Raman spectroscopy, about 1 in  $10^7$  of the incident photons collide with the molecules, give up some of their energy, and emerge with a lower energy. These scattered photons constitute the lower-frequency **Stokes radiation** from the sample (Fig. 12.1). Other incident photons may collect energy from the molecules (if they are already excited), and emerge as higher-frequency **anti-Stokes radiation**. The component of radiation scattered without change of frequency is called **Rayleigh radiation**.

The energy,  $h\nu$ , of the photon emitted or absorbed, and therefore the frequency  $\nu$  of the radiation emitted or absorbed, is given by the Bohr frequency condition,  $h\nu = |E_1 - E_2|$  (eqn 7.14). Emission and absorption spectroscopy give the same information about energy level separations, but practical considerations generally determine which technique is employed. In Raman spectroscopy the difference between the frequencies of the scattered and incident radiation is determined by the transitions that take place within the molecule; this technique is used to study molecular vibrations and rotations. We discuss emission spectroscopy in Chapter 13, for it is more important for electronic transitions; here we focus on absorption and Raman spectroscopy, which are widely employed in studies of molecular rotations and vibrations.

### 12.1 Experimental techniques

**Key points** Vibrational transitions are detected by monitoring the net absorption of infrared radiation; rotational transitions are detected by monitoring the net absorption of microwave radiation. In Raman spectroscopy, rotational and vibrational transitions are observed through analysis of radiation scattered by molecules.

**Fig. 12.2** The layout of a typical absorption spectrometer, in which the exciting beams of radiation pass alternately through a sample and a reference cell, and the detector is synchronized with them so that the relative absorption can be determined.

Common to all spectroscopic techniques is a **spectrometer**, an instrument that detects the characteristics of radiation scattered, emitted, or absorbed by atoms and molecules (see *Further information* 12.1). Figure 12.2 shows the general layout of an absorption spectrometer. Radiation from an appropriate source is directed toward a sample and the radiation transmitted strikes a **dispersing element** that separates it into different frequencies. The intensity of radiation at each frequency is then analysed by a suitable detector. In a typical Raman spectrometer, a monochromatic incident laser beam is passed through the sample and the radiation scattered from the front face of the sample is monitored (Fig. 12.3). This detection geometry allows for the study of gases, pure liquids, solutions, suspensions, and solids.

Modern spectrometers, particularly those operating in the infrared and near-infrared, now almost always use **Fourier transform techniques** of spectral detection and analysis. The heart of a Fourier transform spectrometer is a *Michelson interferometer*, a device for analysing the frequencies present in a composite signal. The total signal from a sample is like a chord played on a piano, and the Fourier transform of the signal is equivalent to the separation of the chord into its individual notes, its spectrum. The technique is described more fully in *Further information* 12.1.

The factors that contribute to the linewidths of the spectroscopic transitions of atoms (Section 9.6) apply to molecular spectra too. Thus, the linewidths of rotational spectra are minimized by working with cool samples and minimizing molecular collisions (to increase the collisional lifetimes). All linewidths have a natural limit determined by the lifetime of the upper state, which (as we show in Section 13.4a) increases as  $\nu^3$ . Thus, rotational (microwave) transitions occur at much lower frequencies than vibrational (infrared) transitions and consequently have much longer lifetimes and hence much smaller natural linewidths: at low pressures rotational linewidths are due principally to Doppler broadening.

## 12.2 Selection rules and transition moments

**Key points** A gross selection rule specifies the general features a molecule must have if it is to have a spectrum of a given kind. Specific selection rules express the allowed transitions in terms of the changes in quantum numbers.

We first met the concept of a ‘selection rule’ in Section 9.3 as a statement about whether a transition is forbidden or allowed. Selection rules also apply to molecular spectra, and the form they take depends on the type of transition. The underlying classical idea is that, for the molecule to be able to interact with the electromagnetic field and absorb or create a photon of frequency  $\nu$ , it must possess, at least transiently, a dipole oscillating at that frequency. We saw in *Justification 9.4* in Section 9.3 that this transient dipole is expressed quantum mechanically in terms of the transition dipole moment,  $\mu_{fi}$ , between states  $\psi_i$  and  $\psi_f$ :

$$\mu_{fi} = \int \psi_f^* \hat{\mu} \psi_i d\tau$$

Definition of transition dipole moment

[12.1]

where  $\hat{\mu}$  is the electric dipole moment operator. The size of the transition dipole can be regarded as a measure of the charge redistribution that accompanies a transition: a transition will be active (and generate or absorb photons) only if the accompanying charge redistribution is dipolar (Fig. 12.4). Only if the transition dipole moment is nonzero does the transition contribute to the spectrum. It follows that, to identify the selection rules, we must establish the conditions for which  $\mu_{fi} \neq 0$ .

A **gross selection rule** specifies the general features a molecule must have if it is to have a spectrum of a given kind. For instance, we shall see that a molecule gives a rotational spectrum only if it has a permanent electric dipole moment. This rule, and others like it for other types of transition, will be explained in the relevant sections of the chapter. A detailed study of the transition moment leads to the **specific selection rules** that express the allowed transitions in terms of the changes in quantum numbers. We have already encountered examples of specific selection rules when discussing atomic spectra (Sections 9.3 and 9.10), such as the rule  $\Delta l = \pm 1$  for the angular momentum quantum number.

### IMPACT ON ASTROPHYSICS

#### 12.1 Rotational and vibrational spectroscopy of interstellar species

Observations by the Cosmic Background Explorer (COBE) satellite support the long-held hypothesis that the distribution of energy in the current Universe can be modelled by a Planck distribution (eqn 7.8) with  $T = 2.726 \pm 0.001$  K, the bulk of the radiation spanning the microwave region of the spectrum. This *cosmic microwave background radiation* is the residue of energy released during the Big Bang, the event

**Fig. 12.3** A common arrangement adopted in Raman spectroscopy. A laser beam first passes through a lens and then through a small hole in a mirror with a curved reflecting surface. The focused beam strikes the sample and scattered light is both deflected and focused by the mirror. The spectrum is analysed by a monochromator or an interferometer.

**Fig. 12.4** (a) When a 1s electron becomes a 2s electron, there is a spherical migration of charge; there is no dipole moment associated with this migration of charge; this transition is electric-dipole forbidden. (b) In contrast, when a 1s electron becomes a 2p electron, there is a dipole associated with the charge migration; this transition is allowed. (There are subtle effects arising from the sign of the wavefunction that give the charge migration a dipolar character, which this diagram does not attempt to convey.) A similar dipolar redistribution of charge occurs in the active rotational and vibrational transitions of molecules, but is not always easy to visualize.

that brought the Universe into existence. Very small fluctuations in the background temperature are believed to account for the large-scale structure of the Universe.

The interstellar space in our galaxy is a little warmer than the cosmic background and consists largely of dust grains and gas clouds. The dust grains are carbon-based compounds and silicates of aluminium, magnesium, and iron, in which are embedded trace amounts of methane, water, and ammonia. Interstellar clouds are significant because it is from them that new stars, and consequently new planets, are formed. The hottest clouds are plasmas with temperatures of up to  $10^6$  K and densities of only about  $3 \times 10^3$  particles  $\text{m}^{-3}$ . Colder clouds range from 0.1 to 1000 solar masses ( $1$  solar mass =  $2 \times 10^{30}$  kg), have a density of about  $5 \times 10^5$  particles  $\text{m}^{-3}$ , consist largely of hydrogen atoms, and have a temperature of about 80 K. There are also colder and denser clouds, some with masses greater than 500 000 solar masses, densities greater than  $10^9$  particles  $\text{m}^{-3}$ , and temperatures that can be lower than 10 K. They are also called *molecular clouds*, because they are composed primarily of  $\text{H}_2$  and CO gas in a ratio of about  $10^5$  to 1. There are also trace amounts of larger molecules. To place the densities in context, the density of liquid water at 298 K and 1 bar is about  $3 \times 10^{28}$  particles  $\text{m}^{-3}$ .

It follows from the Boltzmann distribution and the low temperature of a molecular cloud that the vast majority of a cloud's molecules are in their vibrational and electronic ground states. However, rotational excited states are populated at 10–100 K and decay by the emission of radiation. As a result, the spectrum of the cloud in the radiofrequency and microwave regions consists of sharp lines corresponding to rotational transitions (Fig. 12.5). The emitted radiation is collected by Earth-bound or space-borne radiotelescopes, telescopes with antennas and detectors optimized for the collection and analysis of radiation in this range. Earth-bound radiotelescopes are often located at the tops of high mountains, as atmospheric water vapour can reabsorb microwave radiation from space and hence interfere with the measurement.

Over 100 interstellar molecules have been identified by their rotational spectra, often by comparing radiotelescope data with spectra obtained in the laboratory or calculated by computational methods. The experiments have revealed the presence of trace amounts (with abundances of less than  $10^{-8}$  relative to hydrogen) of neutral molecules, ions, and radicals. Examples of neutral molecules include hydrides, oxides (including water), sulfides, halogenated compounds, nitriles, hydrocarbons, aldehydes, alcohols, ethers, ketones, and amides. The largest molecule detected by rotational spectroscopy is the nitrile  $\text{HC}_{11}\text{N}$ .

Interstellar space can also be investigated with vibrational spectroscopy by using a combination of telescopes and infrared detectors. The experiments are conducted primarily in space-borne telescopes because the Earth's atmosphere absorbs a great deal of infrared radiation (see *Impact I12.2*). In most cases, absorption by an interstellar

**Fig. 12.5** Rotational spectrum of the Orion nebula, showing spectral fingerprints of diatomic and polyatomic molecules present in the interstellar cloud. (Adapted from G.A. Blake *et al.*, *Astrophys. J.* 315, 621 (1987).)

species is detected against the background of infrared radiation emitted by a nearby star. The data can detect the presence of gaseous and solid water, CO, and CO<sub>2</sub> in molecular clouds. In certain cases, infrared emission can be detected, but these events are rare because interstellar space is too cold and does not provide enough energy to promote a significant number of molecules to vibrationally excited states. However, infrared emissions can be observed if molecules are occasionally excited by high-energy photons emitted by hot stars in the vicinity of the cloud. For example, the polycyclic aromatic hydrocarbons hexabenzocoronene (C<sub>42</sub>H<sub>18</sub>, 1) and circumcoronene (C<sub>54</sub>H<sub>18</sub>, 2) have been identified from their characteristic infrared emissions.

1 Hexabenzocoronene

2 Circumcoronene

## Pure rotation spectra

The general strategy we adopt for discussing molecular rotational and vibrational spectra and the information they contain is to find expressions for the energy levels of molecules and then to calculate the transition frequencies by applying the selection rules. We then predict the appearance of the spectrum by taking into account the transition moments and the populations of the states. In this section we illustrate the strategy by considering the rotational states of molecules.

### 12.3 Moments of inertia

**Key points** A rigid rotor is a body that does not distort under the stress of rotation. Rigid rotors are classified by noting the number of equal principal moments of inertia.

The key molecular parameter we shall need is the **moment of inertia**,  $I$ , of the molecule. The moment of inertia of a molecule is defined as the mass of each atom multiplied by the square of its distance from the rotational axis passing through the centre of mass of the molecule (Fig. 12.6):

$$I = \sum_i m_i x_i^2 \quad \text{Definition of moment of inertia} \quad [12.2]$$

where  $x_i$  is the perpendicular distance of the atom  $i$  from the axis of rotation. The moment of inertia depends on the masses of the atoms present and the molecular geometry, so we can suspect (and later shall see explicitly) that rotational spectroscopy will give information about bond lengths and bond angles.

In general, the rotational properties of any molecule can be expressed in terms of the moments of inertia about three perpendicular axes set in the molecule (Fig. 12.7). The convention is to label the moments of inertia  $I_a$ ,  $I_b$ , and  $I_c$ , with the axes chosen so that  $I_c \geq I_b \geq I_a$ . For linear molecules, the moment of inertia around the internuclear axis is zero (because  $x_i = 0$  for all the atoms). The explicit expressions for the moments of inertia of some symmetrical molecules are given in Table 12.1.

**Fig. 12.6** The definition of moment of inertia. In this molecule there are three identical atoms attached to the B atom and three different but mutually identical atoms attached to the C atom. In this example, the centre of mass lies on an axis passing through the B and C atoms, and the perpendicular distances are measured from this axis.

**Fig. 12.7** An asymmetric rotor has three different moments of inertia; all three rotational axes coincide at the centre of mass of the molecule.

**Table 12.1** Moments of inertia\*

## 1. Diatomic molecules

$$I = \mu R^2 \quad \mu = \frac{m_A m_B}{m}$$

## 2. Triatomic linear rotors

$$I = m_A R^2 + m_C R'^2 - \frac{(m_A R - m_C R')^2}{m}$$

$$I = 2m_A R^2$$

## 3. Symmetric rotors

$$I_{\parallel} = 2m_A (1 - \cos \theta) R^2$$

$$I_{\perp} = m_A (1 - \cos \theta) R^2 + \frac{m_A}{m} (m_B + m_C) (1 + 2 \cos \theta) R^2 + \frac{m_C}{m} \{ (3m_A + m_B) R' + 6m_A R [\frac{1}{3} (1 + 2 \cos \theta)]^{1/2} \} R'$$

$$I_{\parallel} = 2m_A (1 - \cos \theta) R^2$$

$$I_{\perp} = m_A (1 - \cos \theta) R^2 + \frac{m_A m_B}{m} (1 + 2 \cos \theta) R^2$$

$$I_{\parallel} = 4m_A R^2$$

$$I_{\perp} = 2m_A R^2 + 2m_C R'^2$$

## 4. Spherical rotors

$$I = \frac{8}{3} m_A R^2$$

$$I = 4m_A R^2$$

\* In each case,  $m$  is the total mass of the molecule.

**Example 12.1** Calculating the moment of inertia of a molecule

Calculate the moment of inertia of an  $\text{H}_2\text{O}$  molecule around the axis defined by the bisector of the HOH angle (3). The HOH bond angle is  $104.5^\circ$  and the bond length is 95.7 pm.

**Method** According to eqn 12.2, the moment of inertia is the sum of the masses multiplied by the squares of their distances from the axis of rotation. The latter can be expressed by using trigonometry and the bond angle and bond length.

**Answer** From eqn 12.2,

$$I = \sum_i m_i x_i^2 = m_{\text{H}} x_{\text{H}}^2 + 0 + m_{\text{H}} x_{\text{H}}^2 = 2m_{\text{H}} x_{\text{H}}^2$$

If the bond angle of the molecule is denoted  $2\phi$  and the bond length is  $R$ , trigonometry gives  $x_{\text{H}} = R \sin \phi$ . It follows that

$$I = 2m_{\text{H}} R^2 \sin^2 \phi$$

Substitution of the data gives

$$\begin{aligned} I &= 2 \times (1.67 \times 10^{-27} \text{ kg}) \times (9.57 \times 10^{-11} \text{ m})^2 \times \sin^2(\tfrac{1}{2} \times 104.5^\circ) \\ &= 1.91 \times 10^{-47} \text{ kg m}^2 \end{aligned}$$

Note that the mass of the O atom makes no contribution to the moment of inertia for this mode of rotation as the atom is immobile while the H atoms circulate around it.

**Self-test 12.1** Calculate the moment of inertia of a  $\text{CH}^{35}\text{Cl}_3$  molecule around a rotational axis that contains the C–H bond. The C–Cl bond length is 177 pm and the HCCl angle is  $107^\circ$ ;  $m(^{35}\text{Cl}) = 34.97m_{\text{u}}$ .  $[4.99 \times 10^{-45} \text{ kg m}^2]$

**A note on good practice** The mass to use in the calculation of the moment of inertia is the actual atomic mass, not the element's molar mass; don't forget to convert from relative masses to actual masses by using the atomic mass constant  $m_{\text{u}}$ .

We shall suppose initially that molecules are **rigid rotors**, bodies that do not distort under the stress of rotation. Rigid rotors can be classified into four types (Fig. 12.8):

**Fig. 12.8** A schematic illustration of the classification of rigid rotors and some typical molecules.

**Spherical rotors** have three equal moments of inertia (examples: CH<sub>4</sub>, SiH<sub>4</sub>, and SF<sub>6</sub>).

**Symmetric rotors** have two equal moments of inertia and a third that is nonzero (examples: NH<sub>3</sub>, CH<sub>3</sub>Cl, and CH<sub>3</sub>CN).

**Linear rotors** have two equal moments of inertia and a third that is zero (examples: CO<sub>2</sub>, HCl, OCS, and HC≡CH).

**Asymmetric rotors** have three different and nonzero moments of inertia (examples: H<sub>2</sub>O, H<sub>2</sub>CO, and CH<sub>3</sub>OH).

Spherical, symmetric, and asymmetric rotors are also called *spherical tops*, etc.

## 12.4 The rotational energy levels

**Key points** (a) The energy levels of a rotor may be expressed in terms of the quantum numbers  $J$ ,  $K$ , and  $M_J$  and rotational constants that are related to its moments of inertia. (b) Symmetric rotors are classified as prolate or oblate. (c) For a linear rotor rotation occurs only about an axis perpendicular to the line of atoms. (d) The degeneracies of spherical, symmetric, and linear rotors are  $(2J+1)^2$ ,  $2(2J+1)$ , and  $2J+1$ , respectively. (e) Centrifugal distortion arises from forces that change the geometry of a molecule.

The rotational energy levels of a rigid rotor may be obtained by solving the appropriate Schrödinger equation. Fortunately, however, there is a much less onerous short cut to the exact expressions that depends on noting the classical expression for the energy of a rotating body, expressing it in terms of the angular momentum, and then importing the quantum mechanical properties of angular momentum into the equations.

The classical expression for the energy of a body rotating about an axis  $a$  is

$$E_a = \frac{1}{2} I_a \omega_a^2 \quad (12.3)$$

where  $\omega_a$  is the angular velocity (in radians per second, rad s<sup>-1</sup>) about that axis and  $I_a$  is the corresponding moment of inertia. A body free to rotate about three axes has an energy

$$E = \frac{1}{2} I_a \omega_a^2 + \frac{1}{2} I_b \omega_b^2 + \frac{1}{2} I_c \omega_c^2 \quad (12.4)$$

Because the classical angular momentum about the axis  $a$  is  $J_a = I_a \omega_a$ , with similar expressions for the other axes, it follows that

$$E = \frac{J_a^2}{2I_a} + \frac{J_b^2}{2I_b} + \frac{J_c^2}{2I_c} \quad (12.5)$$

This is the key equation. We described the quantum mechanical properties of angular momentum in Section 8.7b and can now make use of them in conjunction with this equation.

### (a) Spherical rotors

When all three moments of inertia are equal to some value  $I$ , as in CH<sub>4</sub> and SF<sub>6</sub>, the classical expression for the energy is

$$E = \frac{J_a^2 + J_b^2 + J_c^2}{2I} = \frac{J^2}{2I}$$

where  $J^2 = J_a^2 + J_b^2 + J_c^2$  is the square of the magnitude of the angular momentum. We can immediately find the quantum expression by making the replacement

$$J^2 \rightarrow J(J+1)\hbar^2 \quad J = 0, 1, 2, \dots$$

Therefore, the energy of a spherical rotor is confined to the values

$$E_J = J(J+1) \frac{\hbar^2}{2I} \quad J = 0, 1, 2, \dots \quad (12.6)$$

The resulting ladder of energy levels is illustrated in Fig. 12.9. The energy is normally expressed in terms of the **rotational constant**,  $\tilde{B}$ , of the molecule, where

$$hc\tilde{B} = \frac{\hbar^2}{2I} \quad \text{so} \quad \tilde{B} = \frac{\hbar}{4\pi cI} \quad \text{Definition of rotational constant} \quad [12.7]$$

The expression for the energy is then

$$E_J = hc\tilde{B}J(J+1) \quad J = 0, 1, 2, \dots \quad \text{Energy levels of a spherical rotor} \quad (12.8)$$

The definition of  $\tilde{B}$  as a wavenumber is convenient when we come to vibration-rotation spectra (Section 12.11). For pure rotational spectroscopy it is more common to define the rotational constant as a frequency and to denote it simply  $B$ . Then  $B = \hbar/4\pi I$  and the energy is  $E = hBJ(J+1)$ . The two quantities are related by  $B = c\tilde{B}$ .

The energy of a rotational state is normally reported as the **rotational term**,  $\tilde{F}(J)$ , a wavenumber, by division of both sides of eqn 12.8 by  $hc$ :

$$\tilde{F}(J) = \tilde{B}J(J+1) \quad \text{Rotational terms of a spherical rotor} \quad (12.9)$$

The separation of adjacent levels is

$$\tilde{F}(J+1) - \tilde{F}(J) = \tilde{B}(J+1)(J+2) - \tilde{B}J(J+1) = 2\tilde{B}(J+1) \quad (12.10)$$

Because the rotational constant is inversely proportional to  $I$ , large molecules have closely spaced rotational energy levels. We can estimate the magnitude of the separation by considering  $\text{C}^{35}\text{Cl}_4$ : from the bond lengths and masses of the atoms we find  $I = 4.85 \times 10^{-45} \text{ kg m}^2$ , and hence  $\tilde{B} = 0.0577 \text{ cm}^{-1}$ .

### (b) Symmetric rotors

In symmetric rotors, two moments of inertia are equal but different from the third (as in  $\text{CH}_3\text{Cl}$ ,  $\text{NH}_3$ , and  $\text{C}_6\text{H}_6$ ); the unique axis of the molecule is its **principal axis** (or *figure axis*). We shall write the unique moment of inertia (that about the principal axis) as  $I_{\parallel}$  and the other two as  $I_{\perp}$ . If  $I_{\parallel} > I_{\perp}$ , the rotor is classified as **oblate** (like a pancake, and  $\text{C}_6\text{H}_6$ ); if  $I_{\parallel} < I_{\perp}$  it is classified as **prolate** (like a cigar, and  $\text{CH}_3\text{Cl}$ ). The classical expression for the energy, eqn 12.5, becomes

$$E = \frac{J_b^2 + J_c^2}{2I_{\perp}} + \frac{J_a^2}{2I_{\parallel}}$$

Again, this expression can be written in terms of  $J^2 = J_a^2 + J_b^2 + J_c^2$

$$E = \frac{J^2 - J_a^2}{2I_{\perp}} + \frac{J_a^2}{2I_{\parallel}} = \frac{J^2}{2I_{\perp}} + \left( \frac{1}{2I_{\parallel}} - \frac{1}{2I_{\perp}} \right) J_a^2 \quad (12.11)$$

Now we generate the quantum expression by replacing  $J^2$  by  $J(J+1)\hbar^2$ , where  $J$  is the angular momentum quantum number. We also know from the quantum theory of angular momentum (Section 8.7) that the component of angular momentum about any axis is restricted to the values  $K\hbar$ , with  $K = 0, \pm 1, \dots, \pm J$ . ( $K$  is the quantum number used to signify a component on the principal axis;  $M_J$  is reserved for a component

**Fig. 12.9** The rotational energy levels of a linear or spherical rotor. Note that the energy separation between neighbouring levels increases as  $J$  increases.

**Fig. 12.10** The significance of the quantum number  $K$ . (a) When  $|K|$  is close to its maximum value,  $J$ , most of the molecular rotation is around the figure axis. (b) When  $K = 0$  the molecule has no angular momentum about its principal axis: it is undergoing end-over-end rotation.

**A note on good practice** To calculate moments of inertia precisely, it is necessary to specify the nuclide.

on an externally defined axis.) Therefore, we also replace  $J_a^2$  by  $K^2\hbar^2$ . It follows that the rotational terms are

$$\tilde{F}(J, K) = \tilde{B}J(J+1) + (\tilde{A} - \tilde{B})K^2 \quad \begin{matrix} J = 0, 1, 2, \dots \\ K = 0, \pm 1, \dots, \pm J \end{matrix} \quad \begin{matrix} \text{Rotational terms of} \\ \text{a symmetric rotor} \end{matrix} \quad (12.12)$$

with

$$\tilde{A} = \frac{\hbar}{4\pi c I_{\parallel}}, \quad \tilde{B} = \frac{\hbar}{4\pi c I_{\perp}} \quad [12.13]$$

Equation 12.12 matches what we should expect for the dependence of the energy levels on the two distinct moments of inertia of the molecule. When  $K = 0$ , there is no component of angular momentum about the principal axis, and the energy levels depend only on  $I_{\perp}$  (Fig. 12.10). When  $K = \pm J$ , almost all the angular momentum arises from rotation around the principal axis, and the energy levels are determined largely by  $I_{\parallel}$ . The sign of  $K$  does not affect the energy because opposite values of  $K$  correspond to opposite senses of rotation, and the energy does not depend on the sense of rotation.

### Example 12.2 Calculating the rotational energy levels of a molecule

A  $^{14}\text{NH}_3$  molecule is a symmetric rotor with bond length 101.2 pm and HNH bond angle  $106.7^\circ$ . Calculate its rotational terms.

**Method** Begin by calculating the rotational constants  $\tilde{A}$  and  $\tilde{B}$  by using the expressions for moments of inertia given in Table 12.1. Then use eqn 12.12 to find the rotational terms.

**Answer** Substitution of  $m_{\text{A}} = 1.0078m_{\text{u}}$ ,  $m_{\text{B}} = 14.0031m_{\text{u}}$ ,  $R = 101.2$  pm, and  $\theta = 106.7^\circ$  into the second set of symmetric rotor expressions in Table 12.1 gives  $I_{\parallel} = 4.4128 \times 10^{-47} \text{ kg m}^2$  and  $I_{\perp} = 2.8059 \times 10^{-47} \text{ kg m}^2$ . Hence,  $\tilde{A} = 6.344 \text{ cm}^{-1}$  and  $\tilde{B} = 9.977 \text{ cm}^{-1}$ . It follows from eqn 12.12 that

$$\tilde{F}(J, K)/\text{cm}^{-1} = 9.977J(J+1) - 3.633K^2$$

Upon multiplication by  $c$ ,  $\tilde{F}(J, K)$  acquires units of frequency and is denoted  $F(J, K)$ :

$$F(J, K)/\text{GHz} = 299.1J(J+1) - 108.9K^2$$

For  $J = 1$ , the energy needed for the molecule to rotate mainly about its figure axis ( $K = \pm J$ ) is equivalent to  $16.32 \text{ cm}^{-1}$  (489.3 GHz), but end-over-end rotation ( $K = 0$ ) corresponds to  $19.95 \text{ cm}^{-1}$  (598.1 GHz).

**Self-test 12.2** A  $\text{CH}_3^{35}\text{Cl}$  molecule has a C–Cl bond length of 178 pm, a C–H bond length of 111 pm, and an HCH angle of  $110.5^\circ$ . Calculate its rotational energy terms.   
 [ $\tilde{F}(J, K)/\text{cm}^{-1} = 0.472J(J+1) + 4.56K^2$ ; also  $F(J, K)/\text{GHz} = 14.1J(J+1) + 137K^2$ ]

### (c) Linear rotors

For a linear rotor (such as  $\text{CO}_2$ ,  $\text{HCl}$ , and  $\text{C}_2\text{H}_2$ ), in which the nuclei are regarded as mass points, the rotation occurs only about an axis perpendicular to the line of atoms and there is zero angular momentum around the line. Therefore, the component of angular momentum around the figure axis of a linear rotor is identically zero, and  $K \equiv 0$  in eqn 12.12. The rotational terms of a linear molecule are therefore

$$\tilde{F}(J) = \tilde{B}J(J+1) \quad J = 0, 1, 2, \dots$$

Rotational terms  
of a linear rotor

(12.14)

This expression is the same as eqn 12.9 but we have arrived at it in a significantly different way: here  $K \equiv 0$  but for a spherical rotor  $\tilde{A} = \tilde{B}$ . Note that it is important to set  $K$  identically equal to 0 in eqn 12.12 so that the second term vanishes identically; there is then no need to worry about the consequences of  $\tilde{A} \propto 1/I_{\parallel}$  approaching infinity as  $I_{\parallel}$  approaches 0.

### (d) Degeneracies and the Stark effect

The energy of a symmetric rotor depends on  $J$  and  $K$ , and each level except those with  $K = 0$  is doubly degenerate: the states with  $K$  and  $-K$  have the same energy. However, we must not forget that the angular momentum of the molecule has a component on an external, laboratory-fixed axis. This component is quantized, and its permitted values are  $M_J \hbar$ , with  $M_J = 0, \pm 1, \dots, \pm J$ , giving  $2J + 1$  values in all (Fig. 12.11). The quantum number  $M_J$  does not appear in the expression for the energy, but it is necessary for a complete specification of the state of the rotor. Consequently, all  $2J + 1$  orientations of the rotating molecule have the same energy. It follows that a symmetric rotor level is  $2(2J + 1)$ -fold degenerate for  $K \neq 0$  and  $(2J + 1)$ -fold degenerate for  $K = 0$ . A linear rotor has  $K$  fixed at 0, but the angular momentum may still have  $2J + 1$  components on the laboratory axis, so its degeneracy is  $2J + 1$ .

A spherical rotor can be regarded as a version of a symmetric rotor in which  $\tilde{A} = \tilde{B}$ . The quantum number  $K$  may still take any one of  $2J + 1$  values, but the energy is independent of which value it takes. Therefore, as well as having a  $(2J + 1)$ -fold degeneracy arising from its orientation in space, the rotor also has a  $(2J + 1)$ -fold degeneracy arising from its orientation with respect to an arbitrary axis in the molecule. The overall degeneracy of a symmetric rotor with quantum number  $J$  is therefore  $(2J + 1)^2$ . This degeneracy increases very rapidly: when  $J = 10$ , for instance, there are 441 states of the same energy.

The degeneracy associated with the quantum number  $M_J$  (the orientation of the rotation in space) is partly removed when an electric field is applied to a polar molecule (for example, HCl or  $\text{NH}_3$ ), as illustrated in Fig. 12.12. The splitting of states by an electric field is called the **Stark effect**. The energy shift depends on the square of the permanent electric dipole moment,  $\mu$ , because it depends on the distortion of the rotational wavefunction (a first-order term in  $\mathcal{E}$ ), which favours low-energy orientations of  $\mu$ , and also on the interaction of that distorted distribution with the applied field (another first-order term in  $\mathcal{E}$ ). Thus we can write

$$E(J, M_J) = hc\tilde{B}J(J+1) + a\mu^2\mathcal{E}^2$$

Stark effect on the  
energy of a linear rotor

(12.15)

where  $a$  is a constant that depends on  $J$  and  $M_J$ . The observation of the Stark effect can therefore be used to measure the magnitudes (not the sign) of electric dipole moments, but the technique is limited to molecules that are sufficiently volatile to be studied by rotational spectroscopy. However, as spectra can be recorded for samples at pressures of only about 1 Pa and special techniques (such as using an intense laser beam or an electrical discharge) can be used to vaporize even some quite nonvolatile substances, a wide variety of samples may be studied. Sodium chloride, for example, can be studied as diatomic NaCl molecules at high temperatures.

### (e) Centrifugal distortion

We have treated molecules as rigid rotors. However, the atoms of rotating molecules are subject to centrifugal forces that tend to distort the molecular geometry and

**Fig. 12.11** The significance of the quantum number  $M_J$ . (a) When  $M_J$  is close to its maximum value,  $J$ , most of the molecular rotation is around the laboratory  $z$ -axis. (b) An intermediate value of  $M_J$ . (c) When  $M_J = 0$  the molecule has no angular momentum about the  $z$ -axis. All three diagrams correspond to a state with  $K = 0$ ; there are corresponding diagrams for different values of  $K$ , in which the angular momentum makes a different angle to the molecule's principal axis.

**Fig. 12.12** The effect of an electric field on the energy levels of a polar linear rotor. All levels are doubly degenerate except that with  $M_J = 0$ .

**Fig. 12.13** The effect of rotation on a molecule. The centrifugal force arising from rotation distorts the molecule, opening out bond angles and stretching bonds slightly. The effect is to increase the moment of inertia of the molecule and hence to decrease its rotational constant.

change the moments of inertia (Fig. 12.13). The effect of centrifugal distortion on a diatomic molecule is to stretch the bond and hence to increase the moment of inertia. As a result, centrifugal distortion reduces the rotational constant and consequently the energy levels are slightly closer than the rigid-rotor expressions predict. The effect is usually taken into account largely empirically by subtracting a term from the energy and writing

$$\tilde{F}(J) = \tilde{B}J(J+1) - \tilde{D}_J J^2(J+1)^2 \quad \text{Rotational terms affected by centrifugal distortion} \quad (12.16)$$

The parameter  $\tilde{D}_J$  is the **centrifugal distortion constant**. It is large when the bond is easily stretched. The centrifugal distortion constant of a diatomic molecule is related to the vibrational wavenumber of the bond,  $\tilde{\nu}$  (which, as we shall see later, is a measure of its stiffness), through the approximate relation (see Problem 12.21)

$$\tilde{D}_J = \frac{4\tilde{B}^3}{\tilde{\nu}^2} \quad \text{Centrifugal distortion constant} \quad (12.17)$$

Hence the observation of the convergence of the rotational levels as  $J$  increases can be interpreted in terms of the rigidity of the bond.

## 12.5 Rotational transitions

**Key points** (a) For a molecule to give a pure rotational spectrum, it must be polar. The specific rotational selection rules are  $\Delta J = \pm 1$ ,  $\Delta M_J = 0, \pm 1$ ,  $\Delta K = 0$ . (b) Bond lengths may be obtained from analysis of microwave spectra.

Typical values of  $\tilde{B}$  for small molecules are in the region of  $0.1\text{--}10\text{ cm}^{-1}$  (for example,  $0.356\text{ cm}^{-1}$  for  $\text{NF}_3$  and  $10.59\text{ cm}^{-1}$  for  $\text{HCl}$ ), so rotational transitions lie in the microwave region of the spectrum. The transitions are detected by monitoring the net absorption of microwave radiation. Modulation of the transmitted intensity, which is used to facilitate detection and amplification of the absorption, can be achieved by varying the energy levels with an oscillating electric field. In this **Stark modulation**, an electric field of about  $10^5\text{ V m}^{-1}$  and a frequency of  $10\text{--}100\text{ kHz}$  is applied to the sample.

### (a) Rotational selection rules

We have already remarked (Section 12.2) that the gross selection rule for the observation of a pure rotational spectrum is that a molecule must have a permanent electric dipole moment. That is, *for a molecule to give a pure rotational spectrum, it must be polar*. The classical basis of this rule is that a polar molecule appears to possess a fluctuating dipole when rotating but a nonpolar molecule does not (Fig. 12.14). The permanent dipole can be regarded as a handle with which the molecule stirs the electromagnetic field into oscillation (and vice versa for absorption). Homonuclear diatomic molecules and symmetrical linear molecules such as  $\text{CO}_2$  are rotationally inactive. Spherical rotors cannot have electric dipole moments unless they become distorted by rotation, so they are also inactive except in special cases. An example of a spherical rotor that does become sufficiently distorted for it to acquire a dipole moment is  $\text{SiH}_4$ , which has a dipole moment of about  $8.3\text{ }\mu\text{D}$  by virtue of its rotation when  $J \approx 10$  (for comparison,  $\text{HCl}$  has a permanent dipole moment of  $1.1\text{ D}$ ; molecular dipole moments and their units are discussed in Section 17.1). The pure rotational spectrum of  $\text{SiH}_4$  has been detected by using long path lengths ( $10\text{ m}$ ) through high-pressure ( $4\text{ atm}$ ) samples.

• **A brief illustration**

Of the molecules  $\text{N}_2$ ,  $\text{CO}_2$ ,  $\text{OCS}$ ,  $\text{H}_2\text{O}$ ,  $\text{CH}_2=\text{CH}_2$ , and  $\text{C}_6\text{H}_6$ , only  $\text{OCS}$  and  $\text{H}_2\text{O}$  are polar, so only these two molecules have microwave spectra. •
